Date: Sept 30, 2002

## **ABSTRACT**

This study is an econometric analysis of the Canadian pulp and paper industry using a normalized quadratic profit function for estimation. Two key differences between this study and previous studies are that wood input variables are split into roundwood & wood chips and there is regional representation. Statistical testing reveals that the best model contains regional dummy variables and a correction for autocorrelation. The results from the model are then used to estimate profit, own-price, and cross-price elasticities and also to simulate policy scenarios for a change in energy price policy and a change in stumpage price policy. Roundwood and wood chips inputs are substitutable in the production of total paper and wood pulp. The prices for all variables, except for total paper, are inelastic with respect to profitability.

## ACKNOWLEDGMENTS

I would like to express my gratitude to Dr. Grant Hauer for all of his advice, insight and support throughout my graduate and undergraduate work. He has helped develop someone who was math adverse into an economist. That kind of teaching and understanding is greatly appreciated. I would also like to give thanks to the other members of my thesis committee, Dr. Peter Boxall and Dr. Glen Armstrong for their advice and comments.

I would like to thank the Department of Rural Economy support staff for all of their help throughout my years in this program. They have made life much easier and have been willing to help out whenever needed. To the department graduate students, thanks for making it a fun to come in to the office everyday no matter how tough things were going. A special thank you to Jamie, Tanya, Gord, and Chanchoura for their friendship and support throughout our years together in the graduate program.

I would like to thank my dad, brothers, and many great friends. Everyone has been very supportive during this quest and it certainly hasn't gone unnoticed. I couldn't have done it without you.

Finally, I would like to dedicate this thesis to my mom, Janice Merle Larsen (1938-1998). Thank you for everything and I miss you.

# CHAPTER ONE: INTRODUCTION

## 1.1 Background

The forest industry makes a significant contribution to the Canadian economy. The forest industry is by far the largest net exporter in Canada and without its contribution the country's trade balance would be consistently negative (PWC, 2001). The Canadian forest industry is also one of Canada's largest industrial employers (CCPA, 2001).

Canada is the world's second-largest producer of softwood lumber, with a fifth of world production, and is also the leading exporter with 51% of the world market (NRC, 2001).

Canada is the world's second largest producer of wood pulp, after the United States, but it is the world's leading exporter with 25% of the international market (NRC, 2001).

Canada also has a significant pulp and paper product industry. Pulp and paper products contributed approximately 58% of the \$47.4 billion generated from forest industry exports in the year 2000 (NRC, 2001). Therefore, changes in government policies, that affect forest sector, could have significant impacts upon the Canadian economy (i.e. the softwood lumber dispute with the United States or greenhouse gas agreements).

There are two major subsections in the forest industry: the wood industry and the pulp and paper industry. The purpose of this study is to examine regional differences within the Canadian pulp and paper industry in profitability, technological change, the relationship between profitability and capital inputs, input demand and output supply relationships. The approach is to estimate a dual normalized quadratic profit function. In this study, several improvements upon previous studies are made. First, regional differences in profitability, demand, and input structure are studied for four different regions in Canada. Given that the pulp and paper industry produces different products (ie. pulp vs paper vs newsprint) it is important to model the industry for multiple outputs. A unique aspect of this study is that it considers multiple outputs and multiple wood inputs. A multi-input, multi-output description of the whole industry within a single model seems appropriate (Hseu and Buongiorno, 1997). Also, this study will look at possible impacts on profitability and supply and demand relationships due to potential changes in

energy policy due to a carbon tax upon fossil fuel energy usage and stumpage policy due to an increase in the cost of wood inputs.

## **1.2 Research Objectives**

The specific aims of this study are as follows:

- (1) Estimate dual multiple-output and multiple-input profit functions using regional data for the Canadian pulp and paper industry.
- (2) Estimate profit, own, and cross-price elasticities for each region with respect to supply outputs and demand inputs.
- (3) Examine the effect of technology and capital on profitability and the demand for wood and other inputs over time amongst the regions.
- (4) Effect of policy scenarios on industry profitability for each region. These scenarios will include one for a change in energy input prices and one for a change in stumpage prices.

As stated in objective 1, the approach is to estimate dual profit functions with multiple outputs (wood pulp and total paper) and multiple inputs (roundwood, wood chips, labour hours, energy) with a fixed capital input. Normalized profit functions have application in circumstances where some commodities are variable and other commodities are fixed over the period of production (Lau, 1976). The method of estimation is a systems approach using seemingly unrelated regression with cross equation coefficient restrictions. The advantage of this type of approach is that relationships implied by profit maximization theory can be imposed and tested. The results derived from this functional form provide a variety of econometric results that are discussed in the results and analysis section.

Two main aspects separate this project from previous studies. The first, in this study, is that wood inputs are separated into two parts. In previous studies, this input has been modeled as a single aggregated input but in this project wood input is separated into wood chips and roundwood. This is an important distinction because over the past 30

years the industry has been substituting wood chips for roundwood. The intention of disaggregating this input is to provide more insight into the substitutability of these two inputs. The second aspect is the breakdown of the pulp and paper sector by region in Canada. The four regions being considered are Quebec, Ontario, British Columbia, and the Rest of Canada. Such a breakdown allows for a more detailed analysis of the industry. Estimating regional differences is important given the provincial ownership of major portions of the resource base in Canada and the accompanying policy responsibilities regarding resource availability and use (Meil and Nautiyal, 1988). It can be assumed that each region has differing strengths in producing the multiple outputs and obtaining the inputs necessary for pulp and paper products. With the regional breakdown, we can then observe those differences through supply and demand relationships.

### **1.3 Outline of the Study**

Chapter two is a review of previous studies. The review includes theories of profit functions and past studies done in the forest industry with cost and profit functions.

Chapter three details the research methodology used. This includes the theoretical and econometric aspects of the dual profit function model. In addition, derivation of formulas for the own-price, cross-price, and profit elasticities is discussed. Also, there is a description of the data sources.

Chapter four presents the estimation and results from the econometric estimations. The results include the profit, own-price, and cross-price elasticities for the nation and each region.

In Chapter five, there is an analysis of regional differences and results from policy scenarios. There are two policy scenarios that will be incorporated in this study. The first scenario is, what would happen if there is a carbon tax placed upon emission of carbon from the use of fossil fuels. This is incorporated within the energy input of the

industry. The second scenario simulates a change in stumpage policy as a result of the lumber dispute with the United States. This would have an impact upon the roundwood input for the pulp and paper industry.

Chapter six includes a summary of the results found in the study. Also, the limitations of this study are noted and ideas for further research in the field are included.

## CHAPTER TWO: LITERATURE REVIEW

### 2.1 Overview

This chapter examines literature pertinent to econometric analysis of the Canadian pulp and paper industry. First, there is a description of dual profit function theory. Second, there is a description of two widely used types of dual profit functions, quadratic and translog. Third, there is a review of previous studies and literature from the wood industries, pulp and paper industry, and other sectors. These studies are focused towards research undertaken in those industries and sectors and how they relate to the current study.

### 2.2 Dual Profit Function Theory

In profit function theory, it is standard practice to assume that competitive firms maximize profits given the prices of inputs and outputs and the firm's technology (Chambers, 1988). In most econometric analysis of profit functions, dual profit functions are estimated which is the approach taken in chapters 3 through 5. Hence, the remainder of this chapter emphasizes the properties and estimation procedures for dual profit functions. Duality theory shows that there is a relationship between direct profit and dual profit functions as well as the production technology and input and output supply functions. The first theorem of duality states that the optimal values of the primal and the dual objective functions are always identical, provided that optimal feasible solutions do exist (Chiang, 1984). Chambers (1988) notes the following properties of dual profit functions (where  $p$  are output prices and  $w$  are input prices):

- (1)  $\Pi(p, w) \geq 0$ , profits must be greater than zero;
- (2) if  $p^1 \geq p^2$ , then  $\Pi(p^1, w) \geq \Pi(p^2, w)$ , (non-decreasing in  $p$ );
- (3) if  $w^1 \geq w^2$ , then  $\Pi(p, w^1) \leq \Pi(p, w^2)$  (non-increasing in  $w$ );
- (4)  $\Pi(p, w)$  is convex and continuous in  $(p, w)$ ;
- (5)  $\Pi(tp, tw) = t \Pi(p, w)$ ,  $t > 0$  (positive linear homogeneity);

(6) if the profit function is differentiable in  $p$  and  $w$ , the unique profit-maximizing supply and derived-demand functions are

$$y(p, w) = \frac{\partial \Pi(p, w)}{\partial p} \text{ and } x_i(p, w) = -\frac{\partial \Pi(p, w)}{\partial w_i} \quad \forall i,$$

where  $y(p, w)$  and  $x_i(p, w)$  are the respective profit-maximizing quantities of outputs and inputs. If unique profit-maximizing supply and derived demands exist, the profit function is differentiable (Hotelling's Lemma).

Also, for the case of multiple output profit functions the above six properties exist along with the following:

(7) there exists fixed vectors  $(\bar{y}, \bar{x})$  and  $(\hat{y}, \hat{x})$  such that  $\Pi(p, w) \geq p\bar{y} - w\bar{x}$  and  $\Pi(p, w) \leq p\hat{y} - w\hat{x}$  (which represents a bounded production possibilities set).

Property one follows basic economic intuition. It can be assumed that a rational profit-maximizing firm would not produce any output if the profits are less than zero. By following property one, it would be assumed that if the profits are less than zero then there would be a shutdown of output. For this study, it will be assumed that each region has a positive total variable profit.

Properties 2 and 3 are fairly obvious and provide a benchmark to compare estimated econometric results. Property two states that as the price of output increases, with all other prices being equal, there will be an associated increase in profits. Conversely, property three states that as an input price increases, with all other prices being equal, then there would be a decline in profits. If both of these properties hold true, then it is evident in the results by looking at the elasticity values. For outputs, there should be a positive sign on the elasticity value. For inputs, there should be a negative sign on the elasticity value.

Property four states that the function must be convex and continuous. This suggests that when prices change, the behaviour of the firm changes to adjust its inputs and outputs

accordingly. In terms of demand for inputs, this generally means a downward sloping demand curve and for outputs it means an upward sloping supply curve.

