## Abstract

Buhlmann et al. (2000) studied the minettes and xenoliths from southern Alberta, Canada. They hypothesized that the minettes were derived from a source containing phlogopite + clinopyroxene at pressures  $\geq 1.7$  GPa. To test this hypothesis, we investigated 1) the liquidus mineralogy of a primitive minette; and 2) the melting reactions of a mica + clinopyroxene assemblage. For the minette, we found a multiple saturation point at 1.77 GPa and 1350°C, where liquid coexists with orthopyroxene and olivine. Neither phlogopite nor clinopyroxene were found to be liquidus phases. We suggest that our minette is not primary, but had re-equilibrated with harzburgitic mantle subsequent to formation. For our mica-clinopyroxenite assemblage, we found the solidus is at temperatures above a cratonic geotherm, implying that this mica-clinopyroxenite is stable in a craton. The composition of the melts from our experiments are similar to madupitic lamproites from Leucite Hills, Wyoming, studied by Carmichael (1967).

## **Acknowledgements**

I would like to thank Dr. Robert Luth, my supervisor, for his guidance, insight and the funding he provided me through his Natural Sciences and Engineering Research Council of Canada (NSERC) Discovery Grant. It is through this experience that I have grown to understand the requirements demanded on those who pursue a career in academia. Without Bob, I would not have been given this valuable experience that I will carry throughout my life. Much appreciation and gratitude to my fellow graduate students, Danny Hnatyshin, Andreas Enggist, and Jason Hong, for listening to my endless discussions (and sometimes rants) about my experimental results. Some of those discussions actually ended up being useful. I would also like to acknowledge Sergei Matveev for his valuable and extensive aid during my microprobe analyses. His expertise and guidance made this research possible. To Dr. Thomas Chacko, I thank him for his overall support and guidance over the years, as well as his aid on the microprobe during the last months of my thesis. I would also like to thank Dr. Claire Currie for her help in some of the more geophysical side of this research.

I am grateful for the additional financial support was provided through the NSERC Postgraduate Scholarship granted to me, the numerous Teaching and Research Assistantships I held at the University of Alberta (UofA), the Walter H. Johns Graduate Fellowship (UofA), and the Alberta Advanced Education and Technology Graduate Student Scholarship (Provincial). I am especially appreciative of the Hibb's Student Conference Travel Award (through the Institute for Geophysical Research at the UofA), The Profiling Alberta's Graduate Students Award (through the Faculty of Graduate and Research Studies), and the Graduate Student Association Professional Development Grant for allowing me to travel to Prague, Czech Republic and present my research at the 2011 Goldschmidt conference.

I would like to thank my family for their support over the course of my academic career. A special thanks goes to my best friend and beloved girlfriend, Christine Card, who kept me going and sane during the most stressful times of this research. When things seemed at their darkest, she was my light to keep me going. To my friends, Rob Renz, Benjamin Packianayagam, Branawan Gowrishankar, Vithuran Gowrishankar, Chrse Tham, Charlene Ahorro, Karson Styles, Clair Tolton, Mark Cheung, Jerry Lo, Justine Brilliant, Liz Martin, and Omar Manji, your support was invaluable. Although my scholarly pursuits demanded much of my free time, what little time we did get together was much needed and appreciated.

KC	Kimberlite Corridor
LILE	Large Ion Lithophile Elements
<	Less than
$\leq$	Less than or equal to
LREE	Light Rare Earth Elements
liq	Liquid (melt)
LOI	Loss On Ignition
Lu	Lutetium
Mg	Magnesium

Mg#	Magnesium number
MgO	Magnesia (magnesium oxide)
Mn	Manganese
MnO	Manganese oxide
ms.	Manuscript
MARID	Mica-amphibole-rutile-ilmenite-diopside
μm	Micrometers
mg	Milligrams
mm	Millimeters
Ma	Million years
mW m <sup>-2</sup>	Milliwatts per square meter
min	Mineral (or "minutes" depending on context)
-	Minus (or "to" depending on context)
X <sub>i</sub>	Modal abundance of phase i
$X_{oxide}^{phase}$	Molar Fraction of oxide in phase
nA	Nanoamperes
Nd	Neodymium
Ni	Nickel
Nb	Niobium
n	Number of analyses
ol	Olivine
opx	Orthopyroxene
Os	Osmium
OD	Outer Diameter
O	Oxygen

$D_{oxide}^{min/melt}$	Partitioning coefficient between mineral and melt for oxide
ppm	Parts per million
%	Percent
K	Potassium
K <sub>2</sub> O	Potassium oxide
PRZ	Phi Rho Zed correction
phl	Phlogopite
P	Phosphorous
P <sub>2</sub> O <sub>5</sub>	Phosphorous pentaoxide
Pt	Platinum
+	Plus (or "and" depending on context)
±	Plus or minus ("with or without" or "error" depending on context)
PT-space	Pressure-Temperature space
REE	Rare Earth Elements
Re	Rhenium
Rb	Rubidium
Sm	Samarium
Sc	Scandium
sec	Seconds
SiO <sub>2</sub>	Silica (silicon dioxide)
Si	Silicon
Na	Sodium
Na <sub>2</sub> O	Sodium oxide
σ	Standard Deviation
Sr	Strontium

$\Sigma$	Sum (addition of terms)
$\Sigma R^2$	Sum of residual squares
Th	Thorium
TiO <sub>2</sub>	Titania (titanium (IV) oxide)
Ti	Titanium
W	Tungsten
□	Vacancy
var.	Variable composition
H <sub>2</sub> O	Water
H <sub>2</sub> O <sup>+</sup>	Water added to system
wt%	Weight Percent
KCMAS-H <sub>2</sub> O	6 component system containing K <sub>2</sub> O-CaO-MgO-Al <sub>2</sub> O <sub>3</sub> -SiO <sub>2</sub> -H <sub>2</sub> O

# Chapter 1. Introduction:

## 1.1. Overview:

Lamprophyres, a term first coined by von Gumbel (1874) from the Greek roots *lampros* and *porphyros* (which means "glistening porphyry"), are a heterogeneous group of igneous rocks that are volumetrically small, exotic and rare. Since then, the study of these rocks has produced a plethora of uninformative names (see Rock 1991 for a detailed review). There have been some attempts to rein in the nomenclature (Dawson 1987; Rock 1987, 1991; Foley et al. 1987; Mitchell and Bergman 1991; Mitchell 1994b; Woolley et al. 1996), but they have been generally unsuccessful. These rocks have been the subject of many academic studies, both geochemical (Lloyd and Bailey 1975; Van Kooten 1980; Macdonald et al. 1992; Conticelli and Peccerillo 1992; Carlson and Nowell 2001; Orejana et al. 2008; Rosenthal et al. 2009) and experimental (Edgar et al. 1976, 1980; Edgar and Condcliffe 1978; Barton and Hamilton 1978, 1979; Lloyd et al. 1985; Esperanca and Holloway 1987; Righter and Carmichael 1996; Elkins-Tanton and Grove 2003; Parat et al. 2010). Lamprophyres, and other related mafic alkali-rich rocks, have paradoxical compositions, enriched in both compatible (e.g. MgO) and incompatible elements (e.g. Cr, Ni, Co, Sc, large ion lithophile elements (LILE)) but depleted in high field strength elements (HFSE). They are not easily explained by partial melting of a typical refractory mantle peridotitic source. The high Mg# (65-80%), Sc (15-30 ppm), Cr (200-500 ppm), Ni (90-700 ppm) and Co (25-80 ppm) content are consistent with lamprophyres being primary magmas derived from the mantle (Frey et al. 1978; Rhodes 1981), but the mineralogy of their source region is largely unknown. In an attempt to better define the term, Rock (1977) classifies a lamprophyre as: "an alkali-rich porphyritic dyke-rock (more rarely a plug or lava) showing intermediate to very low SiO<sub>2</sub> content with moderate to high colour index, carrying essential

primary amphibole and/or mica, and typified by lack of felsic phenocrysts and groundmass olivine, by characteristic alteration and by panidiomorphic texture."

In North America, a large number of alkaline rocks, including lamprophyres, lamproites and kimberlites, are restricted to continental interiors, usually within Archean cratons. Some of these rocks are located in the "kimberlite corridor" (KC) (**Figure 1.1**), as defined by Heaman et al. (2003; 2004) and Currie and Beaumont (2011), which is a stretch of land located on the western portion of North America (~1000-1500 km inland). Its northern most extent is located in the Slave craton, Northwest Territories, Canada and it extends down south to include the Wyoming craton and the Colorado Plateau, United States. The main emplacement phase of alkali magmatism in western North America began ca. 110 Ma and lasted to ca. 45 Ma, with a few occurring as late as ca. 25 Ma. The locations of these alkaline rocks in North America do not match with known mantle plume tracks (Heaman et al. 2003), and are located outside regions of known mantle upwellings (Torsvik et al. 2010). Many authors have studied the Montana and Wyoming high-potassium magmas (Fraser et al. 1985; Dudas et al. 1987; Eggler et al. 1987; Meen and Eggler 1987; Mitchell et al. 1987; Hyndman et al. 1988; Scambos and Farmer 1988; Irving 1990; Dudas 1991; O'Brien et al. 1991, 1995; Macdonald et al. 1992; Buhlmann et al. 2000; Carlson and Nowell 2001; Downes et al. 2004; Facer et al. 2009; Smith 2010) and have suggested that the subduction and dehydration of the Farallon plate during the late Cretaceous was the trigger for alkali magmatism. Macdonald et al. (1992), Buhlmann et al. (2000) and Carlson and Nowell (2001) argue that the North American potassic magmas were derived from partial melting of a veined source containing mica and pyroxene at depths approaching the base of the craton. Numerical models (e.g. Currie and Beaumont 2011) have since shown these hypotheses to be plausible.

