NOTICE

The quality of this microform is heavily dependent upon the quality of the original thesis submitted for microfilming. Every effort has been made to ensure the highest quality of reproduction possible.

If pages are missing, contact the university which granted the degree.

Some pages may have indistinct print especially if the original pages were typed with a poor typewriter ribbon or if the university sent us an inferior photocopy.

Previously copyrighted materials (journal articles, published tests, etc.) are not filmed.

Reproduction in full or in part of this microform is governed by the Canadian Copyright Act, R.S.C. 1970, c. C-30.

AVIS

La qualité de cette microforme dépend grandement de la qualité de la thèse soumise au microfilmage. Nous avons tout fait pour assurer une qualité supérieure de reproduction.

S'il manque des pages, veuillez communiquer avec l'université qui a conféré le grade.

La qualité d'impression de certaines pages peut laisser à désirer, surtout si les pages originales ont été dactylographiées à l'aide d'un ruban usé ou si l'université nous a fait parvenir une photocopie de qualité inférieure.

Les documents qui font déjà l'objet d'un droit d'auteur (articles de revue, tests publiés, etc.) ne sont pas microfilmés.

La reproduction, même partielle, de cette microforme est soumise à la loi canadienne sur le droit d'auteur, SRC 1970, c. C-30.

DATED Oct. 15 1987

THE UNIVERSITY OF ALBERTA
FACULTY OF GRADUATE STUDIES AND RESEARCH

The undersigned certify that they have read, and recommend to the Faculty of Graduate Studies and Research, for acceptance, a thesis entitled MODELLING OF ACCELERATING MOVEMENTS IN ROCK SLOPES submitted by JAMES WILLIAM CASSIE in partial fulfilment of the requirements for the degree of MASTER OF SCIENCE.

Supervisor

Date..... 87-10-15

Abstract

The decrease in frictional resistance along the sliding surface with progressive displacement is proposed as a mechanism to explain the accelerating behaviour of the rock slopes of western Alberta open pit coal mines.

The buckling failure of the Gregg River Resources NO Pit in 1985 is used as a case history. Representative slope movement parameters are obtained from the displacement-time record of the wall movement using the computer program CPACK.

Footwall sandstone samples are repeatedly tilt-tested to obtain a relationship between the frictional resistance and the displacement. The tilt-test results exhibit variability in the absolute values and in the amount of sliding angle decrease with successive displacement. The various sliding angle(strength)-displacement behaviours of the samples is classified using the brittleness index concept and the majority of the cases displayed a decreasing angle trend.

The sliding block theory, using regression coefficients from the tilt-tests results, qualitatively modelled the velocity increase behaviour of the NO Pit example. It is therefore concluded that the decrease in frictional resistance with progressive displacement, may be an adequate mechanism to explain the accelerating movements in these western Alberta coal mines.

Acknowledgements

The author would like to thank his thesis supervisor, Dr. D. Cruden, for his topic suggestion and his enthusiasm throughout the research. His expertise, guidance, and patience were all greatly appreciated.

The author would also like to thank Dr. K. Barron and Dr. D. Chan for their useful suggestions and criticisms.

Appreciation should be extended to Mr. R. Casey and the Department of Zoology for the use of the profiler and to Mr. D. Booth of the Department of Mineral Engineering for assistance in the use of the digitizing table and the Shore Scleroscope.

Thanks must also go to Mr. R. Karst and Gregg River Resources for supplying the wall movement information.

The assistance from the technical staff of the Civil Engineering Department, especially Mr. G. Cyre and Mr. S. Gamble, was extremely helpful.

Special thanks must go to my fellow graduate students, notably Christopher Neville, Sam Proskin, and Wim Van Gassen, for their interesting and always challenging discussions, their enthusiasm for géotechnique, and their friendship.

The financial assistance provided by Dr. Cruden and the Department of Civil Engineering allowed the author the opportunity for advance studies and is gratefully acknowledged.

Finally, my deepest appreciation goes to my family for their continued support, encouragement, and love.

1. Introduction

1.1 Background

The north-central Foothills of western Alberta have abundant deposits of coal. These deposits of Cretaceous age are found in a series of asymmetrical synclinal structures which are removed by open pit mining methods.

The combination of the geological structure and the extraction process lead to the development of steep, high footwalls. These walls deform due to loss of support as coal is removed from the hinge area of the syncline. The movement of these slopes may accelerate; the rate of the wall displacement increasing with time until total collapse occurs.

When this process occurs in a temporary excavation, the wall is allowed to deform with constant monitoring (usually employing survey techniques) to ensure the safety of the men and the machinery.

Some western Alberta mines have now accumulated a body of experience regarding strain rate limits for forecasting failure. Little work though, has been done on the mechanism responsible for these accelerating movements. Therefore, the aim of this thesis is to investigate the effect of frictional changes along the sliding surface as a viable mechanism.

1.2 Purpose and Scope

This thesis will attempt to determine whether or not the loss of frictional resistance along the sliding surface as it moves, is an adequate mechanism to cause these accelerating movements.

The method of analysis for this research has three major sections:

1. Firstly, an accelerating movement case history is analysed to determine representative slope movement parameters.
2. Secondly, a laboratory testing program is undertaken on sliding blocks to address the question of strength changes of the sliding surface as the amount of displacement progresses.
3. Thirdly, the results of the case history and the laboratory program are compared to determine their relationship.

Chapter 2 is an analysis of an accelerating buckling failure in the Gregg River Resources Mine south of Hinton, Alberta. The analysis consists of fitting a wall displacement record to two power law representations through the use of the computer program CPACK.

Chapter 3 contains the details of the sliding block testing program. A description of the rock samples used is also included. The rock samples are smooth in comparison to the field conditions. Therefore, some of this chapter discusses the roughness of these samples, the measurement and the characterization of this roughness, and the applicability of small-scale roughness work to larger wavelengths.

Chapter 4 links the work of the previous two chapters together by considering an accelerating rigid block model. A relationship between friction and displacement is proposed to which the results of the tilting tests are fit. Integration of the displacement rate equation used in Chapter 2 and solution of the differential modelling equation by finite difference approximation provides a common basis for comparison of the results.

The final chapter contains a listing of significant conclusions, and some recommendations.

2. Accelerating Movement Case History

2.1 Introduction

The Hinton-Cadomin area of Western Alberta has five operating coal mines in Lower Cretaceous coal-bearing strata of the Luscar Group in the northern and north-central Foothills of Alberta. Stratigraphic terms used follow Langenberg and McMechan (1985).

Both the Cardinal River Coals and Gregg River Resources operations, located adjacent to one another 40 km south of Hinton, extract coal from the Grande Cache Member of the Gates Formation, mining the 10 m thick Jewel Seam.

The Lower Cretaceous coal strata form a series of en echelon folds. Later glacial erosion has removed the tops of the anticlines leaving behind a series of parallel, asymmetric-to-overtained synclines which are mined by open pit methods.

The open pits have steep, high footwalls during the coal extraction. Men and machinery work below the footwall removing the bottom coal. Bedding planes in the footwall unit parallel the footwall face. Therefore steeply dipping-to-overtained sedimentary rocks may lose some of their support by the removal of the synclinal bottom coal and footwall movements are induced.

A dominant failure mechanism in this combination of geology and geometry is by buckling. A buckle can be divided into a planar slab slide between the crest and the

inflection point of the slope" (also referred to as the "roll-over point") and a topple of the overturned beds between the inflection point and the toe of the slope.

Cavers (1981) provided some simple methods to analyze flexural and three-hinge buckles.

These movements are not instantaneous but are characterized by premonitory movements which accelerate until the wall collapses. The wall displacements are monitored as an aid in predicting the time to failure.

On March 6, 1985, at 07:22, the Gregg River Mine experienced such a buckling failure in the southeast corner of its NO pit along the south wall on a straight footwall slope between elevations 1620 and 1680. Slope displacements were monitored continuously to allow mining to continue until four hours before the failure occurred. This case history is examined in detail to illustrate the characteristics of an accelerating slope movement.

2.2 Gregg River Mine

The Gregg River Mine began production in 1983 after a coal sales agreement was reached with several Japanese companies. In 1985, the mine produced 2.2 million tonnes of high quality coking coal with approximately 12 million m³ of material being excavated by truck and shovel. The mine is operated by Gregg River Resources Ltd. and employs 390 people.

The coal is found in a series of parallel, asymmetric synclines. Each successive outcropping of the Jewel Seam of each syncline is assigned an alphabetic designation starting from the northeast end of the property. Hence the name of the NO pit.

2.2.1 Pit Geology

The Lower Cretaceous coal is part of the Luscar Group whose stratigraphy and nomenclature have been recently discussed by Langenberg and McMechan (1985). Coal mining is centered on the Jewel Seam of the Grande Cache Member of the Gates Formation. This member has an abrupt contact with the underlying Torrens Member sandstone which forms a hard footwall unit. The overlying, softer, hangingwall unit of the Gates Formation consists of interbedded shales and siltstones. Karst and Gould (1985) discussed the mine's geology in relation to mine planning and economics while McLean (1982) discussed the various lithologies in detail as well as suggesting possible depositional environments.

The coal thickness increases locally at the fold hinges from typically 10 m along the limbs to 30 m or more due to the weaker, softer coal migrating along the limbs during folding as suggested by Karst and Gould (1985). Therefore synclinal hinges are prime areas for coal removal.

Karst and Gould (1985) reported that the hard footwall sandstone had an unconfined compressive strength of 160 MPa while the interbedded siltstones and shales had a strength

of 50 MPa. The overlying Gates Formation is easily drilled and blasted while the Torrens sandstone forms a hard pit wall. Generally, south walls are benched into the footwall rock while north walls follow the coal-footwall contact. Bench face angles range from 50° to 90°.

The bottom coal is removed by a deep-range (14 m below grade) backhoe and transported by truck.

2.2.2 NO Pit Failure

The buckling failure in the NO pit occurred at 07:22 on March 6, 1985 bringing down 11,000 m³ of rock onto the active mining area. The failure took place on the east end of the south wall on an unbenched slope from elevation 1680 to the pit bottom as illustrated in the cross-sectional view of Figure 2.1. A deep-range backhoe sitting at elevation 1638 digging at elevation 1625 was removed before the failure. The overall slope height of the footwall was 55 m with the strike length of the wall being 75 m.

The straight footwall section dipped into the pit at 58° N at the crest of the slope but the angle steepened at lower elevations. The roll over point where the beds began to overturn was at elevation 1642. The dip of the beds below this point was found to be 80° S. The Gregg River Resources failure report described the final event in the following way:

"As the last of the supporting coal below the 1638 elevation was removed, a 5 m thick slab of

Figure 2.1 Cross-section of the NO pit during the buckling failure. *

overhanging footwall buckled and fell into the pit."

The rupture surface was a bedding plane located 4 to 5 metres behind the coal-sandstone contact. The western boundary of the slide mass was an open cut while a fairly continuous joint surface (strike 180°/ dip 60° E) provided the eastern boundary.

The first indication of wall movement was a hairline crack noticed on March 2, 1985 at 09:00. The crack, approximately 0.8 m in depth, was located at the east end of the footwall and proceeded up and to the right for a length of about 20 m. At 10:00 on March 3, the crack had progressed right across the face with a length of 50 m and had a width of 5 to 10 mm. Overturning of the lower footwall at the toe was then measured.

At 13:30 on March 3, a reflector prism was installed in the crack in order to facilitate remote displacement monitoring.

It is assumed in default of more exact information that the reflector was attached to the upper translating block of a three-hinge buckling movement and that the movement recorded was essentially a translation along a bedding plane. Other models of movement, such as ploughing at the toe or buckling of a plane slab are found in these foothill coal mines and cannot be excluded with the observations available.

On March 5 at 22:00, the surveyor detected 2.5 mm movement between 15 minute readings and the backhoe was

pulled out. The slope then stabilized and the backhoe was sent back in. At 03:30 on March 6, 4.5 mm of movement was detected and machinery was removed and kept out of the pit. By 05:45, the wall was moving 6 mm every 15 minutes. At 07:05 another crack developed on the face and at 07:20, the prism fell out. Finally, the wall failed at 07:22. Karst (1985) provided a more detailed sequence of events.

Johnson (1982) stated that the radial survey method using a theodolite-EDM system was the standard method used by the mining industry for wall monitoring. The three dimensional position of a prism were calculated using measured values of the slope distance and the vertical and horizontal angles. The vectors of movement were computed from changes in the three dimensional position.

Monitoring of the failure was initially done from an instrument station located on the north side of the pit at the corner of the 1650 bench. After 18 hours of readings, no definite movement was recorded and the instrument station was changed to the east side of the pit access ramp located on the far north side of the pit. This location offered greater sensitivity to wall movements.

Masoumzadeh (1985) found that the total resultant of the displacement vectors better represented these slope movement processes rather than the components such as the slope distances or the cumulative horizontal displacements. Figure 2.2 provides a graphical view of the cumulative total displacements versus elapsed time for the NO pit failure.

Figure 2.2 Cumulative total displacement versus elapsed time for the GRR NO Pit failure.

For the most part, the curve displays an accelerating displacement with time except for early in the displacement record when there is a jog. This decrease in displacement may have been due to some drainage affecting the slope movement.

2.3 Computer Analysis of the Displacement Record

Materials under a constant load exhibit deformation with time referred to as creep. Varnes (1982) discussed the general characteristics of creep curves. Firstly, there is some instantaneous strain followed by rapid deformation which decreases in rate which was referred to as primary creep. This creep phase transitions into a steady-state or secondary creep. Finally, it may accelerate into tertiary creep until failure ultimately occurs.

Many equations have been proposed to describe the various creep phases. Varnes (1982) discussed three laws for accelerating creep. These included;

1. the Saito relation,
2. exponential laws, and
3. power laws.

Also, Zavodni and Broadbent (1980), after examining failures in copper porphyry open pit mines, recognized two principal failure stages and produced an empirical relationship for failure prediction. Masoumzadeh (1985) reviewed the above four equations in detail and discussed their usefulness in relation to the Luscar Mine failure case history.

All the above equations are basically curve fitting techniques, which fit separate equations to the two different phases (decelerating and accelerating) independently. There is no consideration for the actual physical processes which are occurring. Varnes (1982, p.114) stated that:

"In working with curves showing both primary and tertiary creep, I found that the tertiary portion often could not be analyzed satisfactorily by itself because the process responsible for primary creep continued beyond the point of inflection."

Unfortunately, he presented no further insight (or equations) which could be used to link the two phases of creep.

Cruden *et al.* (1986) provided a method for estimating the parameters necessary to describe a complete creep curve for coal samples in laboratory creep tests. The following relationship between the strain rate, $\dot{\epsilon}$, and the elapsed time, t (in minutes) was proposed:

$$\dot{\epsilon} = At^B + Ct^D \quad [2.1]$$

where A , B , C , and D were constants. The first term of the equation was used to describe the decelerating portion where A was the displacement at unit time and $0 > B > -2$. The second term described the accelerating portion with $C \ll A$ and $D > 0$, up to values as large as 9 for laboratory creep

experiments.