Property five states that the function must exhibit positive linear homogeneity. This implies that if a value is being multiplied or divided throughout the system, then a function that satisfies property five would have the same result. This is commonly obtained through the use of normalization.

Property six, which is Hotelling's Lemma, when it is combined with property four is a useful mechanism. Property six states that demand and output supply functions can be derived from the dual profit functions. Hence, if input and output quantities are available as well as the prices then supply and demand equations can be estimated simultaneously with the profit function. Properties one through six can be used to derive restrictions on the coefficients estimated that can be both imposed and tested.

There are two types of profit functions that are prominent in the forest sector literature. These are translog and quadratic profit functions. Both types of functions have a great deal of flexibility and are useful tools. This study uses the quadratic functional form for profits and will be described in more detail.

### **2.2.1 The Quadratic and Translog Profit Functions**

The quadratic and translog normalized profit functions are both useful for estimation in econometric studies. Both methods of estimation are applicable for multiple-output, multiple-input profit functions and have been used in previous studies. The use of these functional forms has become increasingly popular since they are less restrictive than other functional forms such as the Cobb-Douglas or CES (Villezca-Becerra and Shumway, 1992). The two functional forms are quite similar in form with a few differences in the formation of equations and how they satisfy the properties of profit maximization given in the previous section. Both types of profit functions are often normalized, which assures linear homogeneity of the profit function in all prices.

A generalized form of the normalized quadratic profit function is given in equation 2.1. With the application of Hotelling's Lemma, direct differentiation of the profit function will yield the derived supply and demand equations and is given in equation 2.2.

$$\begin{aligned} \pi^* = & \alpha_o + \sum_{i=1}^n \alpha_i P_i^* + \frac{1}{2} \sum_{i=1}^n \sum_{h=1}^n \gamma_{ih} P_i^* P_h^* + \sum_{i=1}^n \sum_{k=1}^m \delta_{ik} P_i^* Z_k \\ & + \sum_{k=1}^m \beta_k Z_k + \frac{1}{2} \sum_{k=1}^m \sum_{j=1}^m \phi_{kj} Z_k Z_j \end{aligned} \quad (2.1)$$

where:  $\gamma_{ih} = \gamma_{hi}$  for all  $h, i$  and the function is homogeneous of degree one in prices of all variable inputs and outputs;

$\pi^*$  = the restricted profit (total revenue less total costs of variable inputs normalized by  $P_y$ , the price of output);

$P_i^*$  = the price of variable input  $X_i$  normalized by  $P_y$ ;

$Z_k$  = the  $k$ th fixed inputs:  $i=h=1,2,3\dots n+k=j=1,2,3\dots m$ ;

$\alpha_o, \alpha_i, \gamma_{ih}, \delta_{ik}, \beta_k$ , and  $\phi_{kj}$  = the parameters.

Taking the derivative of equation 2.1 with respect to the normalized price of  $i$  yields equation 2.2. By Hotelling's Lemma this equation represents the derived input demand and output supply equations depending on whether the derivative is with respect to an input price or output price.

$$\frac{\partial \pi}{\partial (p_i / p_n)} = X_i = \beta_i + \sum_{j=1}^n \beta_{ij} p_j^* + \sum_{z=1}^m \beta_{iz} Z \quad (2.2)$$

where:  $X_i$  = the  $i$ th input or output quantities;

$p_j^*$  = the normalized price of  $j$ .

The normalized translog profit function is the most commonly used functional form in profit function literature. A generalization of this functional form is given by Diewert (1974) and is presented as equation 2.3.

$$\begin{aligned} \ln \pi^* = & \alpha_o + \sum_{i=1}^n \alpha_i \ln P_i^* + \frac{1}{2} \sum_{i=1}^n \sum_{h=1}^n \gamma_{ih} \ln P_i^* \ln P_h^* + \sum_{i=1}^n \sum_{k=1}^m \delta_{ik} \ln P_i^* \ln Z_k \\ & + \sum_{k=1}^m \beta_k \ln Z_k + \frac{1}{2} \sum_{k=1}^m \sum_{j=1}^m \phi_{kj} \ln Z_k \ln Z_j \end{aligned} \quad (2.3)$$

where:  $\gamma_{ih} = \gamma_{hi}$  for all  $h, i$  and the function is homogeneous of degree one in prices of all variable inputs and outputs;

$\pi^*$  = the restricted profit (total revenue less total costs of variable inputs normalized by  $P_y$ , the price of output);

$P_i^*$  = the price of variable input  $X_i$  normalized by  $P_y$ ;

$Z_k$  = the  $k$ th fixed inputs:  $i=h=1, 2, 3 \dots n+k=j=1, 2, 3 \dots m$ ;

$\ln$  = the natural logarithm;

$\alpha_o, \alpha_i, \gamma_{ih}, \delta_{ik}, \beta_k,$  and  $\phi_{kj}$  = the parameters.

Differentiation of equation 2.3, with respect to  $\ln P_i$  and  $\ln P_y$ , gives a system of variable input/profit ratio functions ( $S_i$ ) and an output/supply profit ratio function ( $S_v$ ) (Diewert 1974). This is derived by Shephard's Lemma (Diewert and Wales, 1987) and the results are given in equations 2.4 and 2.5 respectively.

$$S_i = -\frac{P_i^* X_i}{\pi^*} = \frac{\partial \ln \pi^*}{\partial \ln P_i^*} = \alpha_i + \sum_{h=1}^n \gamma_{ih} \ln P_h^* + \sum_{k=1}^m \delta_{ik} \ln Z_k \quad (2.4)$$

$$S_v = \frac{V}{\pi^*} \quad (2.5)$$

where:  $V$  is the quantity of output supply.

Diewert notes that because  $S_i$  and  $S_v$  sum to unity, the output supply equation can be ignored, and only the variable input equations and the translog profit function are required for econometric estimation. Equations 2.4 and 2.5 and the use of natural logarithms, are the key differences in application of the normalized translog profit function and the normalized quadratic profit function. One important consideration in deciding to use a translog function is that it is difficult to obtain sufficient conditions on the parameters of the translog variable profit function which will ensure that it is *globally* consistent with the conditions for profit maximization.

Preliminary estimation of the translog function resulted in parameter estimates that implied that the function did not satisfy all the profit maximizing conditions over the whole range of the data. The rationale for choosing the quadratic function, over the translog function for this study, was to provide a more direct route from estimation to derived supply and demand relationships, which is more difficult with profit shares.

## **2.3 Previous Studies of Profitability, Input Demand, Costs, and Technical Change in the Forest Sector**

The majority of previous studies in the forest sector tend to have an emphasis on cost functions and total factor productivity. The studies are broken up into the two main sectors of the forest industry: the wood industry and the pulp and paper industry. There are only a few studies that use profit functions for either industry. The remainder of this chapter reviews these studies.

### **2.3.1 Wood Industries Sector**

The wood industries sector is where the majority of past research studies have been done. This is likely because in the sawmilling industry there have been many important policy issues over the past 20 years, such as the Canada-United States softwood lumber dispute.

The most relevant study, in the literature for this project, is an econometric analysis of output supply and input demand in the Canadian softwood lumber industry. Latta and

Adams (2000), employ a normalized restricted quadratic profit function approach to estimate lumber supply and also analyze Marshallian demand elasticities for three Canadian regions. They chose to regionalize Canada into three producing regions being the coastal British Columbia, interior British Columbia and Alberta, and the rest of Canada. This study, along with Meil and Nautiyal (1988), are the only studies in the literature that use both a profit function approach and that use regional data. Most other studies use a national time series of the sawmilling industry. This is a significant advancement compared to the other previous studies, which have mainly used national time series data sets. However, in the estimation of the profit function in this study, the authors used a single composite output of lumber and wood chips rather than estimating as a multiple output function. The results of the model indicate that coastal British Columbia is most price sensitive compared to the interior region and the rest of Canada. The authors attribute this result to producers experiencing contracting output, declining rates of capacity utilization, and loss of market share to other regions. This paper, along with Constantino and Haley (1988), has the only developed published estimates of Marshallian own and cross-price factor demand elasticities at a regional level. Constantino and Haley studied sawmilling producers for the British Columbia coast and the U.S. Pacific Northwest.

Meil and Nautiyal (1988), as noted previously, developed a variable translog cost function to analyze production structure and factor demand in major Canadian softwood lumber producing regions. It is noted that this is the first study to “statistically test for regional and intraregional differences in softwood lumber production across Canada”. Though this is a cost function, it is very useful to mention in this section because of the regional testing. The authors estimated the cost function for coastal British Columbia, interior British Columbia, Ontario, and Quebec. The results of the study indicate that the “demand for production inputs is not static, but is governed by offsetting dynamic effects”. They found that output effects dominate the demand for wood and energy, while substitution and capital effects dominate the demand for labour.

Constantino and Haley (1988), chose to estimate input and output choices of sawmilling producers in the British Columbia coast and the U.S. Pacific Northwest by using a translog restricted profit function. Though this study is only looking at two separate regions it is still useful to note that it is one of the few attempts to estimate Marshallian own and cross-price elasticities at a regional level. Another significant feature of this paper is that the authors chose to incorporate multiple outputs, being lumber and pulp chips. Since this study is analyzing the sawmilling industry, they also chose to have a variable representing wood quality. The results from this paper indicate that output and input responses to price changes were found to be elastic in most cases and that the output mix is also responsive to changes in relative prices.

The remainder of the literature papers reviewed from the wood industries sector include papers focusing on a particular region in Canada (Banskota et al, 1985; Meil, Singh, and Nautiyal, 1988), the industry within a nation (Baardsen, 2000; Bigsby, 1994; Nautiyal and Singh, 1985; and Singh and Nautiyal, 1986), the Canadian forest sector (Kant et al, 1996; and Martinello, 1985) and inter-regional analysis (Bernard et al, 1997; and Smith and Munn, 1998). All of these studies, except for Bernard et al, employ restricted or unrestricted translog cost functions for estimation and primarily focus on production structure, demand, and economies of scale. Bernard et al use a normalized quadratic profit function and focus their results on lumber trade between Canada and the United States.