Dawson (1884), Weed and Pirsson (1895), Kemp and Billingsley (1921), Williams and Dyre (1930) and Russell and Landes (1940) were among the first to study the alkaline rocks from southern Alberta, and classified them as minettes. We have retained their terminology in this study. The minettes in southern Alberta are the northern outliers of the Eocene-aged Sweet Grass Hills igneous complex. Carried in the minettes are coarse-grained xenoliths composed of phlogopite, clinopyroxene and apatite. Kjarsgaard (1994) conducted an extensive study, including whole-rock major- and trace-element analyses, mineralogy and mineral analyses, on these minettes. Kjarsgaard (1994) noted that the southern Alberta minettes are compositionally similar to other alkaline rocks from Montana, United States.

Much of the foundation for this investigation was based on Buhlmann (1996; MSc thesis) and Buhlmann et al. (2000), who studied both the minettes and the mica-clinopyroxenite xenoliths from the Milk River area, southern Alberta, Canada. The minettes are hydrous, potassic and Mg-rich and, according to these authors, are likely derived from the lithospheric mantle. The most primitive minettes usually have porphyritic textures, with olivine pseudomorphs, phlogopite, and diopside as phenocrysts, and a matrix consisting of clinopyroxene, sanidine, mica, spinel, apatite and sometimes carbonates and analcime. They are light rare earth element (LREE)-enriched with no Eu anomaly, and have strong negative Th and Nb anomalies (Buhlmann et al. 2000). Buhlmann et al. argued that the trace-element and isotopic characteristics of the minettes requires at least three components in the source region: 1) a LREE-enriched, HFSE-depleted, low  $\epsilon_{Nd}$  source, likely ancient lithospheric mantle (O'Brien et al. 1991, 1995); 2) an asthenospheric mantle source with near bulk-Earth Sr and Nd isotopic values; and 3) a source with high  $^{87}Sr/^{86}Sr$ , Rb-Sr, and Sm-Nd (sometimes enriched in Ba and

depleted in Nb and Ti), inferred to be a young component (possibly a subduction-related component).

Based on the work of Esperanca and Holloway (1987) and extrapolating phase boundaries inferred by Wallace and Carmichael (1989), Buhlmann et al. (2000) suggested that the parental melt of the Milk River minettes could have come from a source containing phlogopite + clinopyroxene  $\pm$  olivine at pressures  $\geq 1.7$  GPa. The high concentrations of  $\text{TiO}_2$  (~1.0 wt%),  $\text{K}_2\text{O}$  (>4.44 wt%), Rb (~200 ppm), Cs (~3 ppm), and Nb (~13 ppm) in the minettes are consistent with the melting of phlogopite (Ionov et al. 1997; Pearson et al. 2004). The high CaO (>5.96 wt%) content and enrichments in the rare earth elements (REE) (Menzies 1983) are best explained with clinopyroxene in the source. The concentration of  $\text{P}_2\text{O}_5$  (~1.0 wt%) indicate that apatite is likely a component of the source as well. The high Sr (~900-2000 ppm) content could be due to either clinopyroxene or apatite in the source, whereas the high Ba (~1500-4000 ppm) concentrations are consistent with phlogopite or apatite in the source (Ionov et al. 1997; Pearson et al. 2004). This source region mineralogy of phlogopite + clinopyroxene + apatite agrees with many previous studies, both experimental (Edgar et al. 1976, 1980; Barton and Hamilton 1978, 1979; Edgar and Condcliffe 1978; Nicholls and Whitford 1983; Lloyd et al. 1985; Esperanca and Holloway 1987; Mitchell 1995; Righter and Carmichael 1996; Sato 1997; Elkins-Tanton and Grove 2003) and geochemical (Lloyd and Bailey 1975; Van Kooten 1980; Wallace and Carmichael 1989; Conticelli and Peccerillo 1992; Foley 1992a, 1992b; Macdonald et al. 1992; Carlson and Nowell 2001), on related mafic alkali-rich rocks.

In the cratonic mantle, it is generally accepted that phlogopite-rich clinopyroxenite lithologies are volumetrically small, and one popular model is that these lithologies are present as veins. Foley (1992b) investigated the partial melting behaviour of veined peridotite, and

concluded that the initial melting is dominated by the vein because it is volatile-rich, and therefore has a lower solidus temperature relative to its surroundings. The melts derived from the vein, which are in disequilibrium with the surrounding wall-rock, would infiltrate into the peridotite wall-rock and dissolve some of the minerals. Foley et al. (1999) investigated the melting behaviour on several amphibole + phlogopite + clinopyroxene  $\pm$  accessory minerals vein assemblages at 1.5 and 5.0 GPa. They found that relative to a mica-clinopyroxenite, the addition of amphibole lowered the solidus by  $\sim 50^{\circ}\text{C}$ , and that amphibole was the main factor controlling the composition of the melt. Foley et al. also found that the solidi for the hydrous vein assemblages had a steeper P-T slope relative to a cratonic mantle geotherm, and concluded that at greater depths, minimal heating would be required to induce partial melting. Pilet et al. (2008) conducted sandwich experiments on a hornblendite to study the melting behaviour of the vein assemblage and reactions between the alkali-rich, silica-undersaturated partial melts and the surrounding peridotite. Pilet et al.'s observations are consistent with the dissolution model proposed by Foley (1992b).

A number of workers have invoked a vein-plus-wall-rock melting model to explain magmas in various locales (e.g. Italy: Conticelli et al. 2009; Boari et al. 2009; Nikogosian and van Bergen 2010; Tibet: Jiang et al. 2006). One example that illustrates wall-rock reactions is from Maria and Luhr (2008), who studied the alkaline and mafic rocks from the Western Mexican Volcanic belt. They argued that the lamprophyres found in the region were the result of partial melting of a phlogopite-rich vein assemblage, and that the lamprophyres evolved into basanites, and later basalts, with increasing wall-rock dissolution. Other workers (e.g. Carlson and Irving 1994; Mitchell 1995) have also proposed that the alkaline magmas from the Wyoming

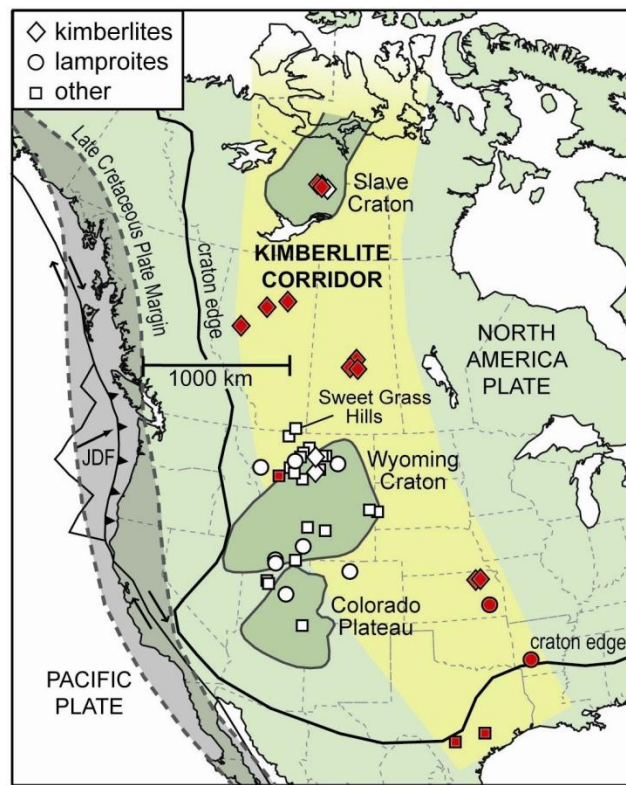

craton were produced by the model proposed by Foley (1992b). Such a model may be applicable to the petrogenesis of the Milk River minettes.

## **1.2. Goals of the study:**

The study of alkali-rich mafic magmas provides a unique insight into the chemical and lithological heterogeneities in the mantle. It is generally accepted that many alkaline magmas are derived from unusual vein lithologies, usually containing large quantities of amphibole and/or mica, and therefore they can be used to constrain the distribution and cycling of alkalis, incompatible elements and hydrous fluids in the mantle. Some of these alkaline rocks, kimberlites and lamproites in particular, are carriers of important economic resources such as diamonds. It was suggested by Wyman and Kerrich (1988) and Rock and Groves (1988) that lamprophyres as well may be a source of gold, silver and diamonds (if their source region is >150 km).

The goal of our study is to 1) determine the conditions (temperature and pressure) at which the minettes formed; and 2) ascertain the mineralogy of the residue in the source region. We conducted two separate sets of experiments to do so. The first series of experiments was to characterize the liquidus mineralogy of the minette. Liquidus experiments are challenging because they must fulfil two criteria: 1) the melt must be in equilibrium with the residue of the source region; and 2) during the melt's ascent, it must remain compositionally unmodified. If this is the case, the multiple saturation point, a single point in PT-space where multiple minerals crystallize at the liquidus, sheds light on two pieces of information: 1) the pressure and temperature of formation; and 2) the mineralogy and composition of the residue.

The second series of experiments involved melting a representative mica-clinopyroxenite lithology and characterizing the melts produced. With these experiments, we are simulating the physical processes that occur in the mantle during melt formation. In these experiments, the location of the solidus in PT-space is of interest. The solidus tells us at what temperatures and pressures this lithology begins to melt. With increasing temperature, we can infer the melting reactions that take place above the solidus.

**Figure 1.1:** The distribution of mafic alkali-rich rocks in North America within the "kimberlite corridor" (modified from Currie and Beaumont 2011). The modern Juan de Fuca plate is shown off the west coast of North America, and is the last remnant of the Farallon plate. Along the Alberta-Montana boundary, the Sweet Grass Hills minettes (Milk River area) is labelled. Symbols: red = Cretaceous emplacement ages; white = Cenozoic ages.

## **Chapter 2: Liquidus phase relations of a minette from the Milk River**

### **Area, southern Alberta, Canada<sup>1</sup>**

#### **2.1. Introduction:**

The study of the liquidus mineralogy of a melt composition sheds light on the phases with which the melt equilibrated. The basic premise of a liquidus study, such as this one, is that the starting material represents a primary melt composition. That is, the melt composition that formed by partial melting has not been modified subsequently. This approach also assumes that equilibrium is achieved between the melt phase and the residue at a specific pressure. Therefore, this method assumes that the magma is derived via isobaric melting and does not react subsequently with its surroundings during ascent. If found, the multiple saturation point, the point at which several mineral phases crystallize at a single point along the liquidus, represents the pressure (P) and temperature (T) of melting, and the mineral assemblage is the residue of the source region from which the magma was derived.