The observations, absolute time and displacement, were used to calculate elapsed times and strain rates which were smoothed by the recursion formulae outlined by Cruden (1971) to account for minor extraneous variations. The smoothed data was then fitted by a weighted least squares method to a decelerating creep power law. This power law was integrated to obtain estimates of the decelerating creep strains. The accelerating strains were calculated by subtracting the decelerating strains from the observed strains. Therefore the decelerating creep phase has an influence on the strain values used for the determination of the accelerating creep parameters which is unlike any of the previous equations such as those of Saito or Zavodni and Broadbent.

An interactive package of computer programs, CPACK, was coded to fit the data of creep movements to power laws.

2.3.1 CPACK

The main program of CPACK outlines the steps of the analysis by calling five subroutines: CRED, BFIT, CFIT, and CPLOT. A flow chart and listings of the above are provided in Appendices A and B.

The fit of the data to the proposed straight lines is assessed by two tests. The first is a test for serial correlation in the residuals for which the Durbin-Watson statistic, d_w , is calculated as suggested by Durbin and Watson (1951). The second is the test of slope significance

which examines the null hypothesis that the fitted line does not have a slope significantly different from zero or that the data could have been represented by its mean.

The functions of the subroutines and the goodness of fit parameters are discussed in more detail in Cruden *et al.* (1986). In this paper, the creep data of a right rectangular prism of subbituminous coal which failed after 159 days at 19.4 MPa was found to fit the equation:

$$\dot{\epsilon} = 4650 t^{-1.01} + 0.588 \times 10^{-53} t^{9.90} \quad [2.2]$$

where the units of time is still in minutes.

Cruden and Masoumzadeh (1986a) used an updated version of their program, CPACKI, to determine slope movement parameters for the displacement record of the 51-B-2 pit failure at the Luscar Mine. The equation relating the displacement rate, \dot{x} , to the elapsed time, t , was:

$$\dot{x} = 0.280 \times 10^{-9} t^{1.23} + 0.129 \times 10^{-24} t^{4.17} \quad [2.3]$$

which actually defined two accelerating phases.

Displacement rate rather than strain rate was used in this case because the slope is given an initial length of unity in the CPACKI program. Hence, the displacement over a certain time interval divided by the original length results in a displacement rate, not a strain rate.

The first term parameters gave a reasonable fit of the initial data to the power law, but the accelerating data did not fit the second term well. They stated that the pit displacement data analyzed using the POW program identified three stages of accelerating creep rather than the two stages computed using the CPACKI program.

The Gregg River displacement record was input into CPACK2 (details regarding the testing of this new version are located in Appendix C) to determine its movement parameters. The input file (given in detail in Appendix D) was derived from survey coordinates obtained from Gregg River Resources Ltd. and the cumulative total displacements were used. The strain record was started at 15:15 on March 3 and lasted for 2405 minutes. The maximum total wall displacement was 96.2 mm.

2.3.2 Results

The CPACK2 output files are located in Appendix F.

The resultant equation for the entire data set is:

$$\dot{x} = 0.130 \times 10^{-1} t^{-0.84} + 0.332 \times 10^{-14} t^{3.99} \quad [2.4]$$

The two terms of the equation are represented by the two straight lines on Figure 2.3.

The first term of the equation with a power coefficient of -0.838 (indicating decelerating creep) provides a good fit to the initial data. The dw value of 1.748 exceeds the

Figure 2.3 Log strain rate vs. log time for GRR full data set.

upper bound value of 1.690 indicating no positive serial correlation while the slope significance value is 26.96.

The second term of the above equation with $D=3.985$ has a dw value of 1.391 which is less than both the upper and lower bound values (1.690 and 1.650 respectively) indicating positive serial correlation. Hence the data points are similar in deviation direction from the fitted line.

Intuitively, we sense that once the sliding mass has begun to move, there are few reasons why the mass should stabilize. The experience of Cruden and Masoumzadeh (1986b) indicated that the slide at the Luscar Mine had three accelerating phases. No decelerating components were found.

An attempt was made to truncate the data set from the beginning in order to remove the observations in the initial decelerating creep phase. Table 2.1 provides a summary of the results.

The first occurrence of two accelerating phases occurs with the Trun5 data set where $B=1.573$ and $D=4.178$. But the Durbin-Watson statistic for the second phase indicates positive serial correlation.

The Trun6 data set with an initial time of 195 also has two accelerating phases. The first term with $B=2.14$ is a good fit for the data range of 1 to 56. The second term has a large exponent, $D=25.78$ and the coefficient C , is reported as 0.221×10^{-87} . The dw value, 1.666, while not greater than the upper bound value of 1.690, is larger than the lower bound value of 1.650 suggesting that positive correlation

Table 2.1 Summary of CPACK results for truncated data sets.

Figure 2.4 Log strain rate vs log time for GRR truncated data set.

may possibly exist. The slope significance value for the data range 48 to 147 is very large at 4849. Hence, the following equation, displayed in Figure 2.4 may be a more realistic representation of the accelerating portion of the Gregg River displacement record;

$$\dot{x} = 0.611 \times 10^{-8} t^{2.14} + 0.221 \times 10^{-87} t^{25.78} \quad [2.5]$$

It is now apparent that the CPACK program will have to undergo some modifications. The increasing experience with fitting these coal mine deformation records indicates the need for a program which fits three (or more) accelerating phases as was the conclusion of Cruden and Masoumzadeh (1986a). Future versions of this program should therefore attempt to implement this procedure.

3. Laboratory Determination of Model Parameters

3.1 Introduction

The shear-deformation behaviour of rock discontinuities is influenced by such factors as normal stress, infilling, geometry and roughness, past displacement history, and strength and deformability of asperities (related to mineralogy and weathering).

Shear stress-shear displacement curves typically consist of two main regions as illustrated in Figure 3.1:

1. the pre-peak region, where a large increase in shear stress over a small displacement occurs, up to a maximum stress τ_{peak} and
2. the post-peak section where the shear stress decreases with increasing displacement, until it reaches a constant value.

Experimental results indicate that both the shear strength and the dilation of discontinuities are functions of the normal force and the shear displacement.

The movements in these western Alberta pit walls show an accelerating displacement with time leading to the failure of the wall. This acceleration suggests a mechanism which produces decreasing frictional resistance along the rupture surface because the driving force of the movement,

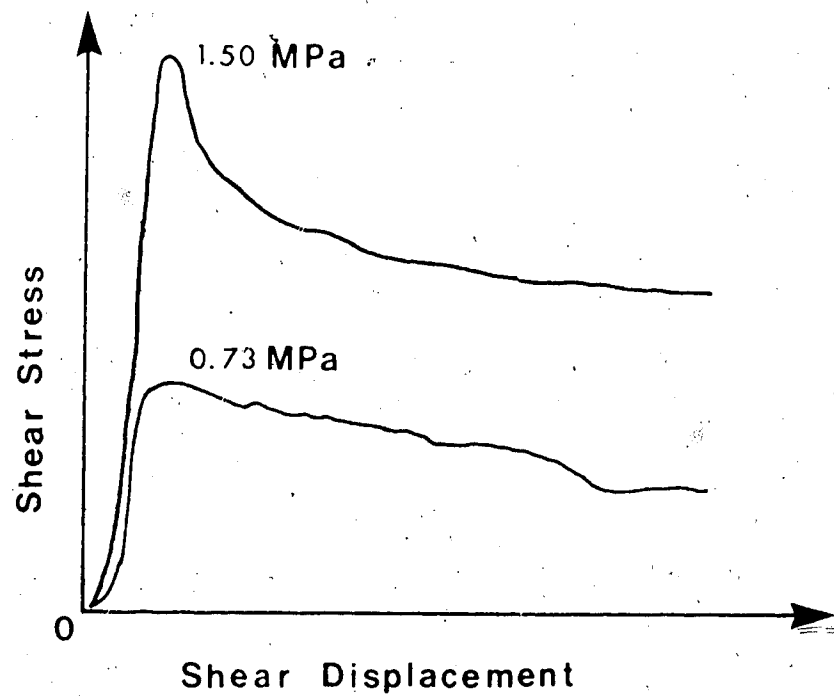

Figure 3.1 Typical shear force-shear displacement curves as a function of the normal stress level displayed.

the sliding block weight, is assumed to be constant here in the absence of observations to the contrary. As the displacement along the rupture surface (usually a bedding plane) proceeds, surface irregularities are sheared off, roughness decreases, and therefore the frictional resistance of the surface decreases.

A laboratory program was set up to determine a relationship between the frictional resistance and the displacement of a model sliding block of sandstone. Rather than using the more conventional direct shear test to measure the frictional resistance, a tilt-table apparatus was used. A series of tilting tests were done on the same sample to determine how the sliding angle (*i.e.* frictional resistance) changed with successive sliding events (*i.e.* increasing displacement). The experimental set-up allows concurrent surface roughness measurements to be made to examine how the sample roughness was changing.

There is, of course, several differences between the two tests. An important difference is the application of normal force during displacement. The tilt-test uses only self-weight of the top sliding block which results in a normal stress application of approximately 0.6 KPa.

This low normal force does not invalidate the usefulness of the tilt-test for several reasons:

1. The tilt-test does occur at a much lower normal force than the insitu conditions, but the roughnesses of the

two surfaces controlling deformation also differ by several orders of magnitude.

An example shall follow to illustrate the concept. The slope is inclined at 60° and the thickness of the failing slab is 5 m. Therefore, the sliding surface is under a normal pressure of 250 KPa. Divide the normal stress by the roughness height controlling roughness, say 2 cm and the ratio of normal stress to roughness is 125.

Applying the same principle to the tilt-tests, the normal stress of 0.6 KPa divided by the roughness, 0.001 cm (400 microinches) results in a ratio of 600.

It seems from this quick quantitative analysis, that the ratio of normal force to controlling roughness height for the field and the tilt-test conditions are within the same order of magnitude. In comparison, it is the tilt-test which actually has the higher ratio.

2. The basic friction angle of rock, ϕ_b , is relatively insensitive to normal force as found by Coulson (1972), within the stress range range significant for surface workings.
3. The tilt-test system models a dilated slab after some movement has sheared off the larger asperities on the rock surface. Bruce *et al.* (1986) found that the sliding angle results of tilt-tests on smooth samples were

similar to the friction angle results of the direct shear tests. There is a similitude of results between the two tests which have different operating forces, perhaps in part to the above normal stress ratio concept.

The frictional characteristics of a flat rock surface are dependent upon the surface preparation. Coulson (1972) found that the smoother the sample, the lower the frictional resistance, which suggested a correlation between the two parameters. The work of Rengers (1970), Barton (1971a), Krahn and Morgenstern (1979), and Tse and Cruden (1979) all suggest a correlation between surface roughness and rock joint shear strength. If a functional relationship could be obtained between roughness and frictional resistance, then extrapolation of the correlation or insight into possible mechanisms might be important in predicting rock joint behaviour.

3.2 Literature Review

Byerlee (1967) developed a theory of friction for geological materials based on brittle fracture rather than plastic deformation of asperities. Sliding of a surface would then occur when asperities fail by brittle fracture. Evidence for the theory were that;

1. true crystalline plasticity can be ruled out at temperatures under 500° C for rocks containing typical

silicate minerals (quartz, feldspar, olivine, or pyroxene) even at high pressures such as 500 to 1000 MPa, and

2. the tensile strength is a very small fraction of the compressional strength.

Direct evidence suggesting this type of friction was the presence of a fine white debris on the sliding surface after shearing. The amount of debris and the size of the debris particles increased with the roughness of the surfaces in contact. Byerlee found for ground surfaces of Westerly Granite that the coefficient of friction decreased as the roughness of the sample decreased, even though the roughness values for the surface were quite variable.

Coulson (1972) performed shear tests on flat rock surfaces of 10 different lithologies with roughnesses ranging from nearly polished to sandblasted at normal forces from 70 to 7000 KPa. He found four different types of strength-displacement curves;

1. Type #1 occurred in 4% of the tests and showed no change in shear strength with displacement. Normal pressures were always less than 420 KPa.
2. Type #2 exhibited a decrease in shear strength with displacement. These occurred at low pressures on dry surfaces and at all stress levels on wet surfaces.

3. Type #3 and #4 curves both had increasing shear strength with displacement with type #3 displaying an initial decrease. These two curves accounted for 60% of the tests and appeared at medium to high stress levels.

He also examined the sliding surfaces and correlated types of surface damage: generation of minor rock flour, formation of gouges with compacted rock flour, polishing, and formation of an indurated crust with these different classes of curves. Coulson stated that the generation of small amounts of rock flour were most often associated with type #2 curves. Since particle interference was low, rolling friction of the debris helped to decrease the shear strength. Type #3 curves appeared as more flour was generated and particle interference increased.

Krahn and Morgenstern (1979) performed direct shear tests on artificially prepared limestone surfaces and made surface roughness measurements with a Talysurf instrument. These traces were digitized for plotting purposes and for analysis. Statistical analysis of digitized profiles indicated a change in the roughness profile after shearing. Frequency-amplitude graphs, before and after shearing displayed an increase in the frequency of amplitudes on the positive side of the mean while there was a decrease in the frequency of the highest asperities. This confirmed the peak truncation and formation of plateaus conclusions made after

viewing the profiles. They also obtained a correlation of 0.881 between Z_2 , the root mean square gradient, and the ultimate friction angle, ϕ_u .

Zongqi (1985) also performed direct shear tests (on granite) with profile measurements before and after shearing. He attributed the minor decrease in the RMS surface slope values to wear of the upper asperities during shear.

3.3 Rock Sample Chosen

The coal removed from the Hinton area mines is taken from the Jewel Seam which is located in the Grande Cache Member of the Gates Formation. Overlying the coal seam are interbedded mudstones, siltstones, and fine-grained argillaceous sandstones.

The unit below the Jewel Seam is the Torrens Member sandstone. It is a massive to thick to medium-bedded sandstone which coarsens upward in grain size. Hill (1980) describes the Torrens Member in the Luscar Mine as medium-grained, light grey, non-calcareous, and containing rare conglomeratic lensoids of chert pebbles.

The stratigraphy was similar at both the Gregg River Resources pit and the Luscar Mine studied by Masoumzadeh (1985). Sandstone samples were collected by Masoumzadeh in August, 1983 at four different locations from the Luscar 51-B-2 pit located approximately 320 km west of Edmonton.

The sample used for this testing program was taken from the location of 101700 N and 104700 E on the Luscar Mine grid at an elevation of 5220 (Masoumzadeh, 1983). It was removed from approximately 3 m below the coal seam at a bend in the access road. This sample was assumed to be from the Torrens Member.

These samples were stored in the Civil/Electrical Engineering Building at the University of Alberta for use in future testing programs.

3.3.1 Sample Preparation

Test specimens were cut from a sample taken from location #2C which had an average thickness of 9 cm. Figure 3.2 shows where the specimens were cut from the top half of the sample. The sample was described as a fine to medium grained sandstone, light grey, carbonate-free (tested for effervescence with 10% HCl), laminated and containing occasional thin shaly partings.

The initial cuts were made by a 60 cm diameter, diamond-tipped saw which was water lubricated. The sliding surface cut was made parallel to bedding by a smaller hand controlled saw as were the final top and bottom cuts. Final sample size was approximately 5 x 5 x 2 cm.