### **2.3.2 Pulp and Paper Industry Sector**

The number of papers that consider the pulp and paper industry is minimal when compared to those of the wood industries. For profit functions, there are studies using a restricted profit function (Muller, 1979), nonparametric methodology (Hseu and Buongiorno, 1997) and a generalized Leontief profit function (Bergman and Brännlund, 1995). The other papers regarding this industry look at cost function methodology (Nautiyal and Singh, 1986; Quicke et al, 1990; and Andrade, 2000) or other factors of

economic performance such as total factor productivity (Bernstein, 1989; Frank et al, 1988;, and Townsend and Uhler, 1986).

Muller (1979) attempts to capture the effects of changes in factor prices on pulp and paper industry prices and outputs. This is the only study in the pulp and paper literature that attempts to estimate an econometric model using a normalized quadratic restricted profit function with multiple outputs for Canada from 1947-1976. The author chose this model type because at the time most industry models did not consider the treatment of multiple outputs. Also, they chose not to include a time variable as a measure of technological change. The results indicate that the model type “has estimated plausible and reasonably stable estimates of own and cross-price elasticities of factor demand and of product supply”. There is also a high degree of autocorrelation found within the estimates as well. However, the author states, “the present estimates do not take into account the demand side of the market for pulp and paper products and hence may be affected by simultaneous equations bias”.

The 1997 Hseu and Buongiorno paper had the objective to estimate output supply and input demand relationships in the Canadian and United States pulp and paper industries. The purpose was to “assess complementarities and substitutions in production, and to improve forecasts”. Their approach was to use methodology that would satisfy the weak axiom of profit maximization. The results from the model indicate that “there exists a range of quantity responses to a given price change that are consistent with economic theory and with a particular data set”. One advantage of only using national data is the ability to separate outputs by pulp, newsprint, other paper, and paperboard. This allows for a better interpretation of what is happening within various sectors of the industry as opposed to a single aggregate output or two outputs.

Nautiyal and Singh (1986) researched long-term productivity and factor demand of the Canadian pulp and paper industry. They chose to estimate an industry translog cost function with a single output and four inputs (labour, capital, materials, and energy). The

results indicate that all inputs in the industry are long-term substitutes “despite some short-run complementarities between energy and materials and energy and capital”.

There are several other studies dealing with the pulp and paper industry. Bergman and Brännlund (1995), attempt to measure oligopsony power in the Swedish pulp and paper industry. To do this, they use a generalized Leontief profit function to represent the production structure. This type of methodology is used because it allows for the functional form to measure for market power and determine the type of power within the industry. The results indicate that there is support for the hypothesis that market power varies in the Swedish pulp and paper industry. Andrade (2000) considers the production technology and cost implications upon the pulp and paper industry for member states in the European Union. For this estimation, the author chose to employ a translog cost function. The results show that there are strong economies of scale within the European Union and that there is “significant but small substitutability between labour and both capital and wood, and complementarities between capital and wood”.

Bernstein (1989), Frank et al (1988), and Townsend and Uhler (1986), all consider economic performance factors of the Canadian pulp and paper industry. Bernstein uses a variable translog profit function in a manner to include the possibility of tax reform to the system. This model incorporates three outputs: newsprint, pulp, and other paper products. The results show that there are increasing returns to scale in the industry and there are significant costs of adjustment that occur with an addition of capital stock. Frank et al (1988), also found that the industry experiences substantial economies of scale. Estimation in this study used a translog cost function. The authors found that input demands for the industry “were revealed to be relatively price inelastic”. The Townsend and Uhler paper had the objective to determine whether the Canadian pulp and paper industry has market power in pricing. The authors chose to use a translog cost function to estimate the results. Their results indicate, “for Canadian producers of pulp and paper products the price-taking assumption is invalid”. This means that the producers do have market power in pricing their own products.

### **2.3.3 Other Industries**

The quadratic profit function is used as an estimation procedure in a wide variety of studies. Stefanou and Saxena (1988) used the quadratic profit function to evaluate for training variables to influence allocative efficiency in the Pennsylvania dairy industry. Shumway et al (1988), used the quadratic profit function to estimate output supply and input demand relationships for five commodity groups and four variable inputs.

Villezca-Becerra and Shumway (1992), use a quadratic profit function (as well as translog and Leontief methodology) to test the difference in functional form used for multiple outputs in 4 major geographically dispersed agricultural states in the United States. The authors found that “while a considerable number of large differences due to functional form were noted, far fewer differences appeared to be important in a statistical sense”. Dupont (1991), used a restricted quadratic profit function to test input substitution effects in a regulated fishery.

### **2.4 Conclusions**

The survey of previous econometric analyses of the pulp and paper and wood industries in Canada suggests that there has been substantial past analysis of productivity and of elasticity of demand and supply. However, for the pulp and paper industry there has been no analysis that examines regional variability in profitability and technical change, that divides the wood input into roundwood and wood chips, or considers multiple outputs. In chapter three, an econometric model is derived that incorporates these three factors.

## CHAPTER THREE: METHODOLOGY

### 3.1 Overview

This chapter is a description of the methodology used in this study. This includes a detailed description of the models used in estimation. This is followed by an explanation of the data used for the study. As mentioned earlier, the model used for this study is a normalized quadratic profit function. Four models were estimated. Two contain regional dummy variables for Quebec, Ontario, British Columbia, and the Rest of Canada and two do not. Two of the models contain correction for autocorrelation. Both of these models are described in this chapter. The results derived from these estimations provide the basis for own-price, cross-price, and profit elasticities estimates which are discussed in chapter four.

### 3.2 Seemingly Unrelated Regression

The normalized quadratic profit function together with the input demand and output supply functions can be estimated using a seemingly unrelated regressions model. The specific function estimated for this study is described in sections 3.4 and 3.5. This section details the simple seemingly unrelated regression model and provides a basis for the econometric development of the quadratic profit functions estimated for this study.

Equation 3.1 follows Kmenta (1986) matrix notation for the following simple example of a seemingly unrelated regression:

$$\begin{aligned} y_{1t} &= \beta_{1t} X_{1t} + \varepsilon_{1t}, \\ y_{2t} &= \beta_{2t} X_{2t} + \varepsilon_{2t}, \\ &\cdot \\ &\cdot \\ y_{Mt} &= \beta_{Mt} X_{Mt} + \varepsilon_{Mt} \end{aligned} \tag{3.1}$$

where:  $m=1,2,\dots,P$ ,  $M$  number of equations;

$T$  is the number of observations;

$K$  is the number of explanatory variables;

$y_M$  is a  $(TX1)$  vector of the sample values of the dependent variable;

$X_M$  is a  $(TXK_M)$  matrix of the sample values of the explanatory variables;

$\beta_M$  is a  $(K_M X1)$  vector of the regression coefficients;

$\epsilon_M$  is a  $(TX1)$  vector of the sample values of the disturbances.

This system of  $M$  equations is called a system of seemingly unrelated regression equations because the covariance matrix represents the only link of the disturbances between the  $m$ th and the  $p$ th equation.

The use of seemingly unrelated regression makes sense when there are reasons to believe that seemingly unrelated equations are correlated through error terms. A profit, demand, and supply system is one example. When prices increase for inputs, one expects that profits will decrease and demands for inputs will decrease. Hence, errors in the profit functions should be correlated with errors in the demand and supply functions. This type of correlation is called contemporaneous correlation.

Seemingly unrelated regressions can be estimated with cross equation restrictions on the parameters. Profit, demand and supply systems provide another example where imposing cross equation restrictions is appropriate (Kmenta, 1986). In chapter 2 it was shown that the derivative of the indirect profit function with respect to input prices yields the input demand functions. Hence, theoretically the coefficients that appear in the profit function should also appear in the input demand functions. These theoretical results can be imposed by placing cross equation restrictions on the parameter estimates.

### **3.3 Autocorrelation**

Kmenta (1986) notes that seemingly unrelated regressions are common for functions with observations made over time such as demand or production functions. However, in time series data sets autocorrelation is often present as well. Autocorrelation occurs when disturbances in one time period tend to be correlated with the previous period

disturbances. In the case of equation 3.1, it could be assumed that there is some correlation between  $\epsilon_{2t}$  and  $\epsilon_{1t}$ . This type of correlation is first-order autocorrelation. There are various corrections for autocorrelation. With respect to equation 3.1, the correction for autocorrelation is given as  $\rho$  in equation 3.2.

$$\begin{pmatrix} \epsilon_{1t+1} \\ \epsilon_{2t+2} \end{pmatrix} = \rho \begin{pmatrix} \epsilon_{1t} \\ \epsilon_{2t} \end{pmatrix} + \begin{pmatrix} \psi_{1t} \\ \psi_{2t} \end{pmatrix}$$

$$= \begin{pmatrix} p_1 & 0 \\ 0 & p_2 \end{pmatrix} \begin{pmatrix} \epsilon_{1t} \\ \epsilon_{2t} \end{pmatrix} + \begin{pmatrix} \psi_{1t} \\ \psi_{2t} \end{pmatrix} \tag{3.2}$$

$$\epsilon_{2t} = \rho \epsilon_{1t} + \psi_{2t},$$

$$\rho = \frac{\sum_{t=2}^T \epsilon_t \epsilon_{t-1}}{\sum_{t=2}^T \epsilon_{t-1}^2}$$

where:  $\epsilon$  is the disturbance term;

$\psi$  is a stationary, non-autocorrelated process;

$\rho$  is the autocorrelation coefficient;

$p_t$  is the autocorrelation correction coefficient for disturbance  $t$ .

It is expected that the quadratic profit functions estimated in this study would have autocorrelation since this problem is common in time-series data. The correction used in this study to correct for first-order autocorrelation was based upon Pagan (1974) and this method of obtaining the correction parameter estimates by minimizing the following objective function is given in equation 3.3. It should be noted that the Pagan method of parameter estimation sets the pre-sample residuals to zero

$$\begin{aligned}
S_1(\beta_1, \rho_1) &= \sum_{t=2}^T \psi_{1t}^2 \\
&= \sum_{t=2}^T [(Y_{1t} - \beta_1 X_{1t}) - \rho_1 (Y_{1,t-1} - \beta_1 X_{1,t-1})]^2
\end{aligned}
\tag{3.3}$$

where:  $S$  = the residual sum of squares.