Most mafic alkaline magmas, including lamprophyres, have paradoxical chemical compositions. They are hydrous, alkali-rich, and enriched in both major compatible (MgO) and incompatible elements (Cr, Ni, Co, Sc, large ion lithophile elements (LILE)), but are depleted in high field strength elements (HFSE), relative to basaltic mantle-derived melts. The mineralogy and composition of the source region for these magmas remains poorly constrained. Because of their unusual composition, they have been the subject of a number of previous petrologic and geochemical (Lloyd and Bailey 1975; Macdonald et al. 1992; Conticelli and Peccerillo 1992; Carlson and Nowell 2001; Orejana et al. 2008; Rosenthal et al. 2009) and experimental studies

---

<sup>1</sup> A version of this chapter was submitted for publication in *Contributions to Mineralogy and Petrology* as Funk S, Luth R, An experimental study of a minette from the Milk River area, southern Alberta, Canada.

(Lloyd et al. 1985; Esperanca and Holloway 1987; Richter and Carmichael 1996; Barton and Hamilton 1978, 1979; Edgar and Condcliffe 1978; Edgar et al. 1976, 1980; Elkins-Tanton and Grove 2003; Parat et al. 2010). By and large, these authors converge on the conclusion that many mafic alkali magmas form by partial melting of a source containing clinopyroxene and phlogopite.

We conducted this study to shed light on the origin and physical conditions required to generate the minettes located in southern Alberta, near the Milk River area. Buhlmann et al. (2000) had previously studied the geochemistry and petrography of these minettes and their associated mica-clinopyroxenite xenoliths. They proposed, based on the experimental work of Esperanca and Holloway (1987), and extrapolating phase boundaries from Wallace and Carmichael (1989), that these minettes were derived from a source containing phlogopite + clinopyroxene  $\pm$  olivine at pressures  $\geq 1.7$  GPa, probably closer to 3.0 GPa. The concentrations of Rb ( $\sim 200$  ppm), Cs ( $\sim 3$  ppm), and Nb ( $\sim 13$  ppm) in the minettes are consistent with the melting of phlogopite (Ionov et al. 1997; Pearson et al. 2004), whereas the high concentrations of Sr ( $\sim 900$ -2000 ppm) and rare earth elements (REE) (Menzies 1983) are best explained with clinopyroxene in the source. The goal of this study was to test Buhlmann et al.'s hypothesis experimentally. Based on their hypothesis, we expected to find a multiple saturation point along the liquidus where clinopyroxene, mica, and possibly olivine, coexisted with liquid.

## **2.2. Starting Material:**

Buhlmann et al. (2000) concluded that the sample RAB90 Au24-1 minette was the most primitive sample in the suite, based on Mg# ( $\sim 73$ ), MgO content (13.63 wt%), Cr (960 ppm) and Ni (664 ppm) concentrations (see Buhlmann et al. 2000 for details). As the most primitive of the

suite, we selected this sample as a possible candidate for a parental magma to study. The RAB90 Au24-1 minette is a fine-grained dyke with phenocrysts of phlogopite, diopside and altered olivine in a groundmass of clinopyroxene, sanidine, mica, oxides, apatite and in some cases carbonates. For our experiments, we used an aliquot of the natural rock powder prepared by Buhlmann in his original study (major element composition is given in **Table 2.1**).

### **2.3. Methodology:**

Approximately 3 mg of powdered sample was packed tightly in a graphite inner capsule with dimensions ~4 mm tall, ~2.65 mm outer diameter (OD), and ~1.2 mm inner diameter (ID); the packed graphite capsule was loaded into a 3 mm OD Pt capsule. No additional water was added to these charges. The samples were placed in a 120°C oven overnight to dry prior to sealing by arc-welding. The capsules were run vertically in 12.7 mm talc-pyrex assemblies in solid-media, piston-cylinder apparatus (Boyd and England 1960) at the C.M. Scarfe Laboratory of Experimental Petrology, University of Alberta. The pressures were calibrated on the quartz-coesite transition at 1000°C, and on the jadeite-albite-quartz transition at 600 and 1000°C. It was determined that a -13% correction was required to correct the nominal pressures. Temperatures were monitored with W95Re5-W74Re26 thermocouples with no corrections made for the effect of pressure on the emf of the thermocouple.

Experiments to locate the liquidus and characterize its mineralogy were conducted between 1.33 GPa to 2.21 GPa and between 1300°C to 1400°C (**Table 2.2**). Each experiment was brought up to ~80% pressure. The sample was then heated to the desired temperature, and finally the pressure was brought up to its final value. The duration of experiments ranged from one to two days, depending on temperature.

The compositions of the phases in the run products were determined using the JEOL 8900R electron microprobe at the Department of Earth and Atmospheric Sciences, University of Alberta. All experiments were analyzed at 15 kV acceleration potential. For the mineral grains, a beam current of 15 nA was used with a beam diameter of 1-3  $\mu\text{m}$ . The beam current was reduced to 10 nA and the beam diameter widened to 10  $\mu\text{m}$  on the glasses. To mitigate the effect of alkali migration during glass analyses, K and Na were analysed first. For all analyses, counting times were 20 seconds on peak, and 10 seconds on the background. Natural mineral standards were used (**Table 2.3**). The data acquired from the electron microprobe was corrected using the phi-rho-zed (PRZ) program provided by JEOL. Standard deviations were calculated to assess compositional variability.

## **2.4. Results:**

### **2.4.1. Liquidus Temperature and Mineralogy:**

The P-T location of the liquidus and its mineralogy for our Milk River minette is well constrained within the investigated pressure range of this study. **Figure 2.1** shows the phase relationships along the liquidus, and **Tables 2.4-2.6** provides the average compositions of the liquidus phases. At 1.33 GPa and 1.77 GPa, the liquidus is bracketed between 1350°C and 1375°C, whereas at 2.0 GPa and 2.21 GPa it is between 1375°C and 1400°C. At 1.55 GPa, the liquidus is bracketed between 1325°C and 1375°C. At 1.33 GPa and 1350°C, olivine with an average  $\text{Mg\#} = 90.9$  coexists with a melt with  $\text{Mg\#} = 75.8$ . At 1.55 GPa and 1325°C, olivine with an average  $\text{Mg\#} = 90.5$  coexists with a melt with  $\text{Mg\#} = 75.9$ . At 2.0 GPa and 1375°C, orthopyroxene with an average  $\text{Mg\#} = 90.9$  coexists with a melt with  $\text{Mg\#} = 76.8$ . At 2.21 GPa and 1375°C, orthopyroxene with an average  $\text{Mg\#} = 89.4$  coexists with a melt with  $\text{Mg\#} = 71.0$ .

At 1.77 GPa, both olivine (Mg# = 88.6), and orthopyroxene (Mg# = 89.2) coexist with a liquid (Mg# = 72.4), forming a multiple saturation point at 1350°C.

#### **2.4.2. Melt Composition:**

Below the liquidus, the composition of the liquid (**Table 2.4**) changes with temperature and pressure depending on the mineral phase or phases crystallizing. At 1.33 GPa, where olivine crystallizes, the SiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub>, CaO and TiO<sub>2</sub> content in the glass increases with decreasing MgO content (**Figures 2.2a-d**). The compositions of Na<sub>2</sub>O, K<sub>2</sub>O, and P<sub>2</sub>O<sub>5</sub> in the glass also increase with decreasing MgO content. Above 1.77 GPa, SiO<sub>2</sub> decreases with decreasing MgO content, a reflection of crystallizing the silica-rich orthopyroxene (**Figure 2.2a**). The behaviour of TiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub>, CaO, Na<sub>2</sub>O, K<sub>2</sub>O, and P<sub>2</sub>O<sub>5</sub> remains unchanged as a function of pressure.

#### **2.4.3. Olivine Composition:**

Olivine grains are typically prismatic and are subhedral to euhedral. They are small, ranging from ~10-50 µm in diameter, and are chemically homogeneous. Olivine is stoichiometric, with Mn and Ca substituting for Mg and Fe (**Table 2.5**). Manganese decreases with increasing temperatures (**Figure 2.3**), consistent with the experimental study of Snyder and Carmichael (1992) of olivine-melt equilibrium. In our experiments, olivine incorporates ~0.2-0.3 wt% CaO (**Table 2.5**), independent of temperature and pressure. As temperatures approach the liquidus, the Mg# in olivine increases (**Figure 2.4**). This is expected because magnesium stabilizes olivine to higher temperatures.

#### 2.4.4. Orthopyroxene Composition:

Orthopyroxene is prismatic and euhedral, growing up to  $\sim 50\ \mu\text{m}$  in diameter. All orthopyroxene grains are homogenous and unzoned. All our orthopyroxene incorporates  $\sim 2\ \text{wt}\%$   $\text{Al}_2\text{O}_3$  (**Table 2.6**), and at 2.21 GPa, the  $\text{Al}_2\text{O}_3$  content decreases as temperature approaches the liquidus. The CaO content in orthopyroxene is  $\sim 2\ \text{wt}\%$  (**Table 2.6**), and does not vary systematically with respect to temperature or pressure.

#### 2.4.5. Iron Loss:

Loss of iron by alloying with the outer Pt capsule was an issue during our experiments. The loss of iron makes the bulk composition more Mg-rich, which would shift the liquidus to higher temperatures. Ascertaining the exact percentage of iron loss is difficult. Modal abundances were calculated without  $\text{FeO}^*$  to remove any bias due to iron loss. The calculated modes were used to reconstruct the bulk composition of our experiments. Comparing the reconstructed composition with the original starting material yields an estimate of the percentage of iron loss (general expression given in **Table 2.2**). We also estimated the percentage of iron loss in other experimental papers (Barton & Hamilton 1979; Lloyd et al. 1985; Esperanca and Holloway 1987; Sweeney et al. 1993) with similar compositions and similar capsule designs using our expression. We obtain a range for iron loss that is similar to those estimated by the previous authors (1-20%), lending credence to our calculations.