Three samples were wet-lapped for one hour on the lapping table with 100 grams of grit being added initially. Afterwards, they were checked for flatness with a straight edge. Various sizes of grits, #80, #220, and #400 were used

Figure 3.2 Location of specimens from the top half of sample #2C. Individual blocks are 5 X 5 cm, for scale.

to prepare the roughness desired. Fifty grams of grit were added with each successive lapping set and the grit was used for 3 sets (3 hours) before being changed. Bruce *et al.* (1986) provides a detailed discussion of lapping equipment and procedures and sample roughness results.

3.4 Roughness Measurements

Roughness measurements were taken during the tilt-testing program for two purposes;

1. to determine if and how the surface roughness changed during tilt-testing, and
2. to look at the question of scaling of surface roughness and determine whether a general scaling law exists.

Recently, there has been an interest in prediction and modelling of rock joint properties (normal and shear stiffness, closure behaviour, and hydraulic conductivity properties) from roughness measurements in such papers as Swan (1981, 1985), Dight and Chiu (1981), Swan and Zongqi (1985), Zongqi (1985), and Brown and Scholz (1986).

3.4.1 Previous Work in Surface Topography

Patton (1966) found from roughness profiles and from evaluation of slopes that there were three orders of roughness on failure surfaces: first order irregularities with wavelengths of 60 cm, second order irregularities with wavelengths of 6 to 10 cm, and third order roughnesses of less than 1 cm. He concluded that first order irregularities

were good estimates of the asperity angle i , and that second order irregularities were not a factor when shearing or overriding of these asperities had occurred.

Piteau (1973) considered that there were two orders of topography: "macroscopic" resistance or waviness and "microscopic" resistance or roughness. Piteau (1973, p.7) states:

"Irregularities which are of such dimension that they are unlikely to shear off are defined as waviness. Roughness is defined as irregularities sufficiently small as to be sheared off during movements of the surface."

Another approach to topography is the random process theory as suggested by Peklenik (1967), Whitehouse and Archard (1970), and Nayak (1971). Instead of two orders of topography where small scale roughness is superimposed on the larger scale waviness, the surface topography is considered as a continuous spectrum of wavelengths down to atomic dimensions. Roughness would therefore be composed of the smallest and shortest wavelengths while waviness would consist of larger and longer wavelengths. Errors of form will have the longest wavelengths and the largest amplitudes.

Therefore the sizes, shapes, and heights of the surface features also formed continuous distributions dependent on this spectrum (Nayak (1971)). Rather than discussing waviness and roughness in terms of fixed wavelengths, Sayles

and Thomas and Brown and Scholz (1985) thought of them in terms of bandwidths of a spectrum.

3.4.2 Surface Characterization Methods

The Talysurf roughness measuring device is a commercially available instrument which drags a 4 sided, 0.0025 mm wide diamond stylus supported by a reference skid across an irregular surface. The device can provide a paper trace of the profile or it can provide a center-line average (CLA) value. American National Standard (1978) B46.1-1978 provides a review of the use and the interpretation of tracer instruments such as the Talysurf.

This instrument traverses a standardized length with the stylus in order to obtain the CLA values. These lengths, referred to as cutoff values are: J, 0.25 mm, K, 0.8 mm, and L, 2.5 mm. The CLA is a commonly used parameter in tribology and is defined as:

$$CLA = \frac{1}{L} \int_{x=0}^{x=L} |y| dx$$

where y = amplitude of the roughness about a mean of zero,

L = the sampling length,

dx = a constant distance between amplitude readings.

The CLA value is recorded in units of microinches.

Samples #1 and #2 were both prepared using #80 grit. These samples were then measured for roughness by traversing the stylus perpendicular to the sliding direction but they were too rough for the upper CLA limit of the instrument, 400 microinches. Consequently another method, the profiler, had to be used to quantify the roughness of these samples.

The profiler apparatus consists of a stylus mounted to a spring-arm attachment which is dragged over the surface by a screw mechanism powered by a small electric motor. The stylus, oriented in an inclined position is attached to an LVDT. As the stylus traverses horizontally and rises up and over asperities, voltage changes in the LVDT are recorded on a paper plotter. This device therefore gives an analog profile on paper, of the rock surface.

The Civil Engineering Profiler has been previously discussed by Krahn (1974) and Tse (1978).

Possible problems with this apparatus were:

1. The stylus is not in a vertical position which is the standard on other profilers such as the Talysurf.
2. The downward force of the spring-arm is greater than that of the Talysurf and its magnitude is unknown. This heavier stylus force might lead to the stylus ploughing through the surface material rather than overriding asperities.

3. The stylus on the Civil Engineering profiler (1.00 mm) is 400 times larger than the Talysurf stylus (0.0025 mm) which conforms to the British Standard and as such might miss vital roughness information.
4. No shoe or skid is provided for a datum like the Talysurf.
5. No lateral support is provided for the spring-arm so stylus deviations out of the traverse plane are possible.

Use of the profiler has one major advantage in that the length of the surface trace taken is variable. Thereby a longer profile can be taken which may better quantify the surface roughness.

The profiler used in this study was made available by the Department of Zoology. This profiler is very similar to the Civil Engineering profiler except it has a much smaller stylus and it has no vertical calibration and therefore profiles were only relative.

The first two samples, #1 and #2 (lapped with #80 grit) were profiled with the zoology instrument. Three traces were taken after each sliding event for sample #1 and after every second event for sample #2. A total of 60 analog traces were taken. A quantitative term was required for each profile,

even if it was only a relative one. In order to do this, the analog traces had to be digitized into discrete X and Y coordinates for computer analysis. This step in the process was done on the CalComp 9000 Digitizer, located in Room 280, Chemical/Mineral Engineering Building.

The CalComp Digitizer converts analog traces into discrete X and Y coordinates. This can be done one point at a time, by incrementing X and/or Y values, or continuously in scan mode. The Digitizer also allows an origin and a scale to be set up for each trace and the input format of the data can be varied in a user created file.

The first attempt at digitizing the traces was in the increment mode using a relatively small X increment (5 discrete amplitude readings per mm or every 0.5% of the full X scale) and a large Y increment (every 120% of the full arbitrary scale). This was for later convenience when computing the parameter Z_2 . As it turned out, the X increment was not constant for every increment.

The digitizing was accomplished by placing the trace under a plastic covering on the digitizing table. The origin, the scale, and the data input format were then entered for each trace. Then the analog profile was traced by moving a set of cross-hairs over the entire length of the profile by hand. Obviously this method of tracing the profiles was subject to error especially on sharp high peaks. Two common errors were;

1. the Y value of the sharp peak might be missed if the X

increment value did not correspond exactly with the X coordinate of the tip, and

2. when tracing the sharp peak, some "backtracking" might occur, i.e. the X values might start decreasing due to poor hand tracing technique.

When the digital files were listed and visually examined for backtracking, some of the tips (maximum Y values) of sharp peaks were seen to be missed.

3.4.2.1 Results From the Profiler

After the files had been examined and corrected for backtracking, the data from sample #1 was run through a computer program to calculate a relative roughness parameter, Z_2 . This parameter was only relative because the profiler had no vertical calibration and the voltage transducer exhibited some nonlinearity (Casey, 1986).

The root mean square gradient, Z_2 is defined as:

$$Z_2 = \sqrt{\frac{1}{L} \int_{x=0}^{x=L} \left[\frac{dy}{dx} \right]^2 dx.}$$

with the parameters being discussed earlier in reference to the CLA.

The assumption was made in the program when calculating Z_2 that the step increment of the digitizer could approximate dx , the constant distance between amplitude readings.

A fine to medium grained limestone sample (Jy 31-4) lapped with #80 grit was obtained from the specimens

used by Eaton (1986). Its surface was smoother in comparison to the much rougher sandstone sample (1F-1). Figure 3.3 illustrates this fact even though the asperity heights were only relative and the scales were distorted. The limestone sample, the smoother surface had a Z_2^* value of 0.05 while the rougher sandstone surface had a value of 1.96. The smooth value was less than the rough one by an order of magnitude even though the number of data points, 162 and 173 respectively were about equal. Hence it was assumed that the program could quantify changes in roughness. Unfortunately, the values were only relative to one another and they could not be compared with other authors' work.

Sample #1 was tilt-tested with profiles taken at the back, middle, and front of the specimen. These were digitized and Z_2^* was computed. Table 3.1 provides a summary of these values from the back and the front portions of sample #1. Although the sliding angles decreased from 28° to about 24° after 18 sliding events, the expected decreasing trend in the Z_2^* values was not observed.

A test was done to determine how the calculation of Z_2^* was affected by the width of the X increment of the Digitizer. Profile 1F-1 was initially digitized using a X increment of approximately 0.2 mm which gave 195 data pairs and a Z_2^* value of 13.58. The same profile was digitized using a much smaller X increment of 0.05 mm.

Table 3.1 Relative root mean square gradient values for sample #1

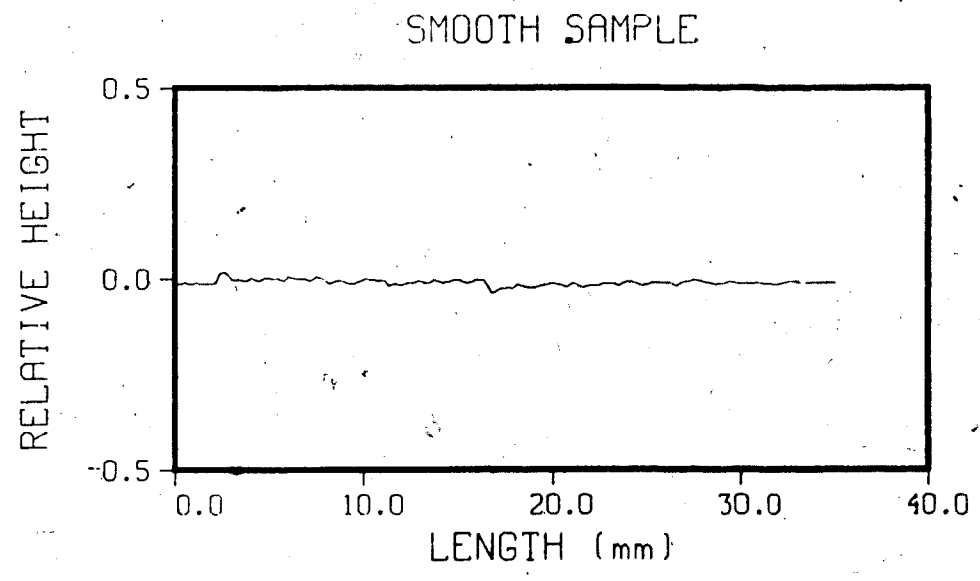

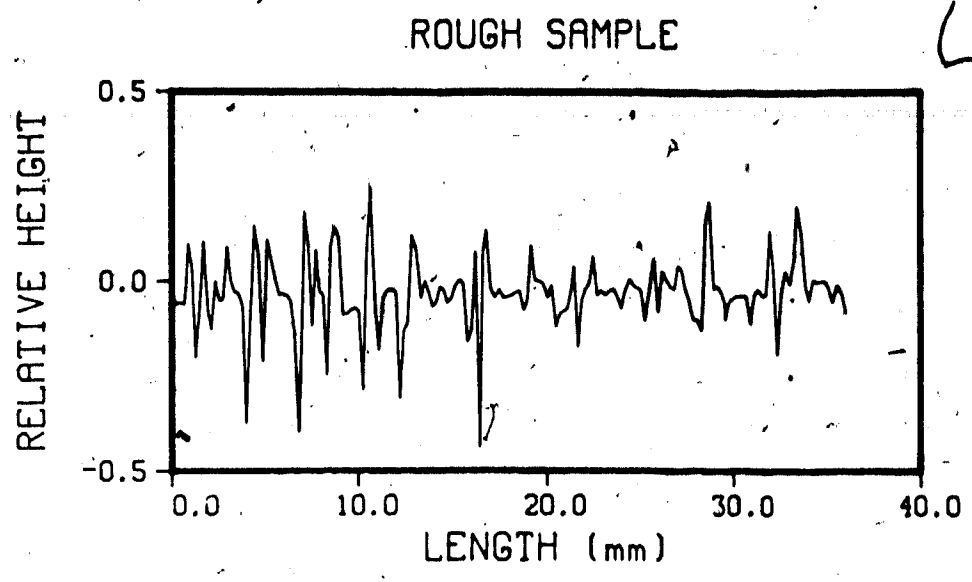

Figure 3.3 Comparison of profiles from a rough and a smooth sample.

This data file had 539 sets of data and a relative roughness value of 83.17.

3.4.2.2 Discussion of the Profiler Results

The procedure of profiling, digitizing, and computing roughness parameters had the ability to differentiate between a smooth and a rough sample as discussed earlier. It has been successfully used by previous authors, specifically Krahn (1974) and Tse (1978).

The inconclusive Z_2^* results from sample #1 indicated that this procedure was inappropriate for this rock type and equipment. The Zoology Profiler had no vertical calibration and exhibited nonlinearity, both of which prevented the calculation of an absolute roughness parameter (e.g. CLA or Z_2). The digitizing process created errors in that maxima of some profile peaks were missed and backtracking of the X values had to be corrected. Also, the computed values of Z_2^* were dependent upon the sampling interval dx which was also the experience of Reeves (1985).

The problem in both using a profiler or a digitizing system is deciding upon a sampling interval dx that will be sufficiently small to characterize the roughness without creating unnecessary data points. Reeves (1985, p.431) states that:

"Failure to include either high or low frequencies may lead to poor estimates of the

RMS height (Z_1), gradient (Z_2), and curvature (Z_3) statistics."

These parameters are dependent upon dx and care must be taken in their interpretation.

The decision was made to use finer grits (#220 and #400) on the lapping table to achieve smoother surfaces and to return to the Talysurf instrument for roughness quantification. Although there were still some problems with this procedure, the Talysurf gave a direct measurement of roughness in a quick and convenient manner without the possibility of errors due to extraneous data manipulation.

3.4.3 Results from the Talysurf Characterization

Sample #4 was lapped with #220 grit while sample #6 was lapped with #400 grit. Both of these samples were tested on the Talysurf and CLA values were obtained. These samples were then put through the tilt-table tests and the surfaces were measured again after the sliding incidents. Tables 3.2 and 3.3 summarize the CLA and the sliding angle values. Even though the tilt-table results showed a general decrease in the sliding angle (representative of the frictional resistance), the before and after Talysurf measurements showed no decrease in roughness.

American Standard B46.1-1978 pointed out that if the cutoff value was too small to include the coarser irregularities of a surface, the measurement would not agree

Table 3.2 CLA values (microinches) and sliding angles for sample #4.

SAMPLE #4	Top	Bottom
Cutoff	Not Recorded	
Initial (recorded at various locations)	315, 230, 250, 355, 255, 210 n=6, x=269 s=55	340, 270, 325 n=3, x=312 s=37
Sliding Angles in Sequence (degrees)	26.6, 23.4, 25.7, 22.3, 22.7, 21.1, 20.1, 19.1, 19.5, 19.2, 19.7	
Cutoff	L	
Final (two traces each at the back, middle, & front)	280, 250, 250, 260, 320, 220 n=6, x=263 s=34	350, 280, 270, 310, 250, 320 n=6, x=297 s=37

Table 3.3 CLA values and sliding angles for sample #6.