When this objective function is minimized, the parameter coefficient  $\beta$  and the autocorrelation coefficient  $\rho$  for the model are estimated jointly. The smaller the value of  $\rho$  means that there is a lower amount of autocorrelation remaining in the model. It is important to note that autocorrelated errors cannot be completely removed from the model but simply minimized to allow for more efficient estimation of parameters. If a model possesses autocorrelated errors, but we ignore or are unaware of the correlation then we are using an estimator that is inefficient and will be using standard errors that are not a proper reflection of the precision of a least-squares estimates (Griffiths, 1993).

### 3.4 Quadratic Profit Function Without Regionalization

Equation 3.4 is the first model and is a normalized quadratic profit function without any regional dummy variables.

The following variables are used in this model and for each variable there are prices and quantities (except for capital and time). The prices ( $X_i$ ) are normalized by a price index of other materials used. The multiple outputs are total paper ( $tp$ ) and wood pulp ( $wp$ ). The multiple inputs are roundwood ( $rw$ ), wood chips ( $wc$ ), labour hours ( $lhr$ ), and energy used ( $e$ ). There is a fixed capital stock ( $k$ ) and time ( $t$ ) is present as well. A description of the data used follows in section 3.7.

The model is as follows:

$$\begin{aligned} \Pi = & c + \sum_{i=1}^n \beta_i X_i^* + \frac{1}{2} \sum_{i=1}^n \beta_{ii} X_i^{*2} + \sum_{i=1}^n \sum_{j=1}^n \beta_{ij} X_{ij}^* + \sum_{i=1}^n \beta_{ik} X_i^* K \\ & + \sum_{i=1}^n \beta_{iy} X_i^* T + \varepsilon \end{aligned} \quad (3.4)$$

where:  $\Pi$  = total variable profits;

$c$  = constant term;

$\beta$  = the coefficients;

$X^*$  = the normalized prices of variable  $n$ ;

$K$  = capital;

$T$  = time;

$n = tp, wp, rw, wc, lbhr$ , and  $e$ ;

$\epsilon$  = the error term.

By following Hotelling's Lemma, we can obtain the derived supply and input demand equations of the profit function. Equations 3.5 and 3.6 are supply and demand equations ( $Q_s$  and  $Q_d$  respectively):

$$Q_s = \beta_s + \beta_{ss} X_s^* + \sum_{i=1}^n \beta_{si} X_i^* + \beta_{sk} K + B_{sy} Y + \varepsilon \quad (3.5)$$

where:  $s$  = total paper or wood pulp;

$n$  = all input variables and the other output variable;

$X_i^*$  = the normalized price of  $i$ ;

$B_s$  = the cross equation coefficient restriction;

$\epsilon$  = the error term.

$$Q_d = -1 * \left( \beta_d + \beta_{dd} X_d^* + \sum_{i=1}^n \beta_{di} X_i^* + \beta_{dk} K + \beta_{dy} Y \right) + \varepsilon \quad (3.6)$$

where:  $d$  = the input being demanded;

$n$  = all other input variables and both output variables;

$X_i^*$  = the normalized price of  $i$ ;

$B_d$  = the cross equation coefficient restriction;

$\epsilon$  = the error term.

The development of the above supply and demand equations (3.5 and 3.6) are dependent upon the cross-equation restrictions imposed from the application of Hotelling's Lemma. What this means is that the cross-term coefficients determined from the profit function (equation 3.4) are used in the supply and demand equations. For example, with respect to wood chips and roundwood, the cross-price coefficient for wood chips and roundwood is used in each respective input demand equation. These allow for the development of unique profit maximizing supply and demands with respect to the estimated profit function.

The results obtained from this model can then be used to estimate elasticities and making other interpretations about the Canadian pulp and paper industry. This model also presents the foundation for estimating a normalized quadratic profit function with regionalization.

### **3.5 Quadratic Profit Function With Regionalization**

Regionalization of the model is accomplished through the use of dummy variables. Ideally, there would be enough data points to run a separate model for each region (Quebec, Ontario, British Columbia, and the Rest of Canada). This would also allow for the regional aspects to be considered for all the cross equation restrictions and the square terms. However, it is still reasonable to estimate the model with regional considerations. In the context of this study, regionalization is taken into account for dummy variables, the initial terms of inputs and outputs, and all aspects of the fixed capital stock and time. Also, the way the data is constructed, it is possible to develop the elasticities for the regions as well.

For this model, there are the same inputs and outputs as mentioned for the model without regionalization above. The four regional factors are generalized as  $r$  for the normalized quadratic profit function with regionalization in equation 3.7:

$$\begin{aligned} \Pi = & \sum_{r=1}^v \alpha_r D_r + \sum_{i=1}^n \sum_{r=1}^v \beta_{ir} X_{ir}^* + \frac{1}{2} \sum_{i=1}^n \beta_{ii} X_i^{*2} + \frac{1}{2} \sum_{r=1}^v \beta_{rk} K_r^2 + \frac{1}{2} \sum_{r=1}^v \beta_{ry} Y_r^2 \\ & + \sum_{i=1}^n \sum_{j=1}^n \beta_{ij} X_{ij}^* + \sum_{i=1}^n \sum_{r=1}^v \beta_{kir} X_i^* K_r + \sum_{i=1}^n \sum_{r=1}^v \beta_{yir} X_i^* Y_r + \varepsilon \end{aligned} \quad (3.7)$$

where:  $D_r$  = the dummy variables for region  $r$  (Quebec, Ontario, British Columbia, and Rest of Canada);

$X_{ir}^* = D_r X_i^*$  = the normalized price of each input and output ( $i$ ) for each region ( $r$ );

$K_r = D_r K_r$  = the capital investment for region ( $r$ );

$Y_r = D_r Y_r$  = the time proxy for technological change for region ( $r$ );

$B_i$  = the coefficient;

all other variables have the same notation as given in equation 3.4.

Once again, by following Hotelling's Lemma, we can obtain the derived supply and demand relationships for the normalized quadratic profit function with regionalization.

These are represented by  $Q_s$  (equation 3.8) and  $Q_d$  (equation 3.9) respectively:

$$Q_s = \sum_{r=v}^v \beta_{sr} R_r + \beta_{ss} X_s^* + \sum_{i=n}^n \beta_{si} X_i^* + \sum_{r=v}^v \beta_{ksr} K_r + \sum_{r=v}^v \beta_{ysr} Y_r + \varepsilon, \quad (3.8)$$

$$Q_d = -1 * \left( \sum_{r=v}^v \beta_{dr} R_r + \beta_{dd} X_d^* + \sum_{i=n}^n \beta_{di} X_i^* + \sum_{r=v}^v \beta_{kdr} K_r + \sum_{r=v}^v \beta_{ydr} Y_r + \varepsilon \right), \quad (3.9)$$

where:  $s$  and  $d$  refer to the respective supply and demand equations given in equations 3.5 and 3.6.

The development of the above supply and demand equations (3.8 and 3.9) are dependent upon the cross-equation restrictions imposed from the application of Hotelling's Lemma. What this means is that the cross-term coefficients determined from the profit function (equation 3.7) are used in the supply and demand equations. The way this differs from

the cross-equation restrictions developed in the model without regionalization is with the capital and time variables and with the first order price term of the input or output being examined. These are the variables where the derivatives will also involve the regional dummy variables.

As stated in the previous section, the results from this model can be used to determine values of elasticities and other interpretations. The big difference is due to the regional differentiation. By having regional values in the profit equation, we can see differences between regions through the elasticity values. Also, because of the multi-output (multi-input) factorization of the model, we can observe the relative strength of the outputs (or inputs) within a region (i.e. if the region's profitability is better suited for production of wood pulp rather than total paper). It should be noted that the model presented, in equation 3.7, regionalizes the capital and time variables but not the price variables for the square terms. Hence, data estimates of elasticities of supply and demand will not incorporate regional variation in coefficients. Differences in elasticities for inputs and outputs for regions will be driven by differences in price and quantity. This is not true with respect to the profit elasticities. The derivative of the profit function with respect to output price, input price, capital, and time will pick up regional variation through the first order coefficients for prices and the first and second order coefficients for capital and time.

### **3.6 Elasticities**

Elasticities are a useful measure to make interpretations about how relative changes in price affect the responsiveness of a variable. This is important when considering supply and demand effects upon the industry. There are three elasticity measures used in this study. They are:

### Marshallian own-price elasticities

$$e_{ii} = \beta_{ii} * \frac{P_i^*}{Q_i}, \quad (3.10)$$

where:  $i$  = the variable being examined;

$p^*$  = the price of  $i$  normalized by the price of other materials;

$Q$  = the quantity of  $i$ .

The own-price elasticity measures the percentage change in quantity demanded for a given percentage change in price along the ordinary demand function or the own-price market demand function (Binger and Hoffman, 1998).

### Marshallian cross-price elasticities

$$e_{ij} = \beta_{ij} * \frac{P_j^*}{Q_i}, \quad (3.11)$$

where:  $i$  and  $j$  = the variables being examined;

$p^*$  = the price of  $i$  normalized by the price of other materials;

$Q$  = the quantity of  $i$ .

The cross-price elasticity measures the percentage change in quantity demanded for a given percentage change in the price of another good (Binger and Hoffman, 1998).

### Profit function elasticities

$$e_{\Pi x} = \frac{\partial \Pi}{\partial P_x} * \frac{P_x^*}{\bar{\Pi}}, \quad (3.12)$$

where:  $x$  = the variable being examined;

$p^*$  = the normalized mean value of  $x$ ;

$\Pi$  = the mean value of profit for the region being examined.

All three are used in the models with and without regionalization. All price and quantity values were taken at the sample means for price and quantity of the respective variables.

### **3.7 Description of the Data**

The data being used for this study has come from a variety of sources. The majority of data has come from the pulp and paper mills (1961-1984), paper and allied products (1985-1995), and Canadian forestry statistics (1962-1995) publications from Statistics Canada. For areas where the data did not exist, estimates were made using the quantity data and price indices from the Statistics Canada CANSIM database.

The raw data set spans from 1961-1995 with the exclusion of 1991 due to a lack of data for that particular year. In total, there are 136 observations for each model being estimated with 34 data points per region. There is an analysis of the raw data in section 4.2, then the normalized quadratic profit functions results will be detailed in section 4.3.