Our results show that our experiments had  $\sim 3\text{-}25\%$  iron loss, although many are within  $\sim 10\text{-}25\%$  (**Table 2.2**). We estimate a similar range for the other studies. Sweeney et al. (1993) argued that  $\sim 14\text{-}18\%$  iron loss was not significant enough to affect the phase relations or the relative appearance of phases. To see how much the phase boundaries would shift with 25% loss

in FeO, we used pMELTS (Ghiorso et al. 2002) to calculate ideal phase diagrams (one diagram had the mineralogy constrained to only allow olivine, orthopyroxene and liquid; the other was left unconstrained) for RAB90 Au24-1. The results from pMELTS show that a 25% loss in FeO shifts phase boundaries up by ~20-30°C, but the relative order of appearance of phases remains unchanged. We also compared the phase diagrams for RAB90 Au24-1 with 10% and 25% loss in FeO. We found that within the investigated pressures of this study and with a 25°C uncertainty, the liquidus temperatures for both phase diagrams were indistinguishable. We conclude that the iron loss experienced in our experiments will not affect the mineralogy of the crystalline phases, and that the range of iron loss between each experiment will not noticeably change the liquidus location in P-T space.

#### **2.4.6. Mineral-liquid Equilibria:**

To ascertain whether our experiments were at equilibrium we used mineral-liquid exchange coefficients. Roeder and Emslie (1970) found that the Fe-Mg exchange coefficient between olivine and liquid,  $K_D(\text{Fe-Mg})^{\text{ol-liq}}$ , varied between 0.26 and 0.36. They concluded that equilibrium, with respect to Fe-Mg exchange, can be assured if  $K_D(\text{Fe-Mg})^{\text{ol-liq}}$  are within this range. Within the resolution of their study, they found that the exchange coefficient was independent of melt composition and temperature. However, subsequent studies on alkaline magmas have found that this is not the case (Sack et al. 1987; Gee and Sack 1988). Gee and Sack (1988) found that  $K_D(\text{Fe-Mg})^{\text{ol-liq}}$  decreases with decreasing silica content, or conversely, increasing alkalis. Tholeiites to alkali basalts have exchange coefficients ranging from 0.33 to 0.27; at lower silica activities, olivine melilitites to nephelinites have exchange coefficients ranging from 0.25 to 0.17. Our calculated  $K_D(\text{Fe-Mg})^{\text{ol-liq}}$  values (0.31-0.36; **Table 2.7**) are

higher than the range given by Gee and Sack (1988), but are within the range given by Roeder and Emslie (1970).

As with olivine-liquid, orthopyroxene and melt have an analogous Fe-Mg exchange reaction. In this case, equilibrium values of  $K_D(\text{Fe-Mg})^{\text{opx-liq}}$  are  $0.29 \pm 0.06$  (Putirka 2008). This value is independent of pressure and temperature (Putirka 2008). All of our values are in this range (**Table 2.7**). Based on these calculations, we believe that our experiments, with respect to Fe-Mg exchange, are in equilibrium and can be used to construct phase relations.

#### **2.4.7. Geothermometry:**

As a second independent test for equilibrium, we calculated temperatures for our experiments using different geothermometers. Detailed explanations of the empirical fitting, statistics, sample calculations and review of the various glass-only and mineral-liquid geothermometers that are used in this study, are in Putirka et al. (2007) and Putirka (2008). **Table 2.8** provides the temperatures calculated from the glass-only, olivine-liquid, and the orthopyroxene-liquid thermometers.

The glass-only thermometer (equation 14 of Putirka 2008) was chosen because the range of pressures, temperatures, and compositions of glasses against which it was calibrated makes it appropriate for our system. This thermometer assumes saturation of hydrous mafic melts with olivine (Putirka 2008), and is applicable therefore only for our low-pressure experiments. The uncertainty of equation 14 is reported to be  $\pm 51^\circ\text{C}$  (Putirka 2008). Of the experiments containing olivine, the calculated temperatures differ from the measured ones by  $\sim 25^\circ\text{C}$ .

In conjunction with the glass-only thermometers, an olivine-liquid thermometer from Putirka et al. (2007), their equations 2 (distribution coefficient) and 4 (the olivine-liquid

thermometer), were used to calculate temperature for our low-pressure experiments. Putirka et al. (2007) used a non-linear regression to produce new olivine-liquid thermometer equations, based on work by Beattie (1993) and building upon the pressure sensitivity noted by Herzberg and O'Hara (2002). Putirka et al. reported an uncertainty of  $\pm 52^{\circ}\text{C}$  for their expression. When the two equations are coupled, the calculated temperatures for our system are systematically lower by  $\sim 20\text{-}50^{\circ}\text{C}$  than the measured temperature of the experiment (**Table 2.8**). They do agree, however, within the stated uncertainty.

At higher pressures, where olivine is no longer stable, an orthopyroxene-liquid thermometer, equation 28a from Putirka (2008), was used. Equation 28a was based on previous work from Beattie (1993). With the exception of experiment SPF40 (and with other experiments not used in this study due to extensive Fe loss; see Appendix E), the thermometer recovers temperatures to within the uncertainty of  $\pm 41^{\circ}\text{C}$  (Putirka 2008). The larger deviation in SPF40 could be due to the significant ( $\sim 20\%$ ) iron loss experienced during the experiment.

Although calibrated on more mafic and less alkaline compositions than ours, these geothermometers reproduce run temperatures well. Of the thermometers utilized in this study, the orthopyroxene-liquid thermometer may be the best test for equilibrium and may be used to flag potential problems with iron loss. We conclude equilibrium is best evaluated using multiple geothermometers. Coupled together, along with textural observations and mineral-liquid exchange coefficients, consistent calculated values argue for equilibrium.

## **2.5. Discussion:**

### **2.5.1. Implications for vein-melting and wall-rock re-equilibration:**

Buhlmann et al. (2000) suggested that the Milk River minettes were derived from a mantle source containing phlogopite, clinopyroxene, and possibly olivine, at ~3.0 GPa (~100 km). This hypothesis is supported by many previous studies. Lloyd and Bailey (1975) studied high-potassium rocks from Uganda, and suggested derivation by partial melting of a phlogopite clinopyroxenite. This was proven plausible by the subsequent forward experimental study of Lloyd et al. (1985). Macdonald et al. (1992) concluded that the potassic mafic lavas from the Bearpaw Mountains in Montana most likely originated via melting of a source containing olivine, phlogopite and clinopyroxene at pressures ~3.0 GPa. Conticelli and Peccerillo (1992) suggested that the potassium-rich magmas from central Italy were produced by melting a phlogopite pyroxenite. Carlson and Nowell (2001) conducted an isotopic study of alkaline igneous rocks from the Colorado Plateau. Using the Re-Os and Lu-Hf isotopic systems, they concluded that the least silica-saturated magmas, known as katungites, were probably derived by partial melting of mica-clinopyroxenites. Based on the isotopic characteristics and geochemistry of alkaline lamprophyres from the Spanish Central System in Western Europe, Orejana et al. (2008) suggested a metasomatized peridotitic source rich in phlogopite. In the study of ultramafic lamprophyres that erupted in northern Labrador and Quebec in eastern Canada, Tappe et al. (2008) suggested these magmas formed by fusion of a mica-amphibole-rutile-ilmenite-diopside (MARID)-type metasome assemblage induced by fluxing of a carbonate-rich fluid. Rosenthal et al. (2009) used Sr-Nd-Hf-Os isotopic systematics to characterize the source region of kamafugites from the western branch of the East African Rift. They found that the

kamafugites were derived from mixing between a phlogopite-rich MARID-like component, and a carbonate- and phlogopite-rich metasome at depths > 100 km.

In addition to petrographic and geochemical studies noted above, most of the experimental studies on mafic alkaline magmas (**Table 2.9**), not confined only to lamprophyres, have nearly all converged on the same conclusion. They mostly found olivine + clinopyroxene + phlogopite as liquidus phases at a multiple saturation point (Esperanca and Holloway 1987; Richter and Carmichael 1996; Barton and Hamilton 1978, 1979; Edgar and Condcliffe 1978; Edgar et al. 1976, 1980; Elkins-Tanton and Grove 2003; Parat et al. 2010). At higher pressures, usually  $\geq 3.0$  GPa, garnet was an additional stable liquidus phase (Nicholls and Whitford 1983; Mitchell 1995). In most studies, with the exception of Edgar et al. (1976, 1980) and Sato (1997), orthopyroxene is absent as a stable liquidus phase. Foley (1992a) suggested that orthopyroxene in alkaline magmas is stabilized by higher CO<sub>2</sub> contents in the coexisting C-O-H fluid. From these studies on alkaline magmas, it has generally been concluded that a phlogopite clinopyroxenite may be the source lithology of many mafic alkaline magmas, and therefore a crucially important lithology in the lithospheric mantle.

Finding orthopyroxene and olivine, rather than clinopyroxene and phlogopite, as major liquidus mineral phases for a composition such as ours is unusual. These findings are inconsistent with the hypothesis proposed by Buhlmann et al. (2000) and does not fit with the overall consensus from geochemical, petrological and experimental studies on magmas of similar compositions. Our experiments are not the first to find multiple saturation of orthopyroxene and olivine. Arima and Edgar (1983) studied the liquidus phase relationships of a leucite lamproite (wolgidite) from the West Kimberly area, Australia between 1.0 to 4.0 GPa and with 3.22 and 13.0 wt% H<sub>2</sub>O added. They found that in experiments with 13.0 wt% H<sub>2</sub>O, olivine was the

liquidus phase up to 2.4 GPa; orthopyroxene was the liquidus phase above 2.4 GPa. Phlogopite and rutile crystallized close to the liquidus in experiments above 1.6 GPa. They concluded that the wolgidite magma could come from a source containing phlogopite, rutile, olivine and orthopyroxene. Foley (1993) conducted liquidus experiments from 4.5 to 5.5 GPa on an olivine lamproite from the West Kimberly region, in the presence of reduced fluids. He found that olivine was the liquidus phase up to 5.0 GPa, above which orthopyroxene and phlogopite co-crystallize along the liquidus. Foley concluded that these rocks were derived from partial melting of a phlogopite harzburgite.