SAMPLE #6	Top	Bottom
Cutoff	Not Recorded	
Initial (recorded at various locations)	130, 140, 155 n=3, x=142 s=13	180, 225, 185 n=3, x=197 s=25
Sliding Angles in Sequence (degrees)	35.5, 31.7, 31.4, 26.6, 26.0, 24.8, 24.0, 24.0, 26.6, 27.4, 22.9, 27.4	
Cutoff	L	
Final (two traces each at the back, middle, & front)	270, 250, 240, 170, 250, 130 n=6, x=202 s=52	215, 140, 265, 215, 205, 145 n=6, x=198 s=48

with those taken with a larger cutoff. When samples #4 and #6 were measured after displacement, using cutoff lengths, L, 2.5 mm, and K, 0.8 mm, in every case, the longer cutoff L gave the higher CLA value as shown in Table 3.4.

Sample #3, lapped with #220 grit, was also tilt-tested and the roughnesses measured by the Talysurf. The sliding angle decreased from 28.1° to 26.5° after six slides and to 27.4° after 12 events. Six Talysurf traces were done after each sliding event, two at the back, the middle, and the front of the sample. The average of the six measurements was then calculated as was the standard deviation. Table 3.5 shows these results. Although the CLA for both the top (T3) and bottom blocks (B3) show a decrease from the initial value, the value does not decrease with increasing displacement consistently but it oscillates. The CLA value decrease was minor, 6.5% for T3, and 5.1% for B3.

3.4.3.1 Distribution of the CLA Results

Whether a sample of CLA readings from a freshly lapped surface would be normally distributed would become important for later statistical analyses of the roughness data.

Sample #12 was used for this testing. The surface was lapped for one hour with #220 grit and the roughness was measured on the Talysurf. Thirty readings were taken in one direction, all parallel (#T12A) and then 31 more (one reading exceeded the upper limit of 400 microinches) were taken perpendicular to the previous

Table 3.4 Comparison of CLA values (microinches) using different cutoff lengths.

set (#T12B). Tables 3.6 and 3.7 show the statistics from the two sample sets as calculated by the program *STPK. Figures 3.4 and 3.5 give histograms for the two data sets and the normal distribution curves fitted by the program.

The two samples have similar means, 285.83 and 295.67 respectively for T12A and T12B and similar standard deviations, 43.67 and 48.65. These values, from perpendicular directions, indicate that there is no directional anisotropy in the surface roughness.

The size of the standard deviation is relatively large in this case and in the following results because the stylus does not resample in the same track every time.

A χ^2 test compares the observed grouped distribution with the fitted normal distribution for the data set T12A, as described by Hald (1952). The calculated χ^2 for the data was 2.63 which was not significant compared to the $\chi^2_{.95}$ value of 3.84 with one degree of freedom. Therefore the observed distribution did not differ significantly from the fitted normal distribution.

Ten samples were relapped with #220 grit and tilt-tested. Talysurf roughness measurements and surface cleaning, removal of debris from the sliding surface with the use of compressed air, were performed during testing to

determine its effect.

The testing procedure followed is discussed in 3.5.1.

The results from this testing are located in Tables 3.8 to 3.17. These tables contain the mean roughness, \bar{x} of the six traces and the estimated standard deviation, s . If more than six traces were done per sample, the number of traces used in determining the distribution parameters is indicated.

In some cases, a CLA reading exceeded the 400 microinch upper limit and therefore the specific value of that reading was unknown. Hald (1952, Sec. 6.9) describes a procedure for estimating the distribution parameters \bar{x} and s for a one-sided censored normal distribution. This procedure was followed for the aforementioned cases and these results are marked with an '*' symbol in the tables.

Four different roughness hypotheses were proposed by an asperity model. The values from the ten tables were examined to test these hypotheses using the Student's t-test to determine the significance of the means of the samples' observations.

The Student's t-test has two underlying assumptions according to Hald (1952). Firstly, the observations within each set must be randomly drawn from the same population and secondly, the two populations must be normally distributed. Hald (1952, p.397) stated:

"The first condition is essential to the validity of the t-test, whereas moderate deviations from

normality usually are of no great importance."

Because the t-test assumes that the samples are from the same population, the sample variances cannot be significantly different. Therefore, the F-test was applied to check the variances of the samples before the t-test was applied. If the variances were significantly different, then the t-test was not appropriate. Kennedy and Neville (1976, Chap. 13) discuss a more useful test of significance for the case of nonhomogeneous variables and this procedure was applied in these special cases.

Significant results are marked on Tables 3.8 to 3.17 with a % sign indicating the significance level used, e.g. the "5%" in Table 3.11 at the second position indicates that increase in roughness from the sixth to the seventh event after cleaning was significant at the 5% level.

The four possible roughness changes and their occurrence follow (looking at the L-scale results only):

1. Surface roughness decreased after six sliding events from the initial value in 15 out of a possible 20 cases (75%). But none of the cases were significant according to the t-test even at the 10% level. Conversely, of the remaining 25% which displayed an increase, none were significant at the 10% level.
2. The roughness increased, after cleaning in 15 of the cases (75%) with two cases being significant at the 5%

level. None of the cases exhibiting a decrease were significant, even at the 10% level.

3. The sample roughness decreased in the final six sliding events in 9 out of 18 cases (50%) with one being significant at the 1% level. One sample though, #13.2 Top, displayed a significant increase in roughness at the 5% level.
4. Lastly, the roughness decreased from the initial CLA value to the final in 11 of 18 cases (61%). Only one case was significant at the 5% level. None of the cases displayed a significant increase in roughness.

3.4.4 Discussion of Talysurf Results.

A simple asperity model consisting of asperity peaks and troughs is proposed to explain the results of the roughness testing. Initially, the troughs may be partially filled with debris from lapping. As sample sliding progressed, asperity peaks would be sheared off by brittle fracture. The material sheared off would fall into the troughs as asperity peaks were truncated. Therefore roughness would decrease as the asperities were sheared off and the troughs filled in (hypothesis #1). Also the frictional resistance (or sliding angle of the tilt-test) should decrease as the sample becomes smoother.

If the surface was cleaned with compressed air, some of the debris would be blown out of the troughs and the roughness would increase (hypothesis #2). Then two possible

results exist. As material is blown from the troughs, increased interlocking of the surfaces may cause the sliding angle to increase over the previous angle before cleaning, but not above the initial sliding angle value due to truncation of the peaks. Alternatively, if interlocking does not occur and sliding occurs as a result of truncated peak sliding on truncated peak, no increase in the sliding angle would be expected.

As the sliding of the two samples progressed, more asperity wear would be expected. Again, roughness and the sliding angle values should decrease slightly (hypothesis #3).

Finally, hypothesis #4 followed that the final roughness would be smoother than the initial value as wear of the asperities occurred.

Of the five statistically valid significant changes in roughness during testing, four were in agreement with the hypotheses proposed by the test model.

The one deviation from the proposed model was for hypothesis #3 regarding a decrease in the roughness from the sixth to the last event. Sample #13.2 Top showed a significant increase which perhaps can be attributed to detritus building-up on the sliding surface. This does not necessarily imply that the sliding angles of the sample would increase; only that the Talysurf measured an increased roughness.

Hypotheses #1 and #2 both occurred in 75% of the possible cases perhaps agreeing with the proposed physical model. The third hypothesis, which results from one of two possible causes (increased interlocking of the surfaces versus truncated peak sliding on truncated peak) occurs in only 50% of the cases possibly reflecting uncertainty and variability in the model and also reflecting variability in the CLA measurements. Another surface model, as suggested by Coulson (1972), indicated that the surface might become smoother or it might become rougher as material breaks off. Hence, multiple surface models which grade into one another might be a better explanation for the variability of the results.

The problem may not lie in the fact that these expected responses did not happen, but in the fact that the method of roughness quantification may have been imprecise.

The Talysurf values may have been imprecise because:

1. the Talysurf did not measure the correct roughness in that the stylus may have ploughed through the frictional surface sensing roughness at depth, and/or
2. the Talysurf did not measure the roughness at the appropriate scale.

The Talysurf instrument, on cutoff value L, traverses a sampling length of 2.5 mm. Perhaps this is sufficient for a finished man-made material (e.g. a metal surface) but it may be insufficient for a finished natural rock surface whose composition was variable (hard quartz grains in a fine,

softer matrix). Reeves (1985, p.438) stated that:

"...surface statistics and shear strength should be measured on the same scale."

This would indicate that for a 5 x 5 cm shear box sample, the surface profile trace should be centimetres in length, not millimetres as in the Talysurf.

Eaton (1986) found that the majority of asperity wear occurred on the leading one third of the sliding surface. Table 3.4 lists the CLA values for two samples after shearing has occurred. The average of the two front readings is lower than the average of the two back readings in 3 out of 4 possible cases when comparing the L-scale results while one case was equal. Looking at Table 3.5 for CLA values as the number of sliding events increased, the front average value was lower than the back in 11 of 13 cases neglecting the initial two readings. Although the means were not tested for significance, the results would seem to indicate agreement with Eaton's work.

Rock sample roughness would therefore vary over the entire surface area. Six Talysurf traces were probably insufficient to properly characterize the surface roughness of the sample. Perhaps if more traces had been taken to quantify the roughness of the entire surface, the differences between the observation means would have been significant according to the t-test.

3.4.5 Surface Scaling

The deformation behaviour of joints is dependent upon the topography of the contacting surfaces. If the topography varies with surface size, then so must the deformation behaviour. Therefore a scaling law for surface roughness would be quite important as it would possibly allow extrapolation of small-scale (lab) measurements to field conditions.

Thomas and Sayles (1975) wrote on the effect of waviness on thermal contact resistance and in 1977, their work was related to the deformation of machine joints. In both cases they assumed the power spectra $G(\omega)$ of the random surfaces to be of the form:

$$G(\omega) = 4a\sigma^2 / (a^2 + \omega^2) \quad [3.1]$$

where a = a constant of decay for the autocorrelation function,

σ^2 = the variance of the height distribution,

and

ω = the frequency

as suggested by Whitehouse and Archard (1970).

The power spectra varies with ω^{-2} and because the area under a power spectral density curve $G(\omega)$ equals the variance (σ^2) of the height distribution, the RMS roughness increases as the square root of the profile length. The RMS value should therefore be most heavily influenced by the

longest wavelengths in a sample. Hence, roughness should be related in some way to the length of the sample or to the measured bandwidth.

Sayles and Thomas (1978) proposed a scaling law for characterizing a wide range of different surface structures. They proposed that:

$$G(\omega) = 2\pi k / \omega^2 = (k/2\pi) \lambda^2$$

or $G(1/\lambda) = k\lambda^2$ [3.2]

where k = the "topothesy" of a surface and
 λ = wavelength.

The topothesy value was a unique value which defined the statistical geometry of an isotropic surface for any given range of wavelengths. In their paper, they show many different surfaces whose roughness data lies along a ω^{-2} curve.

Roughness data from Table 3.8 for sample #T4 was used for comparison to the work of Sayles and Thomas (1978). The roughness values, which were CLA readings in microinches, were converted to RMS values in meters. An RMS value is 11% greater in magnitude than a CLA value for the same surface. The cutoff values used were those of the Talysurf; J (0.25mm), K (0.8 mm), and L (2.5 mm).

Thomas and Sayles (1975) made roughness measurements on a shot-blasted bar of mild steel which was known to be a good example of a random isotropic surface. Figure 7 of this

reference illustrates a log-log plot of RMS roughness versus the diameter of the contact area, d , which was assumed to be equal to the cutoff value divided by two (or $\lambda=2d$).

Figure 3.6 plots these 13 data points on a plot of normalized roughness (RMS roughness divided by the square root of the topography value) versus the cutoff length. Sayles and Thomas (1978) found the topography value for this surface to be 1.7×10^{-8} m. The solid line on the plot represents the theory given by the equation:

$$\sigma^2 = k\lambda_0$$

where σ/\sqrt{k} = the normalized roughness and
 λ_0 = the cutoff wavelength.

Also plotted on Figure 3.6 are the three data points for the roughness measurements made at three different scales for sample #T4. The sandstone was considered fine to medium grained, and assuming an average grain size of 0.5 mm (5×10^{-4} m), the \mathcal{E} -scale on the Talysurf was slightly greater than the average grain size.

The topography value for the sandstone was found to be 4.1×10^{-8} m which is similar to the value for the shot-blasted surface; $k = 1.7 \times 10^{-8}$ m. The #T4 points plot in close proximity to the theory line proposed by Sayles and Thomas (1978) as do the other points.

Figure 3.6 Comparison of T4 initial roughness data to the results of Sayles and Thomas

(1978). 4

Berry and Hannay (1978) in a following discussion paper stated that Sayles and Thomas forced the data to follow a ω^{-2} curve and that each surface had a spectrum with a different slope.

Mandelbrot (1977, 1983) developed a new geometry of nature and identified a family of shapes called "fractals". The concept of fractals can be thought of as a class of mathematical functions which are continuous but nowhere differentiable. Fractals tend to be scaling which implies that the degree of irregularity and/or fragmentation is identical at all scales.

The fractal dimension D is a parameter which describes the "size" of the roughness as the scale changes. It can also be thought of as a fraction lying between the lower bounds of topological geometry ("rubber-sheet geometry") and the upper bounds of Euclidian dimensions. The parameter D describes the degree to which a fractal function fills up Euclidian space.

As D approaches 2, a surface will have a high degree of correlation between points and approaches being differentiable. As D increases, the surface becomes much more jagged and nearby points more independent. When the fractal dimension becomes greater than 2.5, overhangs may appear.

The fractal dimension D is therefore a parameter which describes the scaling properties of surface topography.

Brown and Scholz (1985b) investigated the applicability of

using the fractal dimension in the study of natural rock surface topography.

From stylus measurements, power spectra were computed for each profile using a fast Fourier transform algorithm. Then an ensemble average for each surface was made by averaging the power at each frequency for all profiles (in an earlier paper, 28 profiles were taken per 5 X 5 cm surface) to produce a single smooth spectrum which represented the average character of the surface.

These spectra have the characteristic that power falls off rapidly with spatial frequency ("red noise" power spectra) and each spectrum is approximately linear in log-log space. From the plots of the power spectra, the slopes can be computed by least squares fitting and then the fractal dimension D can be backcalculated.

From figures in Brown and Scholz (1985b), it can be seen that the slopes were not constant but gradually decreased from high to low frequencies. Brown and Scholz suggested that two subjective breaks in the slopes could be seen.

In comparison to natural rock surfaces, studies of flat ground and lapped surfaces (Brown and Scholz (1985a)) show a tendency for the power to flatten out as the frequency decreases. Granite lapped with #80 grit and glass lapped with #80 grit flatten out to white noise below a "corner frequency" which corresponds approximately to the diameter of the grinding powder. This corner frequency may

be caused by the two-stage process of surface grinding and grit lapping.