Table 3.1 includes the units of data used in this study. It details the variables, price in dollars per unit, and quantity in units.

Total variable profit was calculated by dividing total revenue by the total variable cost of the industry. Total paper and wood pulp prices were calculated by dividing total revenue for each variable by the respective total production. Roundwood and wood chip prices were determined by dividing the respective total costs by the quantity of the wood input. Labour price was calculated by dividing the labour cost by the number of hours worked. The price of energy was provided from the Statistics Canada CANSIM database. The quantity of energy used was determined by taking the industry cost of energy and dividing by the price of energy. The capital stock data was the end-year net stock as provided by the industrial monitor data from Statistics Canada. All monetary data was converted into real 1992 dollars by an industrial product price index obtained from the Statistics Canada CANSIM database. All prices in the dataset are normalized by the

price of other materials that was also obtained through the CANSIM source. The time variable was calculated by taking the observation year less 1960. Appendix one contains the data set used for this study.

**Table 3.1 Units of Data in the Study**

<b>Variable</b>	<b>Price</b>	<b>Quantity</b>
Total Variable Profit	----	1992 \$ millions
Total Paper	\$/tonne	10 <sup>3</sup> tonnes
Wood Pulp	\$/tonne	10 <sup>3</sup> tonnes
Wood Chips	\$/m <sup>3</sup>	10 <sup>3</sup> m <sup>3</sup>
Roundwood	\$/m <sup>3</sup>	10 <sup>3</sup> m <sup>3</sup>
Labour	\$/hour worked	millions of hrs
Energy	\$/GJ	GJ
Price of Other Materials	----	price index, 1992=100
Capital	----	1992 \$ millions
Time	----	year

## CHAPTER FOUR: RESULTS and ANALYSIS

### 4.1 Overview

This chapter examines the data used to estimate the models presented in chapter 3 and presents the results of the seemingly unrelated regressions. The chapter is organized as follows. In section 4.2, there is an analysis of the raw data. This involves examining graphs of the data and making some observations and interpretations. The focus on this section is to look at the wood inputs and outputs and with a capital and labour consideration. In section 4.3, the results of the four models are presented. The models for the Canadian pulp and paper industry include either a regional or a national interpretation, along with the use of an autocorrelation command or without. There is an analysis of the coefficients and profit, own-price, and cross-price elasticities. The four models will be compared and reasoning is given as to which model is the best one and why.

### 4.2 Analysis of Raw Data

In this section, trends of input prices, output prices, input quantities and output quantities are presented, analyzed and compared. These interpretations of the historical data will put the forthcoming regression results into perspective and aid in their interpretation.

The most important variables to consider in the analysis are the wood inputs (roundwood and wood chips) and outputs (wood pulp and total paper). By examining the prices and quantities of these respective variables by region, we can observe which regions differ and whether or not these differences are large. This is useful to observe possible trends the industry may be facing and the effect upon profitability.

#### **Total Variable Profit Observations**

Figure 4.1 shows the time trend of total variable profit over time for each region. It should be noted that total variable profit is equal to the total revenue less the total variable costs faced by the industry.

**Figure 4.1 Total Variable Profit (Real \$1992 Cdn)**

The indication from figure 4.1 is that total variable profit for the pulp and paper industry has been positive for all regions throughout the data set. The profit trend appears to be cyclical and correlated for each region. That is, on the downward trend of the profit cycle each region experiences a decline and on the peaks each region experiences an increase in total variable profits. This is not surprising since prices of outputs in the forest industry are typically cyclical.

### Wood Input Observations

Figures 4.2 and 4.3 show quantity of roundwood and wood chips used by the pulp and paper industries over the sample period. The most striking feature of roundwood use in Canada is that roundwood used rises in the 1960s for all four regions and then declines thereafter for Quebec and British Columbia. For Ontario the decline does not occur until the late 1980s. However, for the Rest of Canada wood use continues to increase throughout the sample period. These rises in wood use may be associated with large expansions of the pulp and paper industries in Alberta and Saskatchewan during the late 1980s and 1990s. The most important feature of wood chip use is that it rises in all regions throughout the sample period. This suggests, together with decreases in

roundwood use, that wood chips purchased from sawmills are being used as a substitute for roundwood that is harvested and directly delivered to pulp mills.

**Figure 4.2 Quantity of Roundwood Used (1961-1995)**

**Figure 4.3 Quantity of Wood Chips Used (1961-1995)**

Another important observation can be made about the relative roundwood and wood chip use in BC. British Columbia has the largest wood chip use and lowest roundwood used of all four regions. Also, British Columbia has by far the largest sawmilling industry that produces large quantities of residual wood chips. Hence, British Columbia tends to supply its pulp and paper industry with relatively more wood chips.

### **Wood Product Output Observations**

Figures 4.4 and 4.5 show the quantity of wood pulp and total paper produced. For all regions there has been an increase in production for both outputs. The two largest contributors of wood pulp are British Columbia and the Rest of Canada. For wood pulp, the largest increase over the data set has been seen in the Rest of Canada. British Columbia has been rising with a fairly constant trend, while Ontario and Quebec have both seen a gradual increase over the data set. As mentioned previously, the increase seen in the Rest of Canada could be attributed to the expansion of pulp processing plants in Alberta and Saskatchewan in the 1980s and 1990s.

Once again, there has been a rise in the production of total paper across all regions throughout figure 4.5. The two largest contributors of total paper production are Quebec and Ontario. However, the difference between total paper and wood pulp production appears to be that the increase in total paper is more linear across all regions but Quebec and Ontario have a steeper slope for the data set.

From figures 4.2 and 4.3, it is evident that over time the quantities of wood chips used are rising and the quantities of roundwood used are in decline (except for in the Rest of Canada). When you combine this information with an increasing trend in the production of wood pulp and total paper from figures 4.4 and 4.5, it appears that there is a substitution effect occurring in the industry. If manufacturers are substituting the use of roundwood with wood chips in production of pulp and paper products, this could be the result of a price difference between the two goods and/or from technological processes.

**Figure 4.4 Quantity of Wood Pulp Production (1961-1995)**

**Figure 4.5 Quantity of Total Paper Production (1961-1995)**

**Figure 4.6 Trends in the Prices of Roundwood and Wood Chips for Quebec (real \$1992 Cdn)**

**Figure 4.7 Trends in the Prices of Roundwood and Wood Chips for Ontario (real \$1992 Cdn)**

**Figure 4.8 Trends in the Prices of Roundwood and Wood Chips for British Columbia (real \$1992 Cdn)**

**Figure 4.9 Trends in the Prices of Roundwood and Wood Chips for the Rest of Canada (real \$1992 Cdn)**

### Wood Input Price Observations

Figures 4.6 through 4.9 demonstrate that the price of wood chips and the price of roundwood are very similar throughout the length of the data set except for the in the early 1960s, where wood chip prices tend to be lower than roundwood prices. From 1970-1995, prices of wood chips and roundwood are closer together and exhibit similar trends in the same direction.

A possible reason for the lower prices for wood chips, early in the sample period, is that the demand for wood chips was lower at that time. Over time, wood chips have become more of a substitute for roundwood. As wood chips have become more of a substitute, the demand for wood chips has increased and the price has increased accordingly. Since, it appears that roundwood and wood chips are close substitutes, it can be reasoned that this is why the prices tend to fluctuate in the same direction. This position can be supported with use of figures 4.2 and 4.3, where wood chip use is continuing to rise in all regions and roundwood use is in decline over time except for the Rest of Canada.

Given that roundwood and wood chip prices are similar, the shift in the industry towards the use of wood chips may also be due to higher valued uses for roundwood in other forest products. This could occur because there are many mills which produce not only pulp and paper products but lumber and other forest based products as well. If roundwood has a higher value use in production of the other products, then if wood chips are substitutable it makes sense to have a shift towards wood chip inputs in the pulp and paper sector.

**Figure 4.10 Quebec Capital Stock vs Labour Hours (1961-1995)**

**Figure 4.11 Ontario Capital Stock vs Labour Hours (1961-1995)**

**Figure 4.12 British Columbia Capital Stock vs Labour Hours (1961-1995)**

**Figure 4.13 Rest of Canada Capital Stock vs Labour Hours (1961-1995)**

**Figure 4.14 Ratio of Capital Stock to Labour Hours (1961-1995)**

**Capital Stock vs. Labour Hours Observations**

From figures 4.10 –4.13, the amount of the capital stock is increasing throughout all regions across the whole sample period. Although labour hours worked has been fairly constant, it appears to be declining since 1975 in Ontario and Quebec. In British Columbia and Rest of Canada it appears to be roughly constant since 1975.

From figure 4.14, the capital-labour hours worked ratio is increasing. This is an indication that there is a substitution effect occurring shifting to a decline in labour hours

purchased given an increase in capital stock. This makes sense because it could be assumed that when there is a capital increase, there could be a more time efficient use of labour that could then lead to a decline in labour hours.

As output is increasing, labour hours being used is in decline or staying relatively constant. However, the capital is increasing and the capital-labour hours ratio is increasing as well which indicates that there has likely been a shift to more capital intensive and less labour intensive technology in the pulp and paper industry.

### Ratio of Total Paper to Wood Pulp Production Observations

**Figure 4.15 Ratio of Total Paper to Wood Pulp Production (1961-1995)**

Figure 4.15 shows the ratio of total paper production to that of wood pulp production. Figure 4.15 together with Figures 4.4 and 4.5 demonstrate that Quebec and Ontario are the two main producers of the Canadian total paper, whereas British Columbia and the Rest of Canada produce greater amounts of wood pulp.

Ontario and British Columbia appear to have a slightly declining ratios of total paper to wood pulp production over the sample period. The Rest of Canada appears to have a slight decline over the sample period and this is an indication that there is a greater ratio of wood pulp to total paper in the region over time.

The trends described in this section, along with basic economic intuition, will help us interpret the results of the econometric model, which are presented in the next section.

### **4.3 Results of the Regional and Non-Regional Profit Function Models**

In total, four different models were estimated for the data set. These models may be described as follows. Two models estimated profit functions for the Canadian pulp and paper industry with 4 regional dummy variables and regional dummy interaction terms on first order price terms, capital and time variables (Quebec, Ontario, British Columbia, and Rest of Canada). Two other models pool the regional data and one national profit function model is estimated. Both the regional and non-regional models are estimated with and without corrections for autocorrelation using the Shazam auto option for seemingly unrelated regression.