However, features of our minette whole-rock composition, such as the high  $\text{TiO}_2$  (1.02 wt%), CaO (8.02 wt%) and  $\text{K}_2\text{O}$  (4.44 wt%), are most reasonably explained by melting of a source containing phlogopite and clinopyroxene. This inference is also consistent with the trace element concentrations, such as high Rb (146 ppm), Cs (1.2 ppm), Nb (12 ppm) and Ba (3239 ppm) indicating phlogopite was in the source, whereas high Sr (993 ppm) could indicate clinopyroxene was in the source (Buhlmann et al. 2000). To reconcile this with the observed liquidus mineralogy, we turn to another model.

Navon and Stolper (1987) suggested the upper mantle may act as a chromatographic column. They noted that a magma rising through wall-rock is most likely in disequilibrium with it, thus reactions between the magma and wall-rock are bound to occur. Therefore, when the "primary minette magma" rises through the upper mantle, the melt would re-equilibrate with the wall-rock lithology. Foley (1992b) further refined this idea and proposed a mechanism for vein plus wall-rock assimilation and re-equilibration with potassic magmas: the dissolution of wall-rock minerals. In Foley's model, melts derived from partial melting of veins dissolve the wall-rock minerals to establish equilibrium between the melt and the wall-rock. Foley noted that

olivine and/or orthopyroxene dissolves preferentially through this method as these are the minerals farthest from equilibrium with strongly alkaline magmas. The composition of the liquidus olivine and orthopyroxene at the multiple saturation point falls within the accepted range of mantle values (noteably the Mg#), and therefore it is reasonable to conclude that our "primary minette magma" re-equilibrated with mantle harzburgite during its ascent.

Our results demonstrate that this minette was last in equilibrium with a residue containing orthopyroxene and olivine at ~1.77 GPa (~58 km) at 1350°C. At a depth of ~58 km (which is below the modern-day crustal thickness; Lemieux et al. 2000; Gorman et al. 2002), the temperature of the surrounding wall-rock in the craton is ~600-700°C, based on a 40 mW m<sup>-2</sup> geotherm (Chapman and Pollack 1977). We argue that it is unlikely that the vein-imbedded wall-rock at ~58 km rose by ~600°C to induce partial melting, as the location of the Milk River minettes (ca. 50 Ma; Buhlmann et al. 2000) do not correlate with any known mantle plume tracks (Heaman et al. 2003) or sites of mantle upwelling (Torsvik et al. 2010). Instead, we believe that partial melting likely occurred at the base of the Wyoming craton (~150-220 km; Gorman et al. 2002; Yuan and Romanowicz 2010; Schmandt and Humphreys 2010). At greater depths, the solidus of a mica-clinopyroxenite vein assemblage is closer to the normal cratonic geotherm (~1400°C at 200 km), and therefore minimal heating is required to induce partial melting (Foley et al. 1999). It is generally expected that the presence of xenoliths in volatile- and alkali-rich magmas (such as minettes) supports the hypothesis that they were transported to the surface rapidly through fractures in the lithosphere (Sparks et al. 1977; Spera 1984). A consequence of rapid ascent rates, coupled with slow cooling rates, is that the "primary minette magma" would preserve the high (near-liquidus) temperatures of melting (Sparks et al. 1977; Spera 1984).

Therefore, we propose that the source region for these minettes consists mainly of a harzburgite wall-rock lithology imbedded with metasomatic veins of mica and clinopyroxene located at or near the base of the Wyoming craton. Either some thermal perturbation (e.g. friction from the shallow-angled Farallon plate; Humphreys 2009) or the introduction of hydrous fluids (possibly derived from the Farallon plate; O'Brien et al 1991, 1995; Currie and Beaumont 2011), induced partial melting ca. 50 Ma (Buhlmann et al. 2000). Melting occurred in the veins because of their high abundance of volatiles, and therefore lower solidus temperature. Then, the "primary minette magma" ascends through the lithospheric mantle rapidly, preserving a near-liquidus temperature, where it stalled at ~58 km. Because the "primary minette magma" is in disequilibrium with its surroundings, dissolution of orthopyroxene and olivine into the melt occurs. This process brought the minette melt into equilibrium with olivine and orthopyroxene and imparted a strong refractory harzburgite signal onto the minette.

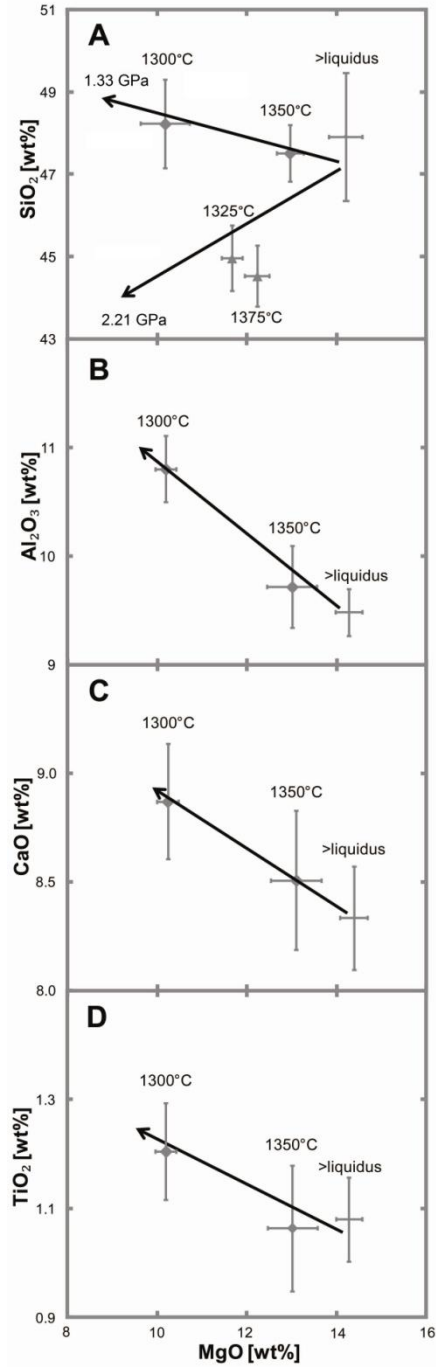

## **2.6. Conclusions:**

The liquidus mineralogy of this minette composition consists of olivine and orthopyroxene. Multiple saturation of these minerals was found at ~1.77 GPa and ~1350°C. This result is inconsistent with many previous studies on similar rocks. Based on the composition of the minette magma (e.g. high CaO and K<sub>2</sub>O contents), we propose that these minettes were likely derived from a source containing mica and clinopyroxene, and later re-equilibrated with a harzburgite. The unusually high temperature of multiple saturation cannot be explained by simple melting models. We argue that partial melting likely occurred at the base of the Wyoming craton (located ~150-220 km depth), where either a slight thermal perturbation or the introduction of hydrous fluids could easily induce partial melting. Rapid ascent rates (coupled with slow cooling rates) of the "primary minette magma" preserved the high temperature of

fusion. We interpret the pressure of multiple saturation (~58 km) as the depth where the "primary minette magma" stalled in the subsurface, where it experienced very near to total re-equilibration with a surrounding mantle harzburgite wall-rock. Therefore, we conclude that the minette studied is not primary, but may still be parental to the other minettes found in the same location.

## **Chapter 3: Melting phase relations of a mica-clinopyroxenite from the Milk River area, southern Alberta, Canada**

### **3.1. Introduction:**

In southern Alberta, Canada, minettes crop out as dykes near the Milk River. Carried in these dykes are coarse-grained xenoliths composed of clinopyroxene, phlogopite, and apatite. Both the minettes and xenoliths were studied by Buhlmann et al. (2000). Based on the experimental study of Esperanca and Holloway (1987) and an extrapolation of phase boundaries inferred by Wallace and Carmichael (1989), Buhlmann et al. postulated that the minettes formed by partial melting of a source containing clinopyroxene, phlogopite and possibly olivine, at pressures  $\geq 1.7$  GPa. Funk and Luth (ms. submitted) conducted liquidus experiments on the most primitive minette from Buhlmann et al.'s study, and found that olivine and orthopyroxene coexisted with a liquid at 1.77 GPa and 1350°C. Neither clinopyroxene nor phlogopite were found to be liquidus phases, so the multiple saturation point found by Funk and Luth is not consistent with Buhlmann et al.'s hypothesis. Funk and Luth suggested that the primary minette magma re-equilibrated with harzburgite during ascent rather than harzburgite representing the source region, given that a harzburgite would lack sufficient K and Ca to be a realistic lithology to form the minette by partial melting.

The purposes of investigating the melting behaviour of the mica-clinopyroxenite xenolith were: first, to ascertain the phase relations of this mica-clinopyroxenite; second, to characterize the compositions of the hydrous, mafic, alkali-rich melts produced; and third, to assess the viability of such lithologies as sources for the minettes found at Milk River, and similar mafic alkali-rich magmas.

### 3.2. Starting Material:

Several mica-clinopyroxenite xenoliths were analyzed by Buhlmann et al. (2000). To select one to study for our experiments, we chose a xenolith with pyroxene Mg#’s (molar  $\text{Mg}/(\text{Mg} + \text{Fe}^*)$ ) that overlap those thought to be realistic for the subcontinental lithospheric mantle. This criterion led us to select the xenolith with the highest MgO content, which should have the highest solidus temperatures, and hence provide one endmember of possible behaviours. Based on this, sample DAT4-5 was selected. For our experiments, we used an aliquot of the natural rock powder prepared by Buhlmann for his original study (major-element composition is given in **Table 3.1**).