Conclusions from the Brown and Scholz work were;

1. natural rock surfaces have a red noise power spectrum over the entire frequency band studied,
2. the slope of the power spectrum is not constant for a given surface and therefore no simple relationship between roughness and surface size exists,
3. no single fractal dimension D can be used to describe the topography of natural rock surfaces. This parameter varies significantly with the frequency band considered, and
4. extrapolation of this scaling parameter D to other scales must be done carefully.

3.5 Tilt-Testing

A tilt-testing program was carried out on the Torrens Member sandstone to examine the change in frictional resistance of the sample with increasing displacement. The 5 x 5 cm samples were to act as a model for the accelerating slab movements.

The tilt-table was chosen rather than the direct shear test because of its better suitability. The driving force in the tilt-test is gravity, similar to the sliding block in an actual wall movement, in comparison to an applied mechanical force in a shear test. Also there are end-effects in the direct shear test due to constraint of the sample by the

shear box while the tilt-test had a free sample sliding on a clamped base.

The tilt-test is performed at low normal stresses. Both Coulson's (1972) and Bruce's (1978) results indicated that ϕ_b did not change significantly over the limited stress range of surface workings. Eaton (1986) found that surfaces lapped with #80 grit approached the ultimate frictional resistance after 50 cm displacement even at normal stresses below 0.6 KPa.

The tests were carried out on a tilting table built by the Department of Civil Engineering Workshop for Eaton (1986) which is shown in Figure 3.7. A rigid frame supports a hinged table and an electric motor assembly. This drive assembly rotates a drum which has a wire cable attached to the hinged tilting table.

A linear voltage displacement transducer (LVDT) is mounted on the table against the top sliding block to monitor displacements. To record angular changes, a rotary voltage displacement transducer (RVDT) is mounted on the end of the hinge of the tilting table. A protractor is also mounted here to provide a quick visual reference.

The output voltages from the RVDT and the LVDT are recorded on an X-Y plotter. Scales of 1 cm = 0.5° on the X axis and 1 cm = 0.1 mm on the Y axis allow sufficient accuracy ($\pm 0.1^\circ$ for the RVDT and ± 0.01 mm for the LVDT).

The bottom half of the sample, the plate, is clamped with brackets to the table. A line level and the three

Figure 3.7 Isometric view of the tilting table.

the legs are used to level the surface of the plate and at 90° to it. The top half, the slider, is placed on top of the plate. The table is inclined to 15° by hand and then the motor is switched on. A 5:1 gear ratio provides rotation at 8° per minute. The front bracket allows the slider 2 cm of displacement.

The failure or sliding angle was estimated as the angle when greater than 1.0 mm of displacement occurred and acceleration of the slider was continuous. This negates minor block movements due to external vibration sources. Most of the samples exhibited sudden acceleration and sliding but some of the samples showed a slow creeping movement while others displayed a step-like, stick-slip movement.

Some of the tests were performed without surface cleaning while others were cleaned with compressed air after a certain number of sliding events.

The tilt testing program was completed between July and October, 1986.

3.5.1 Results

The first series of tilt-tests done were on samples #1 and #2 which were lapped with #80 grit. These surfaces were measured on the Talysurf but in all cases, the CLA values exceeded the upper limit of 400 microinches. Table 3.18 gives a listing of the sliding angles from the initial to the final values while Figure 3.8 provides a graphical

representation.

Sample #1 had an initial value of 28.0° which decreased to 25.2° after 10 events and after some oscillation, decreased to a final value of 24.5° after 18 events. Sample #2 had a higher initial value of 36.0°, which after 6 events decreased to 26.8° and then stabilized at approximately 28 to 29° for the remaining events.

Samples #4 and #6 were lapped with finer grits, #220 and #400 respectively which produced smoother surfaces. Initially sample #4 slid at 26.6° and then decreased consistently (except for one angle of 25.7°) over 6 events to 20.1°. Afterwards, the sliding angles stabilized at approximately 19°. The supposed smoothest sample, #6 slid initially at the high value of 35.5°. It decreased to 24.0° after 8 events and then the sliding angle increased and fluctuated for the remaining 4 events.

Sample #3 (#220) was also tested without surface cleaning. Table 3.16 shows that the sample initially slid at 28.1° and decreased to 26.5° after seven slides. The sliding angles varied over the remaining events with no general decreasing trend exhibited.

This specific test was different from the other uncleaned test as the slider was removed after each displacement to measure the roughness on the Talysurf. The slider was repositioned on the clamped bottom half and testing continued. As a result, this test was carried out in its entirety in the Mechanical Engineering Building.

Figure 3.8 Sliding angle versus number of events for the uncleaned tilt-tests.

Another set of tilt-tests were performed but with surface cleaning. After five sliding events had occurred, samples #3.1 and #4.1 were cleaned (both top and bottom) with compressed air to determine cleaning's effects on the frictional resistance. Table 3.19 shows that both samples decreased in frictional resistance on their first five sliding events. After cleaning, #3.1 increased from 26.7° to 29.3° while sample #4.1 exhibited no increase and oscillated in sliding value over the last four events.

Because no conclusions could be drawn from the two cleaned samples, a more ambitious tilt-testing was undertaken. Ten samples were lapped with #220 grit on two different sets; 4 specimens in set #1 on Sept. 22 and 6 in set #2 on Oct. 10. The testing procedure followed was:

1. Initial roughness traces were measured on the Talysurf by taking six traces at various scales on both the top and bottom halves of the sliding surface.
2. The sample was slid six consecutive times on the tilt-table.
3. Talysurf measurements were done again.
4. The sliding surface was cleaned with compressed air.
5. Roughnesses were measured again after cleaning.

Table 3.19 Sliding angles for cleaned samples #3.1 and #4.1.

SAMPLE	#3.1	#4.1
Grit #	#220	#220
Date	09/16	09/16
Event	Sliding Angles	
1	30.2	31.1
2	28.6	29.0
3	26.5	27.0
4	27.6	24.9
5	26.7	19.4
	Surfaces	Cleaned.
6	29.3	19.0
7	24.7	24.1
8	24.6	19.5
9	24.5	21.1

6. The sample was slid another six times for a total of twelve sliding events.
7. Final Talysurf measurements were done.

Tables 3.20 and 3.21 and Figures 3.9 and 3.10 provide a summary of the results for both sets.

The first set tested consisted of four samples. Two of the samples, #3.2 and #6.2 had high initial angles of 33.1° and 34.4° which decreased after the first four sliding events. On the sixth event, both of the samples' sliding angles increased fairly dramatically ($>2^\circ$). The other two samples in the set started at much lower initial angles, 25.3° for #1.2 and 29.6° for #4.2. Over the next four events, #4.2 decreased to 24.1° while #1.2 increased and then decreased to 24.4° on the fifth slide. Again, both samples had an increase in the sliding angle, but only slightly ($<2^\circ$) after the fifth event.

After cleaning the surfaces with compressed air, three out of four samples decreased in angle. Sample #1.2 changed from 25.1° to 20.0° (5.1° change), #3.2 changed from 30.4° to 27.2° (difference of 3.2°) and #6.2 decreased from 35.2° to 26.9° (8.3° change). Only #4.2 increased in value from 25.9° to 27.5° , an increase of 1.6° .

Sliding angles for the remaining sliding events did not exhibit any obvious increasing or decreasing trends. Sample

Figure 3.9 Sliding angles versus number of events for cleaned set #1.

Figure 3.10 Sliding angles versus number of events for cleaned set #2.

#1.2 oscillated around 21 to 22° while #4.2 fluctuated around 26°. Sample #3.2 seemed to stabilize around the 27° mark with only minor variations. Only #6.2 exhibited a decreasing trend but only three sliding events were done as the sample was dropped and scratched. Hence, testing was discontinued.

Set #2 contained six samples which had a wide variation in initial sliding angles. Two of the samples, #8.2 and #10.2 had initial angles greater than 30°, while the other four were less, with #14.2 sliding at the lowest value of 24.6°. Sample #10.2, which had the highest initial angle of 34.1°, decreased to 29.6° after three slides and then increased to 32.9° and then to 35.8° on the sixth event. The other high initial sample, #8.2 after a minor increase on the third slide, decreased to 27.5° on the sixth slide. The other four samples in the set did not exhibit a decreasing trend as did the two high initial angle samples. These four all had a medium to low value initial angles which increased dramatically ($>2^\circ$) on the second or third sliding event. They then decreased in angle with additional events except for #11.2 and #14.2 which had increases after the fifth slide of 4.2° and 4.7° respectively.

Five of the samples decreased in angle after cleaning with a range of changes from 0.1° to 5.7°. Only #9.2 exhibited an increase after cleaning of 3.4°.

Sample #8.2 showed a decrease from 27.4° to 23.7° over the remaining six sliding events while #13.2 exhibited a

minor decrease from 30.4° on the seventh slide to approximately 28.5° where the angle seemed to stabilize. The other samples exhibited no obvious trends. Sample #9.2 oscillated over the last six events with the final angle being less than the seventh value but higher than the initial. Sample #10.2 also fluctuated around 31° while #11.2 increased dramatically on the eighth slide. Then it bounced between 29.5° and 31.5° for the last four events. The final sample, #14.2 oscillated greatly but it did not show an overall decrease in the sliding angle.

For set #1, the final angle was less than the initial angle for all cases (excluding results for #6.2) while set for #2, it occurred in 3 out of 6 samples. If the final angle was compared to the second angle measured, the reduction observation occurred in five out of six events.

3.5.2 Discussion

Sample #1, lapped with #80 grit exhibited a decreasing sliding angle trend over the first ten events. Then the values began to fluctuate over the remaining 8 events with an overall decreasing trend being shown. The other rough sample, #2 slid initially at 36.0° and then reduced to 26.8° after 6 slides. Afterwards, the sliding angle value began to oscillate until it stabilized around 28.5° with a slightly increasing trend being observed.

Sample #1 decreased in value 7.8° from the initial to seventh event while #2 decreased 9.2° between the initial

and the sixth event. Then the sliding angles began to oscillate and deviate from the decreasing trend.

This behaviour may have been a result of surface asperities wearing off during the initial sliding events (causing the roughness and the sliding angle to decrease) and then accumulating on the sliding surface. The debris, probably being angular as a result of the shear failure of the asperities, would decrease the frictional resistance if the particles acted as rollers. Conversely, the debris may have increased the resistance as it built-up and increased the interlocking of the surfaces. Hence, the behaviour of the surfaces was dependent upon the shape, the amount and distribution, and the compaction of the gouge material. These multiple surface models will be transitional, a concept first proposed by Coulson (1972).

Sample #4, which had a smoother surface preparation slid initially at an angle of 26.6° which was less than the initial values of the rougher samples, #1 and #2. It displayed a continuous and pronounced decreasing trend with a loss of approximately 7° from the initial to the final value.

The sample prepared with the finest grit, #6 had the second highest initial sliding angle of 35.5° . This value rapidly decreased to a value of 24.0° after 8 events and then the value began to oscillate.

Sample #3 displayed a variation in angles but no definite decreasing trend was observed.

The tilt-test results for these samples were quite variable in the absolute values of the initial through final angles, in the form of the sliding angle-number of sliding events (each event is equal to 20 mm displacement) behaviour (e.g. continuously decreasing, oscillating, no obvious trends, etc.), and in the amount of sliding angle decrease (if displayed) over its sliding history.

The factors and their significance affecting these results include:

1. The surface preparation method would alter the heights of the surface asperities and hence control the amount of interlocking and/or peak to peak contact. The rougher surface preparation may have produced more detritus upon shearing which would have compacted and increased the surface interlocking whereas smoother surfaces with small amounts of detritus would have a decrease in resistance as the particles acted as rollers.
2. Climatic conditions, especially moisture would alter the results of the tilt-tests as found by Eaton (1986). The tilt-tests were done at different times of the summer and in different buildings. Therefore the moisture content of the air may have been different. This would have affected only the absolute, not the relative values of the sliding angles.

3. Test conditions and procedures may have been responsible for some of the variation between tests.

The first two rough samples tested, #1 and #2 were, the first two tests carried out by the author; nonfamiliarity with the tilt-table and recording devices may have had some minor contributions.

Also, in some of the tests the upper slider of the halved sample was completely removed from the tilt-table for roughness measurements; in other cases the slider was simply lifted off the bottom half and returned to its original position in preparation for another sliding event. The excessive handling of the block may have caused alteration to any detritus upon the sliding surface.

When replacing the top slider upon the bottom block, care had to be taken not to apply too much normal force which may have caused more interlocking of the surfaces in contact.

4. Definition of the failure angle was at an arbitrary movement of 1 mm as previously explained. Most of the samples displayed an instantaneous acceleration and sliding which made the selection of the failure angle obvious. Other samples displayed a creeping movement while others exhibited a "step-like" movement on the rotation versus displacement recording. The selection of the failure angle in these cases had to be in accordance

with the criterion set earlier.

5. Slight mineralogical differences between samples would have affected its sliding angle values and its amount of decrease. A sample with more clay content would achieve a lower sliding angle than a more sandy sample where harder and stronger quartz grains would be more prominent at the sliding surface rather than having clay particles being in contact. This factor was thought to be significant and will be looked at in more detail in the next section.

Two sets of samples were prepared for tilt-testing to see if some of the previous factors could be eliminated or minimized;

1. all the samples were prepared at the same time and in a similar manner (with #220 grit),
2. the tilt-tests were all done within a narrow time range (about one week for each set) to minimize moisture content effects,
3. the author was now familiar with all the apparatus and had a definite test procedure to follow,
4. definition of the failure angle remained, and
5. subtle differences in mineralogy would be examined for after testing was completed.

The results from the cleaned tests also exhibited a wide variation. Four of the samples had initial sliding angles between 35° and 30° , five were between 30° and 25° , and one was less than 25° ; the range of values was 9.8° . The final angles had a similar range of 9.3° with a distribution of two samples between 35° and 30° , five between 30° and 25° , and two less than 25° .

Only four of the samples exhibited a decrease in angle between the initial and the sixth event. This observation changed to seven out of ten samples when the difference between the first and fifth events were examined. The fifth event seemed to be a limiting amount of displacement which ended the decreasing angle trend. Six sliding events may have caused sufficient debris to build-up on the sliding surface that increased interlocking and hence the strength of the interface.

Seven of the samples decreased in value between the initial and the final angles. The range of reductions were between 1.2° and 9.1° with an average decrease of 4.8° . Three of the samples showed an average increase of 1.9° between the two values. This increase may have been an actual behaviour of the samples or it may have been a result of an abnormally low initial sliding angle such as exhibited by sample #14.2. These results concur with the expected behaviour of the proposed asperity model where surface asperities were worn off with successive sliding events and hence the sliding angle decreased.

The cleaning of the samples after six events lead to a decrease in the angle in eight of the ten samples. The average decrease was 3.3° with a range of 0.1° to 8.3° . An increase in the angle was observed in two of the samples.

The sliding angle behaviour of these samples were quite variable as illustrated by Figures 3.9 and 3.10. Some of the samples initially slid at high angles and then decreased, others started at slightly lower angles but then increased, while others had low initial values which decreased in value thereafter.

A parameter was required which could quantify the decrease (or increase) in sliding angles and which would assist in classifying the behaviours of these samples.