#### **4.3.1 Summary of the Profit Function Results**

As could be seen in the coefficients, there are differences in the signs and size for many of the variables. Given the objectives of this project, it is expected that the models with regional dummy variables would be a superior tool for analysis of the industry. However, this would only be true if significant improvement in model fit is obtained by including regional dummy variables. Otherwise regional variation in the industry profit elasticities would be obtained using the estimates obtained from the pooled data set where no regional dummy variables are included. The  $X^2$  statistic in table 4.1, however, shows that inclusion of regional dummy variables has a highly significant and positive impact upon model fit at the 95 percent significance level. This is true for models with or without autocorrelation corrections.

**Table 4.1 A Comparison of Key Statistical Results from Four Normalized Quadratic Profit Functions**

Statistical Test Result	Autocorrelation Corrected Model		No Correction For Autocorrelation Model	
	Regional	Non-Regional	Regional	Non-Regional
Durbin-Watson Test Statistic Value	1.9149	2.0985	0.9963	0.6457
R <sup>2</sup> value between observed and predicted	0.8667	0.8172	0.7931	0.5852
Sum of Absolute Errors	139.53	158.16	181.41	265.31
Sum of Residual Errors	7.8760	33.783	3.9793	10.141
Residual Variance	2.0136	2.9339	3.1429	6.4789
First-order Autocorrelation Coefficient Value (t-statistic)	0.59349 (15.068)	0.95407 (100.08)	---	---
Log-Likelihood Function Value	-1028.361	-1312.603	-1163.648	-1913.359
X <sup>2</sup> statistic (degrees of freedom)	568.484 (df=73)		1499.422 (df=73)	

The Durbin-Watson statistics for the models without a correction for autocorrelation suggest that autocorrelation is present. Both Durbin-Watson statistics for these models are less than one and this indicates significant autocorrelation at the 95 percent significance level.

The R<sup>2</sup> values between the observed and predicted provide an indication of how well the model fits the data. The models estimated with a correction for autocorrelation are considered to be superior because they have a value closer to one. The model with regional dummy variables is closest to one so this implies that the splitting of the industry into regions is a more useful econometric exercise.

The chi-square statistic is determined through use of the log-likelihood ratio test. Both  $X^2$  values are significantly greater than the  $X^2$  critical value of 90.5312 with 73 degrees of freedom at a 95 percent level of significance. This result indicates that there is a significant difference between estimating the quadratic profit functions with regional dummy variables and those without regional dummy variables.

Therefore, from these results it can be concluded that the most applicable model considered is the regional normalized quadratic profit function using the correction for first order autocorrelation. The results from this model also satisfy the conditions of profit maximization, as given in section 2.2, as all the signs on coefficients are in the correct direction. Therefore, all interpretations of results from this point will refer to this model.

Tables 4.2 – 4.4 contain all of the first-order, square-term, and cross-term interaction coefficient results from the 4 models with the t-statistic values in brackets. The critical t-statistic value is 2.101 for the regional model (18 degrees of freedom) and 2.021 for the non-regional models (91 degrees of freedom) at a 95 percent significance level. The coefficients that are in bold font indicate that they have significant t-statistic values. If there is not a value for a coefficient then it was not used in that model type.

1. Auto refers to a correction for autocorrelation in the estimated model.
2. Regional refers to presence of regional dummy variables for Quebec, Ontario, British Columbia and the Rest of Canada.
3. Total Paper and Wood Pulp refer to normalized output prices
4. Roundwood, wood chips, labor and energy refer to normalized input prices.
5. Capital = Quasi-Fixed Capital Stock Investment;
6. Time = Time Variable as a Proxy for Technological Change;
7. Quebec, Ontario, British Columbia and Rest of Canada refer to regional dummy variables.

### 4.3.2 First Order Coefficient Results

The results for the first order coefficients are presented in table 4.2. With respect to the first term coefficients, they are analyzed in the context of what will happen to the profit function given a price change in the respective variable being examined. While these coefficients are useful in interpreting the results, just examining them does not give a clear interpretation of what is happening in the model because price variables appear in interaction terms and squared terms. To have a clearer interpretation requires the use of elasticities and this will be discussed later in this section.

For the regional model with a correction for autocorrelation, the price coefficients for roundwood, labour, and energy inputs are all significant and all have negative signs. This means that they contribute negatively to the overall profit function for each of the regions. The other input of wood chips does not have any significant variables. For the outputs, the only significant variables are for total paper in Quebec and Ontario, and with wood pulp in British Columbia.

The most interesting result from the first term coefficients is with respect to Quebec. For each variable that is significant, Quebec has the largest coefficient value amongst the four regions. This is an indication that a price change of any variable within the Quebec pulp and paper production system would have a greater impact on profit than a change in any of the other regions. This means that the Quebec pulp and paper industry is quite price sensitive with respect to profitability.

Another interesting result is the coefficient on the British Columbia wood pulp variable. This is the only region where wood pulp has a significant coefficient. This can be interpreted, along with Figure 4.3 in the previous section, that British Columbia is the key producer of wood pulp in the nation. Thus, the effect of a change in the price of wood pulp would have the most significant effect upon the industry profit function in British Columbia.

### **4.3.3 Square Term Coefficient Results**

The results for the square-term coefficients are presented in table 4.3. Due to data limitations, regarding lack of degrees of freedom, square terms for each variable could not be incorporated. However, regionalization is possible for a subset of the variables and it was decided to regionalize the square terms for the capital and time variables.

For the capital and time variables, the square terms have some positive and negative values depending on the region. For the squared price variables, which are not estimated by region, the results for total paper, wood pulp, roundwood, wood chips, labour, and energy all have a positive sign. This is important with respect to the convexity properties of profit maximization. A negative term would indicate non-convexity and would result in an upward sloping demand function and/or a downward sloping supply function. This type of result would violate property four of profit maximization which states that the function must be convex and continuous. Hence, the estimated model is consistent with profit maximization.

### **4.3.4 Profit Elasticities Results**

Profit elasticity estimates are interpreted as the percentage change in profits that arises with a small (or one) percent change in prices, capital stocks or time. The estimates of profit elasticities for the regional model with a correction for autocorrelation are presented in table 4.5. Note that the Canada column results are estimated from this model and are estimated by using the Canadian mean quantities.

**Table 4.5 Profit Elasticities Regional Model Estimation with a correction for autocorrelation**

Variable	Canada*	Quebec	Ontario	BC	Rest of Canada
Total Paper	4.887342	3.049696	2.75359	1.38257	2.04037
Wood Pulp	3.707697	0.525483	0.95167	2.09507	1.95017
Labour Hours	-1.08557	-0.89112	-0.8462	-0.6947	-0.7373
Roundwood	-0.70255	-0.55053	-0.57561	-0.2704	-0.7936
Wood Chips	-1.45009	-0.28613	-0.19047	-0.6105	-0.2462
Energy	-0.81957	-0.40055	-0.3466	-0.2999	-0.406
Capital	-1.26373	0.46365	-0.78187	-0.5534	0.54524
Time	3.641903	0.116538	0.98207	0.92798	0.61546

\* Note that the Canada column results are estimated from this model and are estimated by using the Canadian mean quantities and the square coefficients because the coefficients are not regionalized.

Profit elasticities, for outputs and inputs prices have the expected signs. Profit elasticity with respect to total paper price is elastic for all regions while wood pulp price is only elastic for Canada, British Columbia, and the Rest of Canada. Profit elasticities for labour price, wood chips price, capital, and time are all elastic for Canada and inelastic for the other regions. Roundwood and energy are price inelastic for all regions.

Quebec and Ontario obtain much higher percentage profit increases when there is an increase in the price of total paper than for the same percentage price increase in wood pulp. Conversely, profits in British Columbia are more sensitive to prices of wood pulp than paper production prices. These results correspond to the analysis of the figures 4.3 and 4.4 presented earlier in this chapter regarding outputs of each industry. The Rest of Canada appears more equally sensitive to price changes in the two major outputs. Note that these results are obscured for the national model.

With respect to capital, the profit elasticities have differing signs across the regions. Canada, Ontario and British Columbia have negative signs while Quebec and the Rest of Canada have positive signs and all regions are inelastic. In theory, the difference in signs is an indication of the capital effect upon profitability. For British Columbia and Ontario, it appears that increasing capital stock decreases profitability while for Quebec and the

Rest of Canada increasing capital stock increases profitability. This may indicate some overcapacity in British Columbia and Ontario. However, these results need to be treated with some caution because of the correlation between time and capital stock. With respect to time, the profit elasticities are all positive and inelastic for all regions except for Canada which is positive and elastic. The fact that the sign on capital for the national model is negative and is positive for the sign on time may also illustrate that there is some multi-collinearity. Moreover, capital elasticities are largest for Quebec and the Rest of Canada while elasticities on time for these two regions are the smallest. The situation is reversed for Ontario and BC where the capital elasticities are the smallest and the time elasticities are the largest. However, the result on the time coefficients appear to make sense because as shown in figures 4.3 and 4.4, production of outputs and profits have been increasing for all regions over time. The time effect may be interpreted as the effect of technological change. Hence, the results indicate that technological change has increased profitability in all regions with the largest effects being in BC and Ontario whereas profitability in Quebec and the Rest of Canada has been most affected by increases in capital. In practice, the collinearity between these two variables may be hard to eliminate since new capital investments will usually incorporate new technology.

#### **4.3.5 Own-Price Elasticity Results**

Tables 4.6 displays the own-price elasticity results. The table displays the elasticities for Canada as a whole and for each respective region. Because square terms are not regionalized, each variable has the same coefficient value for each region and hence a weakness of these elasticities is that differences are generated by differences in regional price and quantity values only.