### 3.3. Methodology:

Approximately 3 mg of powdered sample was packed tightly in a graphite capsule with dimensions ~4 mm tall, ~2.65 mm outer diameter (OD), and ~1.2 mm inner diameter (ID). The graphite capsule was loaded into a 3 mm OD Pt capsule. No additional water was added to the sample. The capsule was placed in a 120°C oven overnight to dry prior to sealing by arc-welding. The capsules were run vertically in 12.7 mm talc-pyrex assemblies in solid-media, piston-cylinder apparatus (Boyd and England 1960) at the C.M. Scarfe Laboratory of Experimental Petrology, University of Alberta. The pressures were calibrated on the quartz-coesite transition at 1000°C, and on the jadeite-albite-quartz transition at 600 and 1000°C. It was determined that a -13% correction was required to correct the nominal pressures. Temperatures were monitored with W95Re5-W74Re26 thermocouples with no corrections made for the effect of pressure on the emf of the thermocouple.

Experiments were run at 1.33, 1.77, and 2.21 GPa, at temperatures between 900 and 1350°C (**Table 3.2**). Each experiment was brought up to ~80% pressure, heated to the desired temperature, and then the pressure was increased to the appropriate value. The duration of experiments was 1-6 days, depending on temperature. Due to the difficulty of establishing equilibrium at 1.33 GPa and 1200°C, it was run in a two-step approach. The sample was heated to 1600°C for 5 hrs, then brought down at a rate of ~400°C/min to 1200°C and allowed to equilibrate for several days.

The compositions of the run products were measured with the JEOL 8900R electron microprobe at the Department of Earth and Atmospheric Sciences, University of Alberta. All experiments were analyzed at a 15 kV accelerating voltage. For mineral grains, a beam current of 15 nA was used with a beam diameter of 1-3 µm. For glasses, the beam current was reduced to 10 nA and the beam diameter widened to 10 µm to lessen damage on the hydrous glasses. To lessen the effect of alkali migration during glass analyses, potassium and sodium were analysed first. For all analyses, counting times were 20 seconds on peak, and 10 seconds on the background. Natural mineral standards were used (**Table 3.3**). The compositions of the phases were used to calculate the modal percentages by mass balance (**Table 3.2**).

### **3.4. Results:**

#### **3.4.1. Phase Relationships and Melting Reactions:**

The sub-solidus mineralogy is clinopyroxene, phlogopite and trace amounts of apatite (**Figure 3.1**). It was difficult to determine the location of the solidus precisely because small volumes of melt were difficult to observe in back-scatter electron images on the electron microprobe. With increasing temperature, however, olivine appears and apatite disappears, and

no other phosphorous-bearing mineral is observed. We infer this disappearance marks the position of the solidus, with a solidus reaction of:

Apatite present in trace amounts would be consumed rapidly in melting reaction (1), allowing us to define the location of the solidus by the disappearance of apatite. The solidus is relatively steep in PT-space (**Figure 3.1**). At 1.33 GPa, the solidus is bracketed between 1050°C and 1100°C, and it is bracketed at both 1.77 and 2.21 GPa between 1100°C and 1150°C. Just above the inferred solidus, a few experiments contain only clinopyroxene and phlogopite. We were unable to analyze or image the melt, and did not observe olivine in these capsules. At higher temperatures, olivine and liquid were found to coexist with clinopyroxene and phlogopite, but we were unable to determine the composition of the melt in these experiments. Olivine has been observed as the product of melting phlogopite (Yoder and Kushiro 1969) and phlogopite + diopside (Modreski and Boettcher 1973). Therefore, the observed olivine-in reaction boundary may be taken as an upper bound of the solidus.

Phlogopite disappears by ~50°C above the solidus at 1.33 GPa, and ~100°C above the solidus at 2.21 GPa by reaction (1), leaving only clinopyroxene, olivine and liquid. The modal abundances of both olivine and clinopyroxene decreases with increasing temperature (**Table 3.2**). Therefore, once phlogopite disappears, the melting reaction becomes:

### 3.4.2. Melt Composition:

Liquids quenched to glass with little or no quench phlogopite present. Where quench phlogopite is present, it is restricted to needle-like crystals at mineral-melt interfaces. Low-degree partial melts (<30%) were challenging because they do not form melt pockets large enough to analyze with the electron microprobe. Therefore, we have few constraints on the composition of our near-solidus melts.

Where the melt pockets were of sufficient size to analyze, the coexisting mineral assemblage is clinopyroxene and olivine. The melt compositions are silica-undersaturated, mafic, alkali- and volatile-rich (**Table 3.4**). Glasses are metaluminous (molar  $\text{Al}_2\text{O}_3 < (\text{Na}_2\text{O} + \text{K}_2\text{O} + \text{CaO})$ ) and near the metaluminous-peralkaline boundary ( $\text{Al}_2\text{O}_3 \approx (\text{Na}_2\text{O} + \text{K}_2\text{O})$ ). The Mg# of our glasses range from 68.0 to 81.6 (**Table 3.4**). Fluorine and chlorine concentrations are between 0.67-1.08 wt% and ~0.04 wt%, respectively (**Table 3.4**). Based on the low totals, we infer that our glasses have ~4-9 wt% dissolved  $\text{H}_2\text{O}$  (**Table 3.4**).

Liquids in equilibrium with clinopyroxene and olivine show systematic trends with respect to temperature (**Table 3.4** and **Figures 3.2a-h**) and pressure (**Table 3.4**). With increasing temperature,  $\text{SiO}_2$ , MgO and CaO concentrations increase in the melt (**Table 3.4** and **Figures 3.2a, b**). Elements found almost exclusively in phlogopite and apatite, such as  $\text{TiO}_2$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{Na}_2\text{O}$ ,  $\text{K}_2\text{O}$ ,  $\text{P}_2\text{O}_5$  and F, decrease with increasing temperature due to dilution (**Figures 3.2c-h**). With increasing pressure, the concentrations of  $\text{SiO}_2$ , MgO and CaO decrease in the melt, whereas the concentrations of the other oxides increase (**Table 3.4**).

At lower temperatures, the scatter in the glass compositions tend to be larger than those at higher temperatures. This scatter may result from either compositional heterogeneities in the

glass itself, or overlap of the beam with adjacent minerals, which would be more problematic at low melt fractions.

### **3.4.3. Clinopyroxene Composition:**

Clinopyroxene grains are typically subhedral to anhedral, and are  $\sim 30\ \mu\text{m}$  in diameter in sub- and near-solidus experiments, but are  $>100\ \mu\text{m}$  in experiments with large volumes of melt. The modal abundance of clinopyroxene is constant below the solidus ( $\sim 60\%$ ), and progressively decreases with increasing temperature above the solidus.

With increasing temperature, Mg content in clinopyroxene increases and Ca decreases (**Table 3.5**). We saw no significant pressure dependence on the Mg-Ca exchange reaction within the investigated pressure range. Mg# increases with increasing temperature, and decreases with increasing pressure. Some Ti and Al are incorporated into the clinopyroxene crystal structure (**Table 3.5**). At 1.33 GPa, we observed that Ti and Al contents remain constant below the solidus, but once phlogopite disappears, the concentrations peak and then progressively decrease with increasing temperature (**Table 3.5**). We interpret this trend to result from dissolution of phlogopite into melt, which would increase the  $\text{TiO}_2$  and  $\text{Al}_2\text{O}_3$  activity in the melt, thereby increasing Ti and Al in clinopyroxene. As melting continues beyond phlogopite stability, these elements become more dilute in the liquid (**Table 3.4**), thereby decreasing their activity in the melt. At temperatures above the phlogopite stability field,  $\text{TiO}_2$  and  $\text{Al}_2\text{O}_3$  become less compatible in clinopyroxene with increasing temperature (**Figures 3.3a, b**). This effect is subdued at higher pressures. The concentrations of MnO and  $\text{Na}_2\text{O}$  in clinopyroxene decrease as temperature increases, and increase as pressure increases (**Table 3.5**). At lower temperatures,

MnO is compatible in clinopyroxene, and progressively becomes less compatible with increasing temperature (**Figure 3.3c**).

#### **3.4.4. Phlogopite Composition:**

Phlogopite crystals are typically elongate and are ~100  $\mu\text{m}$  in length. In sub-solidus experiments, the modal abundance of phlogopite remains constant (~40%), but decreases sharply with increasing temperature above the solidus.

Relative to the endmember phlogopite chemical formula  $[\text{K}_2\text{Mg}_6(\text{Al}_2\text{Si}_6\text{O}_{20})(\text{OH})_4]$ , these micas are silica-deficient and alumina-rich, with Si between ~5.73-5.83 and Al between ~2.25-2.52 cations per 22 oxygens (**Table 3.6**). The Mg# of phlogopite increases with temperature, and decreases with increasing pressure. A small amount of sodium substitutes for potassium in the interlayer cation sites, but there are vacancies ( $\text{Na} + \text{K} < 2$ ; **Table 3.6**). With increasing temperature, sodium content decreases, consistent with sodium behaving incompatibly in phlogopite (Carman 1974). At temperatures above the solidus, the concentrations of Ti and F in phlogopite are higher than those in sub-solidus experiments (**Table 3.6**). This observation is consistent with many studies that have shown that F (Foley et al. 1986a; Edgar and Charbonneau 1991; Vukadinovic and Edgar 1993; Edgar and Pizzolato 1995; Melzer and Foley 2000) and Ti (Tronnes et al. 1985; Patino Douce 1993) increase the stability of phlogopite to higher temperatures. At higher pressures, the increase in Ti in phlogopite is subdued. Chlorine is present in trace amounts in sub-solidus phlogopite, but drops below the detection limits above the solidus (**Table 3.6**).

### 3.4.5. Apatite Composition:

Apatite appears only in sub-solidus experiments. They are generally angular and anhedral. The apatite grains are small, typically  $<10\ \mu\text{m}$  in length. The modal abundances are low, usually  $\sim 1\%$  of the sample.