Bishop (1967) proposed the brittleness index I_B , to quantify the post-peak behaviour of soils and rockfill which was defined for drained conditions as:

$$I_B = \frac{\tau_f - \tau_r}{\tau_f} \quad [3.3]$$

where τ was the resistance to shear on the sliding surface for a given effective stress value and the suffixes f and r related to the failure (peak) and residual states.

Brittleness indices were calculated for the above ten samples. The peak value was assumed to be the initial sliding angle because the roughness would have been the greatest during this event. The final angle was taken to be the residual value as this was when the greatest

displacement of the sample had occurred.

Three methods were investigated in calculating I_s to account for minor variations in the sliding angle results:

- I. The first method used the initial point as the peak value and the final angle as the residual value.
- II. The peak value was used as previously defined but the residual value was taken as the average angle of the final six sliding events. This was done to negate variations due to debris build-up on the sliding surface. Hence, trends would be filtered-out to use for the residual value since multiple sliding events had occurred on that sample. The decreasing sliding angle trend which tended to increase on the sixth event seems to agree with this observation.
- III. The peak value was taken as the average of the first two sliding events and the residual value was taken as the average of the last two. Again, this was another filter method used to identify trends.

The results from this analysis were used to classify the behaviours of the samples into three proposed classes;

1. the initial sliding was medium to high in value which

- deceased upon sliding,
2. the initial sliding angle was as above but exhibited an increasing trend upon sliding, and
 3. the initial sliding angle was low in value and decreased upon sliding.

Table 3.22 indicates the results of classifying the behaviour of the samples according to the initial sliding angle and the brittleness index.

The first method tested obtained a range of five positive values for I_b for class #1, two negative values for class #2, and two positive and one negative value for class #3. This method differentiated between class #1 and #2 on the basis of the relative values of the initial angle and that the class #2 results were negative (because the final angle was greater than the initial). Class #3 results were selected on the basis of the initial angle values only as the brittleness index results were inconclusive.

The second method had similar results, except for all three class #3 results were positive. Therefore the initial angle was greater than the average sliding angle for the last six events. The results could now be classified according to two criteria for all the classes.

The third method determined all the I_b values were greater than 8.3 for classes #1 and #3. Class #2 was defined by values less than 1.3, one positive and one negative. This method also allowed the classes to be selected on the basis of two criteria.

Table 3.22 Brittleness indices and classes of behaviour.

Sample (initial angle)	Brittleness Index (%)		
	I	II	III
1. start mid to high and decrease			
3.2 (29.0)	18.1	20.2	10.4
6.2 (31.1)	26.5	24.1	19.2
8.2 (29.7)	23.3	19.1	21.5
10.2 (32.6)	10.3	11.1	10.0
13.2 (31.1)	4.0	3.0	8.3
2. start mid to high and increase			
9.2 (28.7)	-13.2	-8.3	10.0
11.2 (30.2)	-6.9	-12.3	1.3
3. start mid to low and decrease			
1.2 (25.4)	15.8	16.2	19.7
4.2 (26.2)	8.5	10.8	8.3
14.2 (27.2)	-4.5	3.3	14.2

The brittleness indices and the initial sliding angles allowed the behaviour of these samples to be classified into three different types. This particular series of tests were done with the intention of minimizing the factors responsible for variation in the results. Hence, it was felt that the variation in the results must have been due to differences in the samples.

The samples were all prepared at the same times except for the amount of rock flour in the lapping grit would have increased with time. Additional grit was added to the lapping fluid to try and compensate for dilution effect. Therefore, the surface roughness of the samples varied but probably only on the order of 100 microinches or so. This was not a major difference between the samples.

Subtle differences in mineralogy would have had a pronounced effect on the sliding behaviour of the samples. The two basic components of this sandstone were quartz grains and an argillaceous matrix. This topic is discussed in more detail in the following section.

3.6 Material Characterization

The variation in the sliding behaviour of the samples was thought to be due to differences in the mineralogy. The hypothesis was proposed that the clay content of the samples varied and hence the samples with a higher clay content would exhibit the decreasing behaviour (due to the low residual angle of friction for clays) while class #2 samples

with its increasing behaviour were an indication of samples with a higher quartz content.

Three nondestructive tests were utilized to identify any mineralogical differences;

1. density measurements,
2. sonic velocity measurements, and
3. hardness testing.

Other methods were also available such as thin section analysis, X-ray diffraction, or scanning electron microscopy but were not used because of complexity, time requirements, and cost.

3.6.1 Density Measurements

Set #1 was measured for density differences before tilt-testing, while set #2 was measured afterwards. They were measured at the local room humidity initially by the caliper method. Two lengths were taken in each of the three orthogonal directions, with calipers accurate to 0.05 mm, which were averaged. These three average measurements were used to calculate the bulk volume of the block to an accuracy of 0.01 cm³. The samples were then weighed on a scale to the nearest 0.01 grams. The density was calculated to one hundredth of a g/cm³.

The results of the initial density measurements are collected in Table 3.23 for the top and bottom halves in their respective behaviour classes.

Table 3.23 Density results for the different classes of behaviour.

Sample	Density (g/cm ³)	
	Top	Bottom
1. start mid to high and decrease		
3.2 (29.0)	2.56	2.51
6.2 (31.1)	2.60	2.51
8.2 (29.7)	2.56	2.55
10.2 (32.6)	2.47	2.58
13.2 (31.1)	2.57	2.52
2. start mid to high and increase		
9.2 (28.7)	2.58	2.56
11.2 (30.2)	2.63	2.53
3. start mid to low and decrease		
1.2 (25.4)	2.57	2.53
4.2 (26.2)	2.57	2.51
14.2 (27.2)	2.66	2.31

Table 3.24 Densities for different states for samples #6.2, #9.2, and #11.2.

Sample	Atmospheric Condition		Saturated Condition		Dried Condition
	Dens.	M.C.	Dens.	M.C.	Density
T6.2	2.587	0.13%	2.603	0.75%	2.583
B6.2	2.501	0.13%	2.517	0.80%	2.497
T9.2	2.580	0.13%	2.595	0.72%	2.576
B9.2	2.557	0.14%	2.575	0.83%	2.554
T11.2	2.629	0.14%	2.647	0.84%	2.625
B11.2	2.529	0.13%	2.547	0.86%	2.525

If the densities of the samples were ranked in value, both #9.2 and #11.2 from class #2 were third and first heaviest respectively, looking at the top halves. The bottom halves of the two previous samples were second and fourth highest also. This observation tends to agree with the hypothesis that the class #2 behaviour was a result of higher density samples perhaps reflecting a higher quartz content. The other two classes had lower densities between 2.47 and 2.60 g/cm³.

Three of the samples, #6.2, #9.2, and #11.2 were selected for water absorption and drying tests. After being previously oven dried for some measurements, the samples were left in the testing room to determine the moisture content for the testing room conditions. The samples were then saturated in water for an hour under a suction of 25 KPa. The surface water was wiped from the samples and the saturated weights were taken. Afterwards the samples were dried in a 115° C oven for 24 hours in order to obtain the dried weight. Table 3.24 provides a summary of the densities and the moisture for the various states.

All three samples exhibit a similar moisture content under room atmospheric conditions after the samples had initially been dried. The saturated water contents displayed slightly more variation with #11.2 having the highest average content. The final dried densities only confirmed the previous density rankings with #11.2 having the highest value.

If a sample contained more clay than another sample, the water absorbing capacity and hence the water content should have been higher than a more sandy sample. The results from Table 3.24 do not indicate such a trend. Perhaps the time required to remove air bubbles from the pore spaces and to saturate the clay minerals was greater than the one hour time suggested by the ISRM (1979) standards.

3.6.2 Sonic Measurements

Sonic testing was tried as a method of determining the amount of homogeneity between the samples. A sonic pulse from a transducer is sent through a sample and received at the other end. The primary wave velocity, V_p is calculated by measuring the arrival time of the P-wave (as the first deviation from the straight line on an oscilloscope) and the length of the sample is known.

Set #1, consisting of four samples was tested in the direction perpendicular to bedding. Table 3.25 provides a summary of the results. The velocities were in the range between 2025 m/s and 2760 m/s with an average velocity of 2373 m/s for the eight samples. The first three samples indicate a correlation with the higher densities having the higher sonic velocity also. The last sample, #6.2 does not fit into this trend though.

The second set of samples were tested parallel to bedding, in both directions on the samples. Unfortunately,

this did not allow a comparison of sonic velocities between sets but perhaps inhomogeneities such as fractures or mineralogical changes within the samples could be identified. The two directions tested were oriented with the direction of sliding during the tilt-tests;

1. direction A which was parallel to sliding and
2. direction B which was perpendicular to the previous direction.

Table 3.26 compiles the results.

Looking at the velocities for the top halves only, the average A velocity was 3903 m/s while for B it was 3992 m/s with standard deviations of comparable value. This suggests that for the whole sample set, no major differences in velocities were exhibited and the set could be regarded as homogeneous.

The individual differences between A and B velocities for the top halves ranged from 90 to 290 m/s with an average value of 192. Sample #T11.2 from class #2 had the largest difference and the second highest average velocity. The other class #2 sample, #T9.2 had the third highest difference of 220 m/s between A and B but had the second lowest average velocity.

The bottom half results indicated an average velocity of 4043 m/s and a B velocity of 4197 m/s, both higher than their top halves counterparts. The estimated standard deviation were 336 for A and 331 for B which were also greater than their corresponding values for the tops.

Table 3.25 Primary wave velocities (m/s) for set #1.

Sample (& class)	T1.2 (#1)	T3.2 (#1)	T4.2 (#3)	T6.2 (#1)
	B1.2	B3.2	B4.2	B6.2
Primary wave velocity (m/s)	2580 (2.57)	2580 (2.56)	2760 (2.57)	2030 (2.60)
(& density)	2040 (2.53)	2025 (2.51)	2570 (2.51)	2400 (2.51)

Table 3.26 Primary wave velocities (m/s) for set #2.

Sample (& class)	T8.2 (#1)	T9.2 (#2)	T10.2 (#1)	T11.2 (#2)	T13.2 (#1)	T14.2 (#3)
	B8.2	B9.2	B10.2	B11.2	B13.2	B14.2
Primary wave velocity (m/s)	A 3550 B 3640 (2.56)	3670 3890 (2.58)	3840 4080 (2.47)	3990 4280 (2.63)	4130 3950 (2.57)	4240 4110 (2.56)
(& density)	A 3800 B 3810 (2.55)	3840 3930 (2.56)	4070 4010 (2.58)	3700 4650 (2.53)	4260 4310 (2.52)	4590 4470 (2.31)

The differences between the bottom A and B individual values had a range from 10 to 950 m/s with a mean of 213 and an estimated standard deviation value of 363. Five of the values were between 10 and 120 but the difference for #B11.2 was extremely large at 950.

The top half of this sample had also exhibited the largest difference at 290 m/s. Sample #T11.2 was found to have the highest density of the top samples but the bottom half density was only fourth highest in the group.

No correlation was seen to exist between the densities ~~and the various velocities~~ taken. The sonic velocities should have been dependent upon the mechanical properties of the rock but perhaps the changes in mineralogy were too subtle to be identified through sonic testing.

Also the direction of testing relative to bedding would influence the results. The second set of tests were done parallel to bedding and hence only features such as fractures or infilled veinlets which cross-cut the bedding at oblique angles would have been identified. The first set of tests were done perpendicular to the bedding (and the sliding) plane but it is mineralogical variations on the sliding surface and to a very minor depth below that which would control the sliding behaviour. Sonic testing would only identify larger scale features not of interest at this scale of testing.

3.6.3 Hardness Testing

The mineralogy of the sliding surface should be reflected in its hardness.

Various tests are available to determine the hardness of rock samples. The Schmidt Hammer test uses a spring-loaded piston to obtain a rebound value, but it can damage weak specimens. The NCB Cone Indenter measures the resistance to indentation of a hardened tungsten carbide cone. A rock chip, 12 X 12 X 6 mm has to be prepared for the instrument though.

The Shore Scleroscope was finally selected for the hardness testing. A 2.32 gram hammer with a diamond tip is allowed to fall freely through a glass tube 25 cm in length upon the specimen. The rebound height is measured on a scale divided into 140 equal increments which is called the First Shore Rebound Number. Because the indenter tip is quite small, at least 20 readings per sample are required to obtain an average value for the usually nonhomogeneous rock surface according to the ISRM (1978) standards.

The samples, #4.2, #6.2, #9.2, and #11.2 were lapped with #220 grit which deviated from the #1800 grit suggested by the above standard, but the surface was flat. All the specimens were greater than the minimum specified thickness of 1 cm.

The sandstone blocks were sampled on a 5 X 5 point grid with a spacing of 10 mm between adjacent points and with a 5 mm spacing from the sample edge. Twenty-five readings were

taken and the averages and estimated standard deviations are reported in Table 3.27.

No correlation can be seen between the density and the hardness of the samples from this data. It was expected that #T11.2 with the highest density would also have the greatest hardness reflecting, perhaps, the larger amount of quartz content. This relationship was not displayed in the results. Sample #T11.2 had a similar hardness value to that of #T4.2 which had a significantly lower density. Samples #T6.2 and #9.2 display similar hardness and density values; although the hardness values are both greater than the heavier sample #T11.2.

The problem with the Shore Scleroscope is the very small contact area tested by the impact hammer. The average hardness number is then a function of the stochastic process whereby the hammer impacts on a hard quartz grain or on the softer argillaceous matrix. It was hoped that this instrument would be able to detect these subtle changes in mineralogy but such was not the case from these results.

3.7 Conclusions

The following conclusions were determined from the work of this chapter:

1. Roughness measurement and characterization of these smooth ground slider blocks is very difficult and must be done at the appropriate scale.

Table 3.27 Shore Scleroscope results.

Sample	Density	Average Hardness	Standard Deviation
T4.2	2.57	49	6.7
T6.2	2.60	56	6.8
T9.2	2.58	56	7.1
T11.2	2.63	48	6.7

2. The roughness values for these surfaces is dependent upon the length of the sample taken.
3. The distribution of CLA readings from these freshly lapped rock surfaces does not differ significantly from a Gaussian distribution and no directional anisotropy was indicated.
4. The majority of the statistically valid significant roughness changes were in agreement with the proposed asperity model.
5. The Talysurf measurements fit the proposed Sayles and Thomas (1978) scaling law for roughness at various wavelengths.
6. The tilt-test results for the uncleaned and cleaned samples displayed a decreasing angle trend in the majority of cases. These trends were accompanied with extreme variability in both the absolute sliding values and in the amount of strength decrease with increasing displacement.
7. Bishop's concept of a brittleness^o index was utilized to classify the sliding angle-displacement behaviours of the sliding blocks.

8. Of the three simple material characterization methods tested, density measurements seemed the most useful to detect subtle changes in mineralogy.

4. Comparison of Case History and Laboratory Results

4.1 Introduction

The previous two chapters dealt with an accelerating movement case history and a series of model tilt-tests. Equation 2.5 had two accelerating power law terms, the first to the power of 2.135 and the second term with an exponent of 25.775. The model tilt-tests, although exhibiting some variability, for the most part displayed a decreasing angle trend with successive sliding events.