For each of the regions, the elasticities have the sign that would be expected under the assumption of profit maximization. As the price an output increases, there is a corresponding increase expected in production of that output. Conversely, as the price of an input increases, there is a corresponding decrease expected in use of that input. The differences across regions can be readily seen through these elasticities. Though they

have the same sign, the amount of change across regions given the same percent increase in price is different across regions. An interesting result is with respect to the outputs. As noted in the section 4.2, Quebec and Ontario produce more total paper while British Columbia and the Rest of Canada produces more wood pulp. With the own-price elasticities, if there is an increase in the price of each region's respective less significant output, there is a far larger increase expected in production as opposed to the more significant output. For example, British Columbia is a relatively stronger producer of wood pulp than total paper. If there was an 1% to small increase in the price of total paper then there would be a larger increase in production than if there were a similar change in the price of wood pulp. Such a change would present a shift amongst each region's production possibilities frontier. This makes sense following basic economic theory because if a slight reallocation of outputs can produce greater profit for a firm, then they will shift the resources to produce more of the good that provides a greater marginal revenue product.

**Table 4.6 Own-Price Elasticities for The Regional Model Estimation With a Correction for Autocorrelation**

<b>Variable</b>	<b>Canada</b>	<b>Quebec</b>	<b>Ontario</b>	<b>BC</b>	<b>Rest of Canada</b>
Total Paper	0.146279	0.084338	0.15785	0.220595	0.22778
Wood Pulp	0.106469	0.176091	0.16854	0.060186	0.1014
Labour Hours	-0.2371	-0.14594	-0.2042	-0.39235	-0.3319
Roundwood	-0.25376	-0.23038	-0.28995	-0.35405	-0.1951
Wood Chips	-1.06833	-1.20995	-2.79245	-0.39196	-1.0914
Energy	-0.24008	-0.1761	-0.25761	-0.24534	-0.3338

The own-price elasticities in both regional models are relatively inelastic. The only exceptions, to this result, are the wood chip elasticities which are elastic for each region except British Columbia. This means that a percentage change in price results in a large percentage change in quantity. The inelastic elasticity computed for British Columbia is due to the fact that it uses a high proportion of wood chips in the production process relative to other regions. Therefore, a change in the price of wood chips would not have the same substitution impact that it has in the other regions.

### 4.3.7 Cross-Price Elasticities Results

Table 4.7 represents the cross-price elasticities for the model. The results indicate that wood chips and roundwood are substitutes. If there is an increase in the price of roundwood, then there is an associated increase in the demand for wood chips.

Conversely, if there is an increase in the price of wood chips, then there is an associated increase in the demand for roundwood. Also, total paper and wood pulp are found to be complements for each other. That is, if there is a 1% or small increase in the price of total paper, then there would be an associated increase in the production of wood pulp. Conversely, if there is a 1% or small increase in the price of wood pulp, then there would be an associated increase in the production of total paper.

One of the most interesting results is with respect to the relationship between total paper and roundwood. As the price of roundwood increases, the quantity of total paper produced increases and as the price of total paper increases, the amount of roundwood used decreases. Whereas, with the other wood inputs and outputs, if the price of an input increases there is an associated decrease in output and if the price of an output increases then there is an increased demand of the input.

The cross-price result for roundwood and total paper is interesting because if there is an increase in the price of total paper, it would be expected that there would be an increase of production with a resulting increase in demand for inputs. This is perhaps a result of the substitutability of wood chips and roundwood, which is shown by the positive cross-price elasticity estimate for wood chips and roundwood. From the cross-price elasticity results for wood chips and total paper we know that total paper demand increases when wood chip prices decrease. Hence, a shift from roundwood use to wood chip use due to a price increase in roundwood may result in an increase in paper production.

**Table 4.7 Cross-Price Elasticities for Regional Model Estimation with a Correction for Autocorrelation**

#### 4.4 Summary

Of the four models estimated, it was found that the normalized quadratic profit function with regional dummy variables and correcting for autocorrelation is the most appropriate choice. The results indicate that Quebec is the most price sensitive with respect to profitability. For the profit elasticities, total paper was elastic for all regions. However, for the rest of the variables, it was found that the regions are price inelastic. The capital and time profit elasticities indicate that there is a multicollinearity issue. For the own-price elasticities, it was found that the elasticities by region are inelastic with the exception of wood chips. The cross-price elasticity results indicate that the wood chips and roundwood are substitutes, while total paper and wood pulp are complements.

## CHAPTER FIVE: SCENARIOS

### 5.1 Overview

The purpose of this chapter is to simulate two policy change scenarios using the estimated profit and demand system. The first is meant to simulate an increase in energy price due to a carbon tax. The second policy scenario is meant to simulate an increase in stumpage prices, and thereby delivered roundwood prices, due to a change in stumpage pricing policies. This scenario is of interest because of the recent softwood lumber dispute. The assumption in the scenario analysis is that changes in stumpage prices for softwood lumber companies might also affect the pulp and paper industry. Carbon tax simulations range from \$0-200 per tonne of carbon emitted and roundwood price simulations range from \$0-20 per m<sup>3</sup>. The simulations show the impact of the input price changes on own input quantities as well as profits and other input demands and output supplies.

### 5.2 Energy Price Scenario

The energy price scenario is based upon a potential change in energy policy. An example of this would be if the Canadian Government ratifies the Kyoto Protocol. The idea for the model is that if there were ratification of the protocol there could be an associated rise in the price of energy. This would be placed upon the market system with the use of a carbon tax. The tax would then be set at a level that would encourage firms to use less carbon in their production process. This type of tax could be in the form of a dollar amount per unit of carbon produced from fossil fuel energy. For this scenario, there will be a range of potential taxes used from \$0/t of Carbon, which is the baseline, to \$200/t of Carbon. This range in carbon prices is consistent with the range of prices found in Hourcade (1996).

However, simulating a carbon tax in the model is not completely straightforward. For the Canadian pulp and paper industry, energy use in the estimated model is given in terms of dollars per Gigajoule of energy used. To properly incorporate a carbon tax, it is

necessary to determine how much carbon is being used in the pulp and paper energy system, because there are a variety of fuel types including coal, natural gas, refined petroleum products, hydro and nuclear electricity, steam, coke, and bio-energy. For this analysis, the variable carbon contents of coal, natural gas and refined petroleum products are used to calculate a carbon emission per Gigajoule emission rate. One difficulty with this approach is that if carbon taxes are applied they will have differential impacts on fuel prices that could lead to substitution among coal, natural gas and refined petroleum and also with other energy sources. These substitutions are not explicitly modeled here.

Table 5.1 provides the CO<sub>2</sub> conversion factors for fuels. The CO<sub>2</sub> factors for fuels are given in terms of kilograms of CO<sub>2</sub> produced per Gigajoule of energy generated (Simons Consulting Group (1999)). For this study, these numbers are taken and are converted into kilograms of carbon per Gigajoule of energy and tonnes of carbon per Gigajoule of energy.

**Table 5.1 CO<sub>2</sub> Factors for Fuels**

<b>Fuel Type</b>	<b>Kg CO<sub>2</sub> / GJ</b>	<b>Kg C / GJ</b>	<b>TC / GJ</b>
Electric	0	0	0
Purchased Steam	0	0	0
Coal	90	24.561	0.024561
Residual Oil (#6)	75	20.4675	0.0204675
Distillate (#2)	70	19.103	0.019103
Natural Gas	50	13.645	0.013645
Light Petroleum gases	65	17.7385	0.0177385
Hog Fuel	0	0	0
Pulping Liquor	0	0	0

The conversion is done by taking the percent of carbon per molecule of CO<sub>2</sub> and using that percentage along with the Kg of CO<sub>2</sub> per Gigajoule generated given in table 5.1. In a molecule of CO<sub>2</sub>, carbon is 27.29 % of the mass of the molecule. Therefore, 27.29% of a kilogram of CO<sub>2</sub> will give the amount of carbon produced, which is then easily converted into tonnes.

Data on the percentage of coal and natural gas used in the Canadian pulp and paper industry was obtained from Statistics Canada. The data obtained is the quarterly supply and demand of primary and secondary energy in Terajoules (Statistics Canada, d) and is from the years of 1978 to 2000. Table 5.2 includes the average percentage of coal, natural gas, and refined petroleum products used in the pulp and paper industry energy process. It also includes the respective values used in the year 2000.

**Table 5.2 Percentage of Energy Used in The Canadian Pulp and Paper Industry**

Region	Average Percentage (1978-200)			Year 2000 Value		
	Coal	Natural Gas	Refined Petroleum Products	Coal	Natural Gas	Refined Petroleum Products
Canada	1.3	27.7	24.6	0.6	29.4	14.9
Quebec	0.6	14.7	30.1	0.0	18.0	22.0
Ontario	3.4	51.9	9.2	1.2	48.9	6.0
British Columbia	0.0	4.7	22.1	0.0	4.6	7.5
Rest of Canada	1.9	52.4	35.8	1.4	54.4	20.6

Equation 5.1 is the formula used to determine the energy equivalent tax (EET). The formula is constructed in a way to represent a range of carbon tax values given the amount of carbon produced within the pulp and paper energy use system. Coal, natural gas, and refined petroleum products are used because they are the only fossil fuel energy sources given that emit CO<sub>2</sub> into the atmosphere. To estimate the amount of CO<sub>2</sub> generated from refined petroleum products it is assumed that the value would be close to that of residual oil. The year 2000 percentage values for energy type are used in the formula because it provides a more accurate representation of the current energy regime in the pulp and paper industry.

The formula for the energy equivalent tax is:

$$EET = t * (\alpha_c * p_c + \alpha_n * p_n + \alpha_r * p_r) \tag{5.1}$$

where: EET= Energy Equivalent Tax (\$/GJ);

$t$ = Carbon tax (\$/t of Carbon produced);

$\alpha$ = Conversion factor (tonnes of carbon per GJ of energy);

$p$  = percentage of total energy in pulp and paper industry;

$c$  = coal;

$n$  = natural gas;

$r$  = refined petroleum products.

The above formula is used for carbon taxes (\$ x/t) ranging from \$0/t (the baseline) and \$200/t. The conversion factors are the CO<sub>2</sub> factors for fuels provided earlier in table 5.2. This energy equivalent tax is then added to the mean price of energy value for the respective region to create the newly adjusted price of energy. This new adjusted energy price is placed into the estimated profit-demand-supply model to estimate the impacts on input and output quantities and profits given the carbon tax.

Tables 5.3 – 5.7 present the results from the scenarios for each region.