The apatite in our system is fluorine-rich ( $\sim 1.70\ \text{wt\% F}$ ; **Table 3.7**). Small concentrations of chlorine were observed as well. Relative to the idealized apatite chemical formula  $[\text{Ca}_5\text{P}_3\text{O}_{12}(\text{OH}, \text{Cl}, \text{F})]$  our apatites are deficient in Ca ( $\sim 4.7$ ) and P ( $\sim 2.85$ ) (**Table 3.7**). All of our apatites contain measureable amounts of  $\text{SiO}_2$  ( $\sim 0.4\ \text{wt\%}$ ),  $\text{FeO}^*$  ( $\sim 0.5\ \text{wt\%}$ ) and  $\text{MgO}$  ( $\sim 0.5\ \text{wt\%}$ ) (**Table 3.7**). It is possible that Fe, Mn, Mg, Na or K could substitute for Ca, whereas P is exchanged for Si. However, due to the difficulty of analyzing small grains, the presence of these oxides may be the result of overlap of the beam with adjacent minerals.

### 3.4.6. Olivine Composition:

Olivine forms during melting, and is not present in sub-solidus experiments. Olivine grains are generally rounded and are anhedral to subhedral. At lower temperatures, olivine grains are only  $\sim 10\ \mu\text{m}$  in diameter, increasing to  $>200\ \mu\text{m}$  in high-temperature experiments. The modal abundance of olivine initially increases with increasing temperature (maximum olivine modal percentage  $\sim 17\%$ ), but it decreases with increasing temperature after phlogopite disappears.

Olivine is stoichiometric, and does not contain measureable amounts of Ti, Al, Na, or K (**Table 3.8**). The Mg# of olivine increases with increasing temperature and decreases with increasing pressure. The CaO content in olivine is consistently between  $0.3\text{-}0.5\ \text{wt\%}$ , and has no obvious temperature or pressure dependence (**Table 3.8**). Manganese behaves compatibly at

lower temperatures, but becomes less compatible with increasing temperature (**Figure 3.4**), as found previously by Snyder and Carmichael (1992).

### 3.4.7. Mineral-liquid Equilibria:

Determining if our experiments were in equilibrium is crucial for the interpretation of our results. Roeder and Emslie (1970) found that the exchange coefficient for Fe-Mg between olivine and liquid,  $K_D(\text{Fe-Mg})^{\text{ol-liq}}$ , is  $0.30 \pm 0.03$ , independent of melt composition and temperature. Subsequent studies on alkali-rich magmas found that the olivine-liquid exchange coefficient depends on the liquid composition (Sack et al. 1987; Gee and Sack 1988). Gee and Sack (1988) found that  $K_D(\text{Fe-Mg})^{\text{ol-liq}}$  decreases with decreasing silica and increasing alkali contents. Tholeiitic to alkali basalts have exchange coefficients ranging from 0.33 to 0.27; at lower silica activities, olivine melilitites to nephelinites have exchange coefficients ranging from 0.25 to 0.17.

An analogous mineral-melt Fe-Mg exchange coefficient can be calculated for clinopyroxene. Putirka (2008) noted that there is a shortcoming in using only Fe-Mg exchange reactions to evaluate equilibrium because they do not measure the extent of Na-Al and Ca-Na exchange. However, Putirka noted that deviations in calculated exchange coefficients are correlated to differences in diopside-hedenbergite, so a simple Fe-Mg exchange may be sufficient to test for equilibrium. A  $K_D(\text{Fe-Mg})^{\text{cpx-liq}}$  of  $0.28 \pm 0.08$  was found to indicate equilibrium (Putirka 2008).

The mineral-liquid Fe-Mg exchange coefficients (**Table 3.9**) calculated for our experiments are in the same range as those reported by Roeder and Emslie (1970), Gee and Sack

(1988) and Putirka (2008), which suggests that our experiments achieved Fe-Mg exchange equilibrium. This conclusion is consistent with the observed homogeneity of the mineral grains.

#### **3.4.8. Geothermobarometry:**

As a second independent test for equilibrium, temperatures and pressures were calculated using a range of glass-only and mineral-liquid geothermometers and a mineral-liquid geobarometer. Putirka et al. (2007) and Putirka (2008) have a detailed explanation of the empirical fitting, statistics, sample calculations, and review of the glass-only and mineral-liquid geothermometers and geobarometers used in this study.

The glass-only geothermometer, equation 15 from Putirka (2008), was used to calculate temperatures of experiments with appreciable quantities of liquid present. Equation 15 is applicable for any liquid saturated with olivine. The range of pressures, temperatures, and compositions of experimental glasses used in the calibration of this expression makes it appropriate for our system. The uncertainty for temperatures calculated with equation 15 is  $\pm 60^{\circ}\text{C}$  (Putirka 2008). Within the uncertainty, equation 15 reproduces temperatures of our experiments accurately (**Table 3.10**).

In the same experiments with large volumes of glass, the olivine-liquid thermometer of Putirka et al. (2007; their equations 2 and 4), was also used to calculate temperatures. Putirka et al. reported an uncertainty of  $\pm 52^{\circ}\text{C}$  for their expression. When these equations are coupled, the calculated temperatures for our mafic alkali-rich system are systematically lower by  $\sim 20 - 40^{\circ}\text{C}$  than the measured temperatures of the experiments (**Table 3.10**). They do agree, however, within the stated uncertainty.

Along with the above thermometers, a clinopyroxene-liquid geothermometer and geobarometer were utilized (**Table 3.10**). Putirka et al. (1996), Putirka (1999) and Putirka et al. (2003) developed several clinopyroxene-liquid barometers and thermometers, using a variety of experimental data from several pressures and temperatures to calibrate their equations. The geobarometer, equation 31 from Putirka (2008), was chosen because the equation was empirically fitted with data excluding 1 atm and  $P \geq 4.0$  GPa experiments, but still accounted for the presence of alkalis and water in the glass. The geothermometer, equation 33 from Putirka (2008), was chosen because the equation accounts for the effect of water and alkalis in the melt on temperature, within an uncertainty of  $\pm 60^\circ\text{C}$ . Within the geobarometer's uncertainty of  $\pm 0.29$  GPa (Putirka 2008), this equation reproduced our experimental run pressures well (**Table 3.10**). The calculated temperatures for our experiments fell within the range of uncertainty of equation 33.

The results of these geothermometers and geobarometers, along with mineral-liquid Fe-Mg exchange coefficients, and the observed homogeneity of the mineral grains, are consistent with equilibrium being achieved in our system.

#### **3.4.9. Iron Loss:**

The loss of iron by alloying with the outer Pt capsule was a concern for our experiments. To mitigate this problem, we enclosed our sample in a graphite capsule, as has been done in previous experimental studies. Nevertheless, we detected iron when analysing the Pt capsule on the electron microprobe. Assessing the exact magnitude of iron loss is difficult. Using the modal abundances for each phase (given in **Table 3.2**), assuming all Fe-bearing phases were analysed, we reconstructed the bulk composition of our experiments. A comparison of the reconstructed

composition with the original starting material yields an estimate on the percentage of iron loss (general expression given in **Table 3.11**). Using the same methodology, we also estimated the percentage of iron loss in other experimental papers (Barton and Hamilton 1979; Lloyd et al. 1985; Esperanca and Holloway 1987; Sweeney et al. 1993; Richter and Carmichael 1996; Holbig and Grove 2008) with similar compositions and capsule designs. We obtain a range for iron loss for our experiments that is similar to those estimated by the previous authors (~1-20%), lending credence to our calculations.

The calculations show that our experiments had ~7-25% iron loss (**Table 3.11**). Sweeney et al. (1993) argued that ~14-18% iron loss is not significant enough to affect phase relations or the relative appearance of phases. However, we have three experiments with > 20% iron loss. To see how much the phase boundaries would shift with 25% iron loss, we used pMELTS (Ghiorso et al. 2002) to calculate ideal phase diagrams. Unfortunately, pMELTS was unable to calculate the phase diagram for DAT4-5, likely due to the presence of CO<sub>2</sub>, F and Cl in our system. Instead, we calculated phase diagrams for a mantle peridotite (MM3) and mantle pyroxenite (G2) (**Table 3.12**). These compositions were chosen because they are well characterized in pMELTS, and are mineralogically similar to our system. The calculations from pMELTS show that a 25% loss in FeO shifts phase boundaries up by ~20-30°C in MM3 and <10°C in G2. However, the relative order of appearance of phases remains unchanged. Assuming that we can extrapolate to our composition, a phase boundary shift of 20-30°C is less than the 50°C spacing of our experiments, and is unlikely to significantly change our phase diagram.

### **3.5. Discussion:**

#### **3.5.1. Milk River alkali magmatism:**

Buhlmann et al. (2000) hypothesized that the minettes in southern Alberta were derived from partial melting of a source containing phlogopite and clinopyroxene at pressures  $\geq 1.7$  GPa. This is consistent with many previous studies, both experimental (Edgar et al. 1976, 1980; Barton and Hamilton 1978, 1979; Edgar and Condcliffe 1978; Nicholls and Whitford 1983; Lloyd et al. 1985; Esperanca and Holloway 1987; Mitchell 1995; Righter and Carmichael 1996; Sato 1997; Elkins-Tanton and Grove 2003) and geochemical (Lloyd and Bailey 1975; Van Kooten 1980; Wallace and Carmichael 1989; Conticelli and Peccerillo 1992; Foley 1992a, 1992b; Macdonald et al. 1992; Carlier and Lorand 1997; Carlson and Nowell 2001), on related mafic alkali-rich rocks. Buhlmann et al. (2000) predicted that if liquidus experiments were performed on the most primitive minette, a multiple saturation point where clinopyroxene, phlogopite and possibly olivine would co-crystallize at pressures  $\geq 1.7$  GPa.

Funk and Luth (ms. submitted) conducted liquidus experiments on the most primitive minette from Milk River (RAB90 Au24-1; see Buhlmann et al. 2000 for composition), and found a multiple saturation point at 1.77 GPa and 1350°C, where olivine and orthopyroxene coexisted with a liquid. Neither clinopyroxene nor phlogopite were liquidus phases. This multiple saturation point is inconsistent with Buhlmann et al.'s hypothesis. Funk and Luth argued that the high concentrations of CaO and K<sub>2</sub>O of the minette is still best explained by the partial melting of a mica-clinopyroxenite. Based on the work of Navon and Stolper (1987) and Foley (1992b), they proposed that the primary minette magma had re-equilibrated with a harzburgite wall-rock

during ascent. The dissolution of wall-rock minerals, proposed by Foley (1992b), is believed to be the dominant mechanism for re-equilibration for the Milk River minettes.