The purpose of this chapter is therefore to;

1. introduce a sliding block model which has a decreasing frictional resistance,
2. propose a frictional relationship to which the results of the tilt-testing are to be fit,
3. provide a basis for comparison of the sliding block model to the behaviour of the NO Pit failure, and
4. decide whether the loss of frictional resistance with progressive displacement along the sliding surface is an adequate mechanism to explain these accelerating movements.

4.2 Sliding Block Model

Consider a sliding block of weight W on an inclined plane at an angle of β as illustrated in Figure 4.1. The forces tending to cause acceleration of this block will be the excess of the driving over the resisting forces.

Neglecting water pressure, this can be expressed as:

Accelerating Forces	Driving Forces	Resisting Forces,	or
$m\ddot{x}$	$= W \times \sin \beta$	$- W \times \cos \beta \times \tan f,$	
$m \frac{d^2x}{dt^2}$	$= mg \times \sin \beta$	$- mg \times \cos \beta \times \tan f,$	[4.1]

where

m = the mass,

x = the displacement,

t = the time,

$\frac{d^2x}{dt^2}$ = the acceleration

g = gravity, and

f = the frictional resistance (in degrees).

Suppose that f , the frictional resistance, is dependent upon the displacement, x . A function is proposed, where the friction decreases as the displacement progresses (shown in Figure 4.2) of the form:

$$f = A (1 - Bx^n) \quad \text{for } x < 220\text{mm} \quad [4.2]$$

where A = the initial friction angle, and

B , and n = constants derived from tilt-tests.

The 220 mm limit was the maximum amount of displacement imposed upon the sliding block. Equation 4.2 could be substituted in Equation 4.1 in order to model the accelerating movements.

Looking at Equation 4.2 in reference to the sliding angle results of the tilt-tests, it will be assumed that ϕ_1 , the initial sliding angle, is equal to A when no

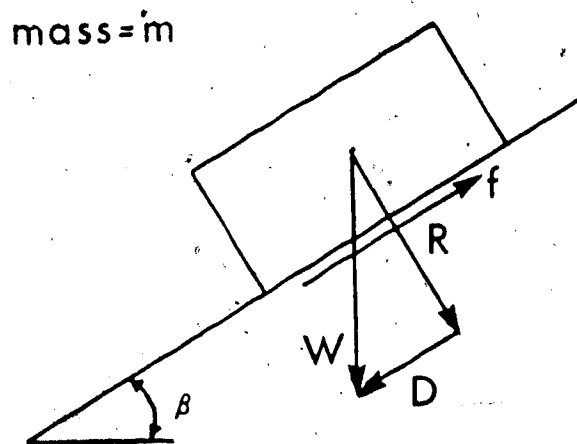

Figure 4.1 Sliding block model on an inclined plane.

Figure 4.2 Proposed decreasing friction function with progressive displacement.

displacement has occurred ($x = 0$).

The following formulation is proposed:

Initial
Condition

$$\phi_1 = A \text{ at } x = 0 ;$$

Relation

$$\phi_2 = \phi_1 (1 - BL^n),$$

where

ϕ_2 = the second sliding angle, and

L = the length of displacement during an individual tilt-test which is equal to 20mm.

$$\text{hence } \phi_1 - \phi_2 = \phi_1 BL^n,$$

$$\phi_1 - \phi_3 = \phi_1 B(2L)^n,$$

$$\phi_1 - \phi_4 = \phi_1 B(3L)^n.$$

General
Form

$$\phi_1 - \phi_{i+1} = \phi_1 B(iL)^n.$$

[4.3]

4.2.1 Regression of Tilt-Test Results

Regression of the tilt-table results was attempted using a modified version of the general form: —

$$\log(\phi_1 - \phi_{i+1}) = \log\phi_1 + \log B + n \log(iL) \quad [4.4]$$

with the friction angle as the indefinite variable.

Therefore, the values of the exponent n and the coefficient B could be determined.

The tilt-test results of the class #1 samples from Tables 3.20 and 3.21 for the cleaned data sets were used for the regression analyses. The differences between the initial

sliding angle, ϕ , and successive angles, ϕ_i , were calculated as were their logarithms. The amount of displacement per sliding event, L (20 mm), was accumulated and the logarithms calculated. These displacement values were tabulated along with the sliding angle differences as illustrated for #3.2 in Table 3.1, for example.

The data was input into the public computer program *ST.Package (Computing Services, 1980), which is an interactive statistical graphics package supporting statistical calculations and plotting routines. The polynomial regression feature of the package was utilized to determine the fit of the data to an equation for a straight line with the following form and parameters:

$$Y = b + mX$$

where, in relation to Equation 4.4;

$$Y = \log(\phi_i - \phi_{i+1}),$$

$$b = \log \phi_i + \log B,$$

$$m = n, \text{ and}$$

$$X = \log(iL).$$

The logarithmic values were input with the displacement values as the independent variable (X) and the angle differences being the dependent variable (Y).

In some of the samples, especially #13.2, some of the angle difference values were negative (due to later events having higher angle values than the initial). Hence, no

logarithmic values could be obtained at those displacements points. The assumption was made to delete these data points from the regression. This may have lead to some bias in the regression analyses as no increasing trends in the sliding behaviour was accounted for. These samples were selected earlier as having overall decreasing trends by the brittleness indices, although the amount of decrease may have been small.

The regression equations and their correlation coefficients, r , are located in Table 4.2 (the actual plots are located in Appendix G). The equations exhibited a variety of results for both the intercept B , and the slope n ; B had a range between 0.000232 and 0.416 while n varies between -0.445 and 1.309. Of the five equations of the class #1 results, four had positive values for n . The negative value obtained for #13.2 was due to the low amount of overall angle decrease (displayed in its very low I_s value) combined with the fluctuating nature of the sliding angle results. The value of n should be positive as this is indicative of an increasing series of difference values.

The fit of the data to the equations was poor in most instances. Two of the five equations showed significant correlation coefficients at the 5% level. Sample #6.2, with $n=0.345$, showed significant correlation, but with only 7 data points. The other significant sample, #8.2, with an n value of 1.309 displayed a high correlation value of 0.957. The wide variation in values is a result of the poor fit of

Table 4.1 Displacement and sliding angle difference values for the example case of #3.2.

iL (mm)	log(iL)	$\phi_1 - \phi_{i+1}$ (degrees)	log($\phi_1 - \phi_{i+1}$)

the data and the different behaviours exhibited by the sliding samples.

Sample #4.2 data, from the third class of sliding behaviours (low initial sliding angle followed by a decreasing strength trend), was also subjected to regression for comparison purposes. The regression equation, displayed in Table 4.2, for this sample determined B to equal 0.08257 and an n value of 0.072, reflecting the small amount of angle decrease from the initial to the final reading, 2.5°. This value compares well with the other small reduction samples such as #10.2 which had a decrease of 3.5° and an n value of 0.202, while #13.2, with an overall decrease of 1.2° displayed a negative slope with $r = -0.445$.

The recursion formulae proposed by Cruden (1971) was applied in order to smooth the data sets in an attempt to obtain better fitting equations. The sliding angles were smoothed to be continuously decreasing with increasing displacement. An example of the results of this process are displayed in Table 4.3 which can be compared to the original data set. The most noticeable feature is that the number of observations becomes severely reduced.

The resultant equations for the four regressions are located in Table 4.4. The values of B range between 0.000069 and 0.042 while n varies from 0.305 to 1.550. The number of significant correlations increased to three out of four cases, even with the low number of data points per regression, reflecting the influence of smoothing the data

Table 4.3 Original and smoothed data for the example case of #3.2.

Sliding Angle	Cumulative Displacements (mm)	Sliding Angle	Cumulative Displacements (mm)

points.

In summary, the n values from significant correlations of class #1 samples ranged from 0.345 to 1.309. After smoothing, the values ranged from 0.731 to 1.550 for n. These values may be regarded as bounds for use in the solution of the modelling equation.

4.2.2 Solution of the Modelling Equation

The sliding block is assumed to be separated from the surrounding rock mass, either by an open cut or by some geological discontinuity and it is also assumed to be initially at rest. After a small initiating acceleration is applied to the block (such as a horizontal acceleration due to blasting or due to rainfall seeping into the separation crack and ultimately draining), the block becomes displaced, the frictional resistance begins to decrease, and the block moves downslope in an accelerating fashion.

The sliding blocks are to be modelled with the equation:

$$\frac{d^2x}{dt^2} = g \times \sin\beta - g \times \cos\beta \times \tan[A (1-Bx^n)]$$

which defines the acceleration in terms of the displacement, x. This second order nonlinear differential equation can be solved by the finite difference method using the following boundary conditions:

1. Initially, the sliding block is at rest,

$$\therefore \text{ at } t=0, x=0, \text{ and } \frac{dx}{dt} = 0.$$

2. At the next time instant, after some initiating acceleration is applied to the block,

$$\therefore \text{ at } t + \Delta t, x > 0, \frac{dx}{dt} > 0, \text{ and } \frac{d^2x}{dt^2} > 0.$$

Only a one dimensional finite difference net is required to solve this equation for x and t . The difference in the displacement values over the time-step interval could be used to calculate the velocity. This velocity value could be associated with an average displacement value and a plot of velocity versus displacement could be produced from the modelling equation.

A listing of the finite difference program is located in Appendix H.

For the block to be initially at rest, the driving force must be equal to the resisting force. Hence, the initial friction angle A was made equal to the inclination angle β (equal to 60° , the dip of the NO Pit wall at the crest). The time step variable (T) was kept small, generally less than 0.0005 minutes and the number of points (N) could be adjusted until a sufficient amount of displacement had occurred.

Figure 4.3 displays the finite difference results using the raw coefficient values. For the curve with an n value of 1.309, the velocity changes from 124 mm/min at 1.0 mm displacement to 22860 mm/min after 97.3 mm in a nearly linear fashion. In a relative sense, the equation predicts over two orders of magnitude velocity change in comparison to two orders of displacement change.

The other curve, with $n = 0.345$, displays a pronounced nonlinearity (a concave downwards shape) at lower displacement values and has higher displacement rates than the curve with $n = 1.309$. The velocity ranges from 2180 mm/min to 41510 mm/min after 99.2 mm of displacement, a change of over one magnitude.

Comparing the two curves of Fig. 4.3, as n decreases from 1.3 to 0.3 (and conversely, as B increases from 0.0002 to 0.04), the shape of the function changes from slightly concave upwards to concave downwards, the resultant displacement rates at 1.0 and ± 100.0 mm is greater, and the relative slope (the number of orders of magnitude velocity change divided by the two orders of displacement change) decreases from over 1 to less than 1.

Figure 4.4 illustrates the predicted velocities using the smoothed coefficients in the finite difference equation. The curve with the higher exponential value, $n = 1.550$, has a slight concave upwards shape with a velocity change from 65.1 mm/min to 20640 mm/min after 97.1 mm displacement. The relative slope of this function is greater than 1.

Figure 4.3 Displacement rate versus displacement results from finite difference using the raw coefficients.

Figure 4. Displacement rate versus displacement results from finite difference using the smoothed coefficients.

When n decreases, and B increases as in the second curve on Fig. 4.4, the resultant curve has a slightly concave downwards shape. The displacement rate changes from 487 mm/min to 24410 mm/min after 100 mm of displacement which is a change of over one order of magnitude.

Similar observations as made before can be seen when comparing the two curves; as n decreases, the shape of the resultant function changes to concave downwards, the displacement rates at equivalent amounts of displacement is greater and the relative slope decreases. The two curves of Fig. 4.4 were closer in shape and in displacement rates than the two in Fig. 4.3 presumably due to the two n values being much closer. If these two figures were superimposed upon one another, the curve for $n = 1.309$ would plot down the middle of the two smoothed coefficients curves.

A parametric study was attempted to investigate the influence of each of the variables. The original function chosen was from Fig. 4.3 with $n = 1.309$, $B = 0.00023$, and $\beta = 60^\circ$. The results are displayed on Fig. 4.5 and can be summarized as follows:

1. As the inclination angle β decreased from 60° to 45° , the displacement rates at 1.0 and ± 100.0 mm decreased. The function retained its slight concave upwards shape and its relative slope was still greater than 1.
2. As the coefficient B was increased, the resultant

Figure 4.5 Parametric study results with the original curve having $n=1.309, B=0.00023$, and $\beta=60^\circ$.

displacement rates increased with the relative slope remaining greater than 1. When B was decreased from 0.00023 to 0.00005, the velocities decreased but the function still had a relative slope of greater than 1 with its slightly concave upwards shape.

3. More significant changes were found when n was varied. The displacement rate was lower at 1.0 mm and higher at ± 100 mm when n increased from 1.3 to 1.8. The relative slope was still greater than 1 but the function now displayed a more exaggerated concave upwards form. Conversely, as n decreased to 0.8, the form changed to a nearly linear-to-concave downwards shape with a relative slope less than 1.

The main conclusion was that, while the variables β and B can affect the absolute values of the displacement rates, it is only the exponential term n which can alter the shape and the relative slope of the resultant function. An n value of approximately 0.8 seems to be the boundary between functions which are concave downwards and which are concave upwards.

4.3 Relation of NO Pit Displacement Record

The displacement rate equation of the wall movement from Chapter 2 was in terms of time. In order to compare this equation with the results of previous section where only displacements were measured, it will have to be in

terms of displacement also. Hence, (the following derivation is an attempt to alter the equation;)

$$\dot{x} = \frac{dx}{dt} = At^B + Ct^D. \quad [4.5]$$

The two terms in the equation were meant to represent two different creep phases and, arguably, different physical processes occurring in a slope. The first term is dominant at low time values while the second term only becomes significant at larger times. Hence, a simplification of the equation will be made on the grounds that only the process responsible for the acceleration to failure will be considered.

So the derivation considers the second term such that:

$$\dot{x} = Ct^D \quad [4.6]$$

$$\begin{aligned} \therefore x &= C \int_0^t t^D dt = \frac{Ct^{D+1}}{D+1} \Big|_0^t \\ &= \frac{Ct^{D+1}}{D+1} \quad [4.7] \end{aligned}$$

Solving for t:

$$t = \left[(x \times (D+1)) / C \right]^{1/(D+1)} \quad [4.8]$$

Substituting Equation 4.12 into 4.10:

$$\begin{aligned}
 \dot{x} &= C \left[\left[(x \times (D+1)) / A \right]^{1/(D+1)} \right]^D \\
 &= C \left[(x \times (D+1)) / C \right]^{D/(D+1)} \\
 &= C \left[((x \times (D+1))^{D/(D+1)} \times (1/C)^{D/(D+1)}) \right] \\
 &= C \left[((x \times (D+1))^{D/(D+1)} \times C^{-D/(D+1)}) \right] \\
 \dot{x} &= C^{1/(D+1)} \left[(x \times (D+1)) \right]^{D/(D+1)} \quad [4.9]
 \end{aligned}$$

Figure 4.6 illustrates the trend of the function when the constants for the Trun6 data set are placed into it. The function produced is nearly linear (an exponent of 0.963). Over 96 mm displacement (the amount of displacement displayed by the NO Pit wall before failure), the velocity predicted by the equation changed from 0.0126 mm/min to 1.0199 mm/min. This is a velocity change of less than two orders of magnitude over a displacement change of just under two orders, giving the function a relative slope of 1.