The effect of an energy equivalent tax, upon the pulp and paper profit-demand-supply system, is most significant in the Rest of Canada region. The percent change from baseline to the \$200/t of carbon produced would decrease total variable profit by approximately 18% and would increase wood chip use by approximately 11%. This effect is not unexpected since the amount of CO<sub>2</sub> used is greatest in this region since close to 76% of energy use produces CO<sub>2</sub>. Conversely, the influence of a carbon tax would have a lesser effect in British Columbia since the system produces CO<sub>2</sub> from fossil fuel sources for only about 12% of its total energy sources. In British Columbia, the total variable profit decreases by about 2% and the wood chip demand increase would be about 0.4%. In Quebec and Ontario, respectively, the amount of CO<sub>2</sub> producing energy types account for approximately 40% and 56% of energy use in the pulp and paper industry and hence the effects in Quebec and Ontario are greater than in British Columbia.

Across all regions there are decreases in total variable profit, total paper produced, wood pulp produced, roundwood use, and energy consumption. There is an increase in labour hours used and wood chip use across all regions indicating a substitution effect that shifts wood input from roundwood to wood chips. The results show this substitution effect is greater in regions using higher amounts of carbon emitting energy. An interesting factor is the impact upon the outputs in each region. As noted in the chapter 4, Quebec and Ontario are large producers of total paper whereas British Columbia and the Rest of Canada are large producers of wood pulp. When the tax is applied, the percent decrease from baseline output for each region is greatest for the smallest output level among the two outputs (wood pulp for Quebec and Ontario; total paper for British Columbia and Rest of Canada). Another interesting factor is the effect upon total labour hours. As the tax increases, there is an increasing use of labour hours. This implies that labour is substituted for energy at a higher energy price.

The results illustrate the importance of examining regional differences. For Canada as a whole, fossil fuel energy use is approximately 45% of the total energy use in the pulp and paper industry. If this value were to be used, then the far-reaching impact upon the Rest

of Canada and British Columbia would not be fully explored. It should also be mentioned that this scenario only takes into account CO<sub>2</sub> emissions from fossil fuel energy generation. The pulp and paper industry also uses bio-energy, from wood waste, to generate steam which creates CO<sub>2</sub> output. This value is not taxed in this model. This could be another reason for the increase in wood chip use in the results presented here. That would be an indication that as energy price increases wood chips are a substitute for purchased energy, which may indicate a shift toward bio-energy embodied in the wood chips.

### **5.3 Roundwood Scenario**

This scenario is motivated by recent changes in Canada-United States trade policy regarding softwood lumber. The United States has been arguing that Canadian companies receive an unfair subsidy in harvesting wood under Canada's stumpage system. This argument has led to a tariff on Canadian lumber products being shipped into the United States. In this section, it is assumed that the threat of a lumber tariff could lead policy makers to increase Canadian stumpage prices and that this would apply to both wood and pulp and paper industries.

For this analysis, the range of stumpage prices explored is \$0/m<sup>3</sup> to \$20/m<sup>3</sup>. The high end of this range would be roughly equivalent to a 29% increase in the price of lumber due to a tariff. The simulation presented here assumes that provincial lumber sectors have a choice between operating under the tariff or increasing stumpage prices, since low stumpage prices are allegedly the source of the subsidy in the lumber dispute. However, raising the price of stumpage for the lumber sector may have to be accompanied by an increase in stumpage prices for the pulp and paper sector. This is the assumption made in this analysis. As in the energy scenario section, the scenario is run at the mean input and output prices for each region. The only variable that changes is the price of roundwood.

The following tables 5.8-5.12 are the results by region given an associated increase in the price of roundwood.

As the roundwood price increases, there is a percentage decrease in total variable profit, wood pulp production, roundwood use, labour hours, and energy use for all regions.

There is an increase in wood chip use and total paper production for all regions. The impact upon total variable profit is greatest in the Rest of Canada with approximately 33% decline at the \$20/m<sup>3</sup> level and has the least impact in British Columbia with about an 8% decline at the same level. There is a substitution effect that shifts wood input use from roundwood to wood chips. The largest percent decline for roundwood use is in British Columbia at close to 19% and the smallest decline is in Quebec and Rest of Canada at close to 10%. The wood chip use percentage increase is greatest in Ontario at approximately 24% and is lowest in British Columbia at approximately 5%. The total paper production percentage increase is minimal across all regions ranging from about 0.1-0.25%. Labour hours and energy use have similar percentage decreases in variable use and are relatively minimal ranging from about 2-5%.

A limiting factor in this analysis is that the price of roundwood is increasing while the price of wood chips is being held constant. It should be noted that a potential change in stumpage prices could also have an impact upon the price of wood chips and likely limit the observed substitution effect between roundwood and wood chips. This is because a stumpage price increase in the wood industry would likely lead to a decrease in the supply of wood chips, thus raising the price of wood chips. It is also interesting how total paper production is relatively unchanged while there is more of a decline in wood pulp production. The decline in the production of wood pulp is greatest in Quebec and Ontario where there is less wood pulp production. This could mean that the use of roundwood has a much higher priority in total paper production than in wood pulp production. With an overall decrease in production activity, it is expected that there would be an associated decrease in labour hours and energy use.

## **5.4 Summary**

The main result of this chapter is the effect of energy and roundwood prices on profitability. Under both scenarios, it is observed that there could be substantial decreases in profitability across all regions, depending on the size of the price increases. Under the energy and stumpage price scenarios, the region that would experience the

greatest percentage loss in profitability is the Rest of Canada and the region that would have the least change in profitability is British Columbia.

Under the energy scenarios there was a decrease in both outputs while in the roundwood price scenario there was a slight increase in total paper production but a decrease in wood pulp production. As in chapter 4, the scenarios demonstrate a substitution effect between the input use of roundwood and wood chips with a trend towards using more wood chips. The use of energy declines under both policy scenarios for all regions, while labour use increases with an increase in energy price and decreases with a increase in roundwood price.

The benefits of doing the regional analysis are revealed by the results presented above. If the analysis had been limited to a national level, then it would not have been apparent where the greatest impacts of potential policy changes occur.

## CHAPTER 6: CONCLUSIONS and SUMMARY

### 6.1 Overall Results and Conclusions

One of the main objectives of this thesis was to estimate a dual multiple-output and multiple-input normalized quadratic profit function for the Canadian pulp and paper industry using regional data for Quebec, Ontario, British Columbia, and the Rest of Canada. Quadratic profit function estimation techniques were used for four different model types. It was found that the best model, given this data set, is a normalized quadratic profit function with regional dummy variables and a correction for autocorrelation. The estimated function satisfies the properties for profit maximization. Given the results from this function, it was then possible to estimate profit, own-price, and cross-price elasticities with respect to the multiple outputs and inputs. For the profit elasticities, total paper was elastic for all regions. However, for the remainder of the variables it was found that regional profits are price inelastic with respect to profitability. The difference occurs with respect to the capital variable. Canada and British Columbia had positive influence on profitability, while Quebec, Ontario, and the Rest of Canada had a negative influence. This may mean that the industry is at capacity in Canada and British Columbia for the pulp and paper industry. It was also found that over time, technology is a positive factor on profits in all regions. There is, however, an issue of multicollinearity between the capital and technology variables. This occurs because with new capital investments, usually incorporate new technology. Hence, if capital stocks increase over time, the time trends that are used as proxy for technological change will be naturally correlated with capital stocks. From the own-price elasticity results, it was found that the regional elasticities are inelastic with the exception of wood chips. Wood chips demand is elastic in all regions except for British Columbia. Cross-price elasticities are all relatively inelastic and many of them are positive which indicates that the wood variables are substitutable with each other. The key cross-price elasticity result is that there is a substitution effect regarding the prices and quantities of roundwood and wood chips. Total paper and wood pulp outputs were found to be complementary.

One of the key differences between this study and previous research was the separation of wood inputs from a total materials input. This was a useful approach as there is an apparent substitution effect occurring from the use of roundwood towards the use of wood chips over time.

Two policy scenarios were simulated using the results from the regional profit function. One was a simulation with an increase in the price of energy due to a change in energy policy. The second was a simulation with an increase in the price of roundwood due to a change in Canadian stumpage policy. It was found for both scenarios that there would be a decline in profitability for all regions given the inputs increase in price change. The region most affected is the Rest of Canada and the region least affected is British Columbia for both scenarios. From the results, it was found that there would be an expected substitution effect from roundwood use to wood chip use for all regions.

## **6.2 Limitations and Future Research**

A limitation of this study is the lack of data provided that is needed to estimate the model from a complete regional perspective. If there were a greater amount of regional data available, it would have been beneficial to run the model with regional price square terms as well as the regional terms for capital and time. In the models presented here regional differences in own-price and cross-price elasticities were entirely driven by differences in quantity and price among the regions.

Significant regional differences were found by separating outputs into total paper and wood pulp. Further, benefits might be obtained by separating the paper output into newsprint and other papers. This might be difficult to do, however, because of the lack of data. Another possible extension would be to treat capital as a variable input rather than as a fixed stock. Yet another possible way of dealing with the capital input would be to estimate a capital investment equation. This would make it possible to study in a more dynamic framework, the long-term impacts upon capital investment on profitability, input demand and output supply.

An idea for future research would be to estimate supply and demand systems for each region separately without the use of a profit function. This would allow for a great comparison of results between regions because this type of estimation would require fewer variables, than this study, and have more degrees of freedom. This could allow for having regional differences in all prices rather than just capital and time variables. This notion assumes that there is sufficient data that can be obtained for estimation.

If the data were available, then it would be useful to estimate profit systems given every type of output in the industry rather than grouping the outputs as total paper and wood pulp. This would allow for interpretations of the various industries within the pulp and paper industry such as paperboard and fine papers. Then it could be seen how these industries are changing over time and then attempt to gain an understanding of how the demand for these products has been changing over time as well. This could not be attempted with this data set because the lack of data would not allow sufficient degrees of freedom.

Finally, it would be useful to develop a multiple-output-multiple input profit function for the entire forest sector in Canada. This system would use data from both the wood industries and the pulp and paper industry to examine dynamic effects between the two industries within the forest sector. An ideal study would examine these effects at both the national and regional levels. This type of model would be especially useful for policy scenarios that affect both industries, such as the previously mentioned change in stumpage pricing.