4.4 Comparison and Discussion

There would seem to be some difficulty with comparing the results of the sliding block model to that of the accelerating movement. The displacement rates predicted by the sliding block theory using the coefficients from the tilt-tests are much greater than the case history, by several orders of magnitude.

Figure 4.6 Behaviour of the integrated displacement rate equation using the coefficients of the truncated data set, Trun6.

An attempt was made to alter the input coefficients (e.g. decrease B) to achieve displacement rates which were of a similar magnitude to those of the case history. Even with values as such, $\beta = 45^\circ$, $B = 1 \times 10^{-15}$, and $n = 1.1$, the displacement rate was 5.7 mm/min at 1.0 mm displacement, which is still two orders of magnitude off.

The comparison between the two aspects of this study will have to be based on the shapes of the two functions and on the relative slope observations, rather than on the absolute values.

The sliding block theory, for $n > 1.3$, predicts a displacement rate increase of just over two orders of magnitude in approximately 100 mm of displacement. The NO Pit displacement record displays a similar amount of displacement rate increase over the same displacement range. Hence, this theory, using the friction-displacement parameters from the tilt-tests, appears to qualitatively model the velocity increase behaviour of the accelerating rock movements.

5. Conclusions and Recommendations

5.1 Conclusions

The major conclusions of this study were:

1. The equation;

$$\dot{x} = 0.611 \times 10^{-8} t^{2.14} + 0.221 \times 10^{-87} t^{25.78},$$

was found to be a realistic representation of the accelerating portion of the NO Pit displacement record.

2. The measurement and the characterization of roughness from smooth rock samples is difficult and is dependent upon the sampling length used.
3. The majority of the statistically valid significant roughness changes were in agreement with the hypotheses of the proposed asperity model.
4. The sliding blocks displayed a decreasing sliding angle trend with successive displacement in the majority of the tests. Variability of the results was associated with transitional surface processes in conjunction with subtle differences in mineralogy between samples.
5. Density measurements were found to be the most useful technique to identify these mineralogical differences of the three nondestructive and convenient methods

attempted:

6. The sliding block formulation, using a frictional relationship based on the tilt-test results, appears to qualitatively model the velocity increase behaviour of the accelerating movements. The conclusion to be drawn from this is that the loss of frictional resistance with progressive displacement may be an adequate mechanism to explain accelerating rock movements.

5.2 Recommendations

1. The CPACK program should be altered to allow for three or more accelerating creep phases to be fit to displacement records.
2. More study is required with respect to the fitting ability of CPACK. The fitting procedures of the program may require some modifications to account for the overestimation of the second term exponent.
3. If another Civil Engineering profiler is constructed, it should conform to ANSI B46.1-1978 with regards to a smaller, vertical stylus, a lighter tracking force and other modifications as mentioned in Section 3.4.2.

Interfacing the profiler with a microcomputer would allow for easier data recording and manipulation.

4. Sliding surfaces which decrease in frictional resistance with displacement, require more study as they may be part of the process leading to accelerating rock movements. Surfaces which display an increasing resistance are of less importance as they would not contribute towards a catastrophic rockslide.
5. The sliding block theory may be too simple, especially in assuming the slope inclination angle β to be constant. This angle increases as the slope elevation decreased, until the toe of the slope was overturned. Alteration of the theory could account for a changing slope angle.
6. Rather than a tilt-test, perhaps a creep shear test could be employed to track the frictional resistance of a rock surface with displacement. This relationship could then be substituted into the sliding block model for comparison to the actual movement.

The creep shear test would allow for the application of normal stress, although at relatively low levels, and for a more continuous deformation of the surface, unlike the tilt-test where the sample was removed after every slide. Problems would still exist,

such as the disturbance of gouge material if the sample was sheared more than one cycle and of course, scale effects.

14 C*****
15 C THIS VERSION WAS MODIFIED AND DOCUMENTED BY J.W.
16 C CASSIE IN APRIL, 1987.
17 C*****
18 C THE PROGRAM IS INVOKED BY THE COMMAND:
19 C $RUN CPACK2+CIVE:GRAPH+*IG+*PLOTLIB 4=INPUT 7=OUTPUT T=5S
20 C THE PLOT (IF REQUIRED) WILL BE LOCATED IN THE FILE -PDF.
21 C A HARDCOPY OF THE PLOT MAY BE OBTAINED BY RUNNING:
22 C $RUN *CALCOMPQ PAR=FILE=-PDF T=2s
23 C*****
24 C          VARIABLE DOCUMENTATION
25 C BBO: CONTAINS INTERCEPTS OF FITTED LINES.
26 C BB1: CONTAINS SLOPES OF FITTED LINES.
27 C ELPST: ELAPSED TIME IN HOURS COMPUTED BY SUBTRACTING
28 C          THE TIME OF THE FIRST DEFLECTION READING.
29 C TT: AS ABOVE BUT WITH THE FIRST RECORD DELETED.
30 C ESTRN1: ENGINEERING STRAIN FOR LVDT#1.
31 C E1: AS ABOVE BUT WITH FIRST RECORD DELETED.
32 C ESTRN2: ENGINEERING STRAIN FOR LVDT#2.
33 C E2: AS ABOVE BUT WITH THE FIRST RECORD DELETED.
34 C LT: CONTAINS THE LOGS OF TIME AS CALCULATED IN BFIT2.
35 C LE: CONTAINS THE LOGS OF STRAIN RATE AS CALCULATED IN BFIT2.
36 C W1: CONTAINS THE ABOVE RECORD WEIGHTINGS AS CALCULATED
37 C          IN BFIT2.
38 C NC1: NUMBER OF RECORDS IN THE ABOVE ARRAYS.
39 C EEM1: INTERMEDIATE VALUE USED IN CALCULATING THE
40 C          SLOPE SIGNIFICANCE STATISTIC.
41 C TP: TIMES OF THE TRANSFORMED DATA.
42 C ERP: STRAIN RATES OF THE TRANSFORMED DATA.
42.1 C ANSM1: INTERACTIVE RESPONSE THAT INDICATES WHETHER
42.2 C          TO PLOT THE DECELERATING DATA BEFORE THE
42.3 C          ACCELERATING DATA IS FIT.
42.4 C ANSM3: INTERACTIVE RESPONSE THAT INDICATES WHETHER OR NOT
42.5 C          TO USE CFIT.
42.58 C K: NUMBER OF THE FIRST RECORD USED IN THE FIT OF THE
42.66 C          ACCELERATING CREEP DATA.
42.74 C L: NUMBER TO INDICATE THE DECELERATING (L=1) AND THE
42.82 C          ACCELERATING (L=2) PHASES.
42.9 C NFIT: NUMBER USED TO INDICATE WHETHER ALL THE DATA
42.91 C          HAS BEEN FIT TO THE DECELERATING CURVE.

Appendix C: Assessing the Fitting Ability of CPACK2

The author could not locate any previous work where the fitting ability of CPACK or its versions had been tested. Hence, this appendix outlines the procedure followed and the results of such a study carried out on the latest version, CPACK2.

An equation was assumed with simple coefficients, such as:

$$\dot{\epsilon} = 1000 t^{-1.0} + 10^{-10} t^{3.0} \quad [C.1]$$

Time intervals were chosen, and the strain rate was calculated with Equation C.1 at the time interval midpoint. The amount of displacement per time interval was computed by multiplying the midpoint strain rate by the elapsed time of the interval. The amount of total displacement was accumulated by successive summation of the interval displacements. The total displacements were then associated with the final time value of the interval. These two parameters were input into CPACK2 in order to see what equation was calculated by the program.

Three different values, 3.0, 6.0, and 9.0 were substituted for the exponential coefficient D in the second term of the equation. This was done to investigate the fitting ability of the program as the second term's slope became steeper and as the slope difference between the two terms became greater.

Tables C.1, C.2, and C.3 display the input files for the third-order, the sixth-order, and the ninth-order equations respectively. Figures C.1, C.2, and C.3 illustrate the fit of the program-derived equations in relation to the data points. The output for the three respective runs are located just past the above figures.

The three resultant equations from CPACK2 were;

$$\dot{\epsilon} = 939.7 t^{-0.984} + 0.5316 \times 10^{-11} t^{3.360} \quad [C.2]$$

$$\dot{\epsilon} = 525.0 t^{-0.793} + 0.3551 \times 10^{-11} t^{6.687} \quad \text{and} \quad [C.3]$$

$$\dot{\epsilon} = 734.1 t^{-0.859} + 0.2894 \times 10^{-12} t^{10.759} \quad [C.4]$$

In all three cases, the values for the coefficients A, B, and C were less than the values assumed for calculation of the input points. Also, the exponent D value was greater than the assumed in all cases. It should also be noted that the Durbin Watson and the Test of Slope Significance statistics indicated a good fit to the data for all six terms.

Values for both A and B were all lower than assumed with the greatest deviation for both occurring with the sixth-order equation. The deviation from the assumed value of the C coefficient became greater (in absolute terms, C became smaller) as the order of the equation increased. This smaller-than-expected value for C can be correlated with the

larger-than-expected value observation for the exponent D. The program calculates a steeper slope (conservative error) for the second term of the equation. The amount of deviation, with respect to the assumed value for D was 12%, 11%, and 20% respectively.

The program seems to fit some of the effect of the second term to that of the first, before the statistics indicate a bad fit. This would explain the reasons for the lower values of both A and B. Because now, some of the second term has already been fit by the first term close to its start, the slope of the second term became steeper than the true case. Therefore D became larger while C decreased in value.

It is possible, that there may be some limits to the power difference of the two terms that the program can differentiate between. This phenomena requires more study and the program may have to be modified to "sharpen-up" the fitting procedure, by cutting-off the first term sooner, using stricter statistical criteria perhaps.

Table C.1 Input file for the third-order equation.

Appendix E: Example Run with CPACK2

```
1 University of Alberta - Computing Services Device: V831 Task: 4275
2 # Terminal,Prime,Internal/Teaching,Research
3 # $run cpack2+cive:graph+*ig+*plotlib 4-grfcp2 7--7 t-3a
4 # 14:43:56
5 THIS PROGRAM ACCEPTS DATA IN THE FOLLOWING FORMAT:
6 LABEL, TIME CLOCK, 3 COUNTERS, LOAD, CELL PRESSURE, DEF. 1, DEF. 2
7 IS YOUR DATA IN THIS FORM? (Y,N)
8 N
9 DO YOU HAVE AN LVDT CALIBRATION FACTOR?
10 Y
11 INPUT THE LVDT CALIBRATION FACTOR (MULTIPLIER):
12 0.001,
13 INPUT DIAMETER(MM), LENGTH(MM), AND WEIGHT(GM),
14 SEPARATED BY COMMAS:
15 1., 1000., 1.,
16 INPUT SAMPLE NUMBER (8 CHARACTER MAX.):
17 FULL
18 INPUT TEST NUMBER (8 CHARACTER MAX.):
19 GRR NO
20 INPUT NUMBER OF ELEMENTS IN EACH LINE (+ COMMA):
21 10,
22 INPUT NUMBER OF STRAIN GAUGES (LVDTs); (1 OR 2):
23 1,
24 THE ONLY DATA THAT THIS PROGRAM REQUIRES FOR INPUT
25 IN DEVICE 4, IS TIME AND DISPLACEMENT. LIST THE ELEMENTS IN
26 ONE LINE OF YOUR INPUT DATA, IN PROPER ORDER, USING "R1"
27 FOR THE FIRST STRAIN GAUGE READING, "R2" FOR THE SECOND (IF
28 THERE IS ONE), AND "TN", "TD", "TH", "TM", "TS", FOR THE TIME
29 IN: MONTHS, DAYS, HOURS, MINUTES, AND SECONDS (YOU MAY HAVE ONLY
30 ONE OF THESE TIME PARAMETERS). USE THE DUMMY VARIABLE "DU"
31 FOR ALL OTHER VALUES. (SEPARATE THE ELEMENTS WITH COMMAS)
32 DU, DU, DU, DU, TM, DU, R1, DU, DU, DU,
33 WOULD YOU LIKE THE DECELERATING CREEP DATA
34 PLOTTED BEFORE THE PROGRAM ATTEMPTS TO ISOLATE
35 ACCELERATING CREEP?
36 NO
37 WOULD YOU LIKE THE PROGRAM TO EXAMINE THE
38 ACCELERATING DATA FOR AN OPTIMUM FIT?
39 YES
40 INPUT DESIRED LIMIT FOR TEST OF SLOPE SIGNIFICANCE IF
41 OTHER THAN 10. (REAL NUMBER, TERMINATED WITH A COMMA):
42 9.0,
43 WOULD YOU LIKE A LOG STRAIN RATE - LOG TIME PLOT?(Y,N)
44 Y
45 WOULD YOU LIKE A STRAIN RATE - TIME PLOT?(Y,N)
46 Y
47 FOLLOWING ARE THE EXTREME VALUES IN THE T VS E PLOT:
48 MINIMUM STRAIN RATE: 0.000185
49 MAXIMUM STRAIN RATE: 0.500049
50 FINAL TIME: 2402.498
51 INPUT DESIRED STRAIN RATE VALUE AT ORIGIN OF Y AXIS (TERMINATE WITH CO
52 0.0,
53 INPUT DESIRED Y AXIS SCALE (UNITS/INCH):
54 0.15,
55 INPUT DESIRED LENGTH OF Y AXIS (INCHES):
56 5.0,
57 INPUT DESIRED X AXIS (TIME) SCALE (UNITS/INCH):
58 500.,
```

59 INPUT DESIRED LENGTH OF X AXIS (INCHES):
60 5.0,
61

Appendix F: Example Output File from CPACK2

The following contains the two output files from CPACK2 for the full and the truncated data sets.

Listing of FULL-OP at 15:00:36 on JUN 23, 1987 for CCID=GSB7 on UALAMTS

TEST NUMBER = GRR NO.
 SAMPLE NUMBER = FULL
 SAMPLE LENGTH = 1000.000 mm
 SAMPLE DIAMETER = 1.000 mm
 SAMPLE WEIGHT = 1.000 gm

INITIAL LOAD = 0.0 KN
 INITIAL CELL PRESSURE = 0.0 KPA
 INITIAL READING FOR LVDT1 = mm
 INITIAL READING FOR LVDT2 = mm

NUMBER	TIME HOURS	LOAD KN	CELL PRESSURE KPA	ENGG. STRAIN #1 (MICRO)	ENGG. STRAIN #2 (MICRO)

Appendix H: Finite Difference Program

The following contains an example listing of the finite difference program used to solve and plot the results of the sliding block modelling equation. The program is not interactive and hence any parameter changes have to be made in the file before the program is compiled.

The program is invoked by typing in the following two commands:

```
$Run *Fortgtest Scards=Programfile T=0.3s
```

```
$Run -Load#++Displa 7=-Output 9=-Plotfile T=0.5s
```

An example output file is also included.

```

1      REAL Y(500),YP(500),DIS(500),RATE(500)
2      C-- "A" is the inclination angle and must be expressed
3      C--      in radians. Note that "A" is equal to the
4      C--      inclination angle BETA for initial stability.