To determine the mineralogy of the source region of the RAB90 Au24-1 minette and to test the wall-rock re-equilibration hypothesis of Funk and Luth (ms. submitted), we compared the compositions of our melts with those of the Milk River minettes. Based on the multiple saturation point found by Funk and Luth, we restricted the compositions of melts to those  $\geq 1.77$  GPa. The lowest-degree partial melts from 1.77 GPa (52X;  $\sim 37.6\%$  at  $1250^\circ\text{C}$ ) and 2.21 GPa (49X;  $\sim 37.1\%$  at  $1300^\circ\text{C}$ ) were chosen as "representative primary melts" (**Table 3.4**). We plotted our representative melts along with the RAB90 Au24-1 minette and populations of mantle orthopyroxene and olivine (representative plots for SPF52X melts shown; **Figures 3.5a-f**).

Because our primary melts are in equilibrium with olivine, we would not expect to see a reaction trend toward the mantle olivine population. From Funk and Luth (ms. submitted), orthopyroxene is the other phase that could plausibly interact with our primary melt. Therefore, we explored a binary mixing model to our system (shown as a black arrow in **Figures 3.5a-f**), assuming that the primary (experimental) liquid is only dissolving orthopyroxene. Within the uncertainty of the endmember compositions, we observed that the RAB90 Au24-1 minette lies on a linear trajectory between the 52X melt and mantle orthopyroxene (**Figures 3.5a-f**). Similar results were found for the 49X melt. Because the minette lies between our primary (experimental) melt and mantle orthopyroxene, the composition of the minette can be explained with dissolution of orthopyroxene into the original melt, consistent with the wall-rock dissolution model proposed by Foley (1992b). The  $\text{Na}_2\text{O}$  and  $\text{P}_2\text{O}_5$  content in our primary melts is too low (0.76 wt% and 0.66 wt%, respectively, for SPF52X) to explain their concentrations in the minette (1.3 wt% and 1.02 wt%, respectively; Buhlmann et al. 2000). This compositional

discrepancy may be a result of either the high melt fraction (~37%) of the representative experimental melts, which would dilute these oxides, or the low concentrations of these oxides in the DAT4-5 starting material (e.g. low modal abundance of apatite; low Na<sub>2</sub>O concentrations in phlogopite and clinopyroxene).

Pilet et al. (2008) investigated the effect of wall-rock mineral dissolution on the composition of hornblende-derived partial melts at 1.5 GPa. They conducted sandwich experiments between 1225 and 1325°C, where the hornblende vein was packed between a moderately depleted peridotite. At temperatures below the peridotite solidus, they observed that the dissolution of orthopyroxene was the main reaction between the partial melt and the surrounding peridotite, consistent with Foley (1992b) and our model above. Glasses from the sandwich experiments increased in SiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub> and MgO, and decreased in TiO<sub>2</sub>, FeO\*, CaO, Na<sub>2</sub>O and K<sub>2</sub>O as dissolution progressed (Pilet et al. 2008). Albeit a different compositional system, Pilet et al.'s observations are consistent with our analysis for the Milk River minettes (**Figures 3.5a-f**).

We conclude that, within the constraints of Buhlmann et al. (2000) and Funk and Luth (ms. submitted), the RAB90 Au24-1 minette could be derived from a mica-clinopyroxenite source at pressures  $\geq 1.7$  GPa, but re-equilibrated with mantle orthopyroxene via dissolution.

### **3.5.2. Global alkali magmatism:**

The melting of vein assemblages has been invoked to explain the origin of many alkaline rocks (e.g. Italy: Conticelli et al. 2009; Boari et al. 2009; Nikogosian and van Bergen 2010; Tibet: Jiang et al. 2006). Unfortunately, there have been few experimental studies on the melting

behaviour of realistic vein compositions. In the FeO\*- and P<sub>2</sub>O<sub>5</sub>-free KCMAS-H<sub>2</sub>O system, Modreski and Boettcher (1973) observed the peritectic melting reaction:

at ~1175°C, ~1200°C and ~1275°C at 1.5 GPa, 2.0 GPa and 2.5 GPa, respectively. Their melting reaction is similar to the solidus reaction observed in our study. Compared to our system, the addition of iron and sodium in clinopyroxene and phlogopite should shift melting reaction (3) to lower temperatures, whereas fluorine and titanium in phlogopite may shift it to higher temperatures. Modreski and Boettcher (1973) also found that phlogopite, diopside, forsterite and liquid coexisted for ~75°C above the solidus at 1.5 GPa, similar to our findings.

Lloyd et al. (1985) performed melting experiments on a natural phlogopite clinopyroxenite nodule from south-west Uganda, at 2.0 and 3.0 GPa and between 1175-1300°C. The composition of the glasses are similar to K-rich lavas from the region, and they argued that these magmas were derived from source rocks similar to the phlogopite clinopyroxenite nodule. The glasses produced in our experiments are generally similar to those analyzed by Lloyd et al. (see that paper for details), but differ greatly (> 50% difference in compositions) in TiO<sub>2</sub>, FeO\*, Na<sub>2</sub>O and P<sub>2</sub>O<sub>5</sub>. These deviations can be explained by differences in the accessory minerals (4% titanite, 6.5% magnetite, 0.5% jadeite in Lloyd et al.'s starting material), mineral chemistry, and modal abundances for each phase (2% apatite in Lloyd et al.'s study).

Sweeney et al. (1993) conducted melting experiments on a natural mica-amphibole-rutile-ilmenite-diopside (MARID) at 2.0-3.5 GPa and between 800 and 1450°C. They found that the "dry" (no additional water added to bulk composition) solidus was greater than a cratonic mantle geotherm (40 mW m<sup>-2</sup>; Chapman and Pollack 1977), and the addition of 10 wt% H<sub>2</sub>O

depressed the solidus by  $\sim 250^{\circ}\text{C}$ . Sweeney et al. noted that it was unclear if water saturation was achieved, and the addition of more water could depress the solidus further. We found that the solidus for DAT4-5 is above a normal cratonic geotherm, and therefore, our mica-clinopyroxenite composition would be stable in cratonic mantle in the investigated pressure range unless the surrounding wall-rocks were heated (e.g. mantle plume) or hydrous fluids were introduced. Because our system does not contain amphibole, direct comparison of our experiments and those conducted by Sweeney et al. is difficult. The addition of water to DAT4-5 would be required in future experiments to quantify the depression of the solidus for our mica-clinopyroxenite.

Foley et al. (1999) investigated the melting behaviour of various model clinopyroxene + phlogopite + K-richterite vein assemblages at 1.5 and 5.0 GPa. They found that the addition of K-richterite to the clinopyroxene-mica assemblage reduced the solidus temperatures by  $\sim 50^{\circ}\text{C}$ , and that amphibole was the main factor in controlling the composition of the melt. Foley et al. also found that the solidus for their vein assemblage was steep relative to the normal cratonic geotherm, and that it approaches the geotherm with increasing pressure. They argued that at pressures  $> 5.0$  GPa, minimal heating would be required to induce partial melting. This conclusion likely applies to our experiments as well. The inferred solidus for DAT4-5 is steep and intersects at  $40 \text{ mW m}^{-2}$  geotherm at  $\sim 7.5$  GPa (**Figure 3.6**). To test this, higher pressure experiments would need to be performed for the purpose of comparing the solidus of DAT4-5 to a cratonic geotherm.

The high-degree partial melts produced in our study are similar to some mafic alkali-rich magmas studied by other authors (Carmichael 1967; Barton and Hamilton 1978, 1979; Holbig and Grove 2008; Prelevic et al. 2008) (**Table 3.13**). Carmichael (1967) characterized several

volcanic rocks from the Leucite Hills, Wyoming, one of which was a madupitic lamproite (**Table 3.13**). Later, Barton and Hamilton (1978, 1979) conducted a series of high-pressure experiments on this madupitic lamproite. They found that the dominant liquidus phases were clinopyroxene and olivine between 0.5-0.7 GPa, solely clinopyroxene between 0.7-1.25 GPa, clinopyroxene and spinel between 1.25-1.75 GPa, and solely clinopyroxene >1.75 GPa. Phlogopite appears ~50°C below the liquidus. Barton and Hamilton (1979) proposed that the madupitic magmas could be produced by the partial melting of an olivine-mica-pyroxenite or a mica-pyroxenite. Comparing our glasses with the madupitic lamproite, we find similarities (**Table 3.13**). Of the major and minor oxides, TiO<sub>2</sub> and P<sub>2</sub>O<sub>5</sub> are the only oxides that are outside the given range of concentrations. This is likely a reflection of a higher titanium content in phlogopite and a slightly higher modal percentage of apatite in the source region. Therefore, we concur with Barton and Hamilton that a mica-clinopyroxenite (similar to DAT4-5) could be the protolith for the madupitic lamproites seen at Leucite Hills, Wyoming.

### **3.6. Summary and Conclusions:**

Melting experiments were conducted on the most Mg-rich mica-clinopyroxenite xenolith from southern Alberta, Canada, near the Milk River area. These xenoliths were brought up in minette dykes (Buhlmann et al. 2000). Buhlmann et al. hypothesized that the minettes were derived from a source containing clinopyroxene + phlogopite ± olivine at pressures ≥ 1.7 GPa. Funk and Luth (ms. submitted) conducted liquidus experiments on the most primitive minette and found a multiple saturation point where olivine and orthopyroxene coexisted with a liquid at 1.77 GPa and 1350°C. They suggested that the primary minette magma may have been derived from a mica-clinopyroxenite source, and then re-equilibrated with a harzburgite during ascent. The goals of this study were to determine the phase relations of a mica-clinopyroxenite,

characterize the melt compositions, and test the hypotheses proposed by Buhlmann et al. (2000) and Funk and Luth (ms. submitted).

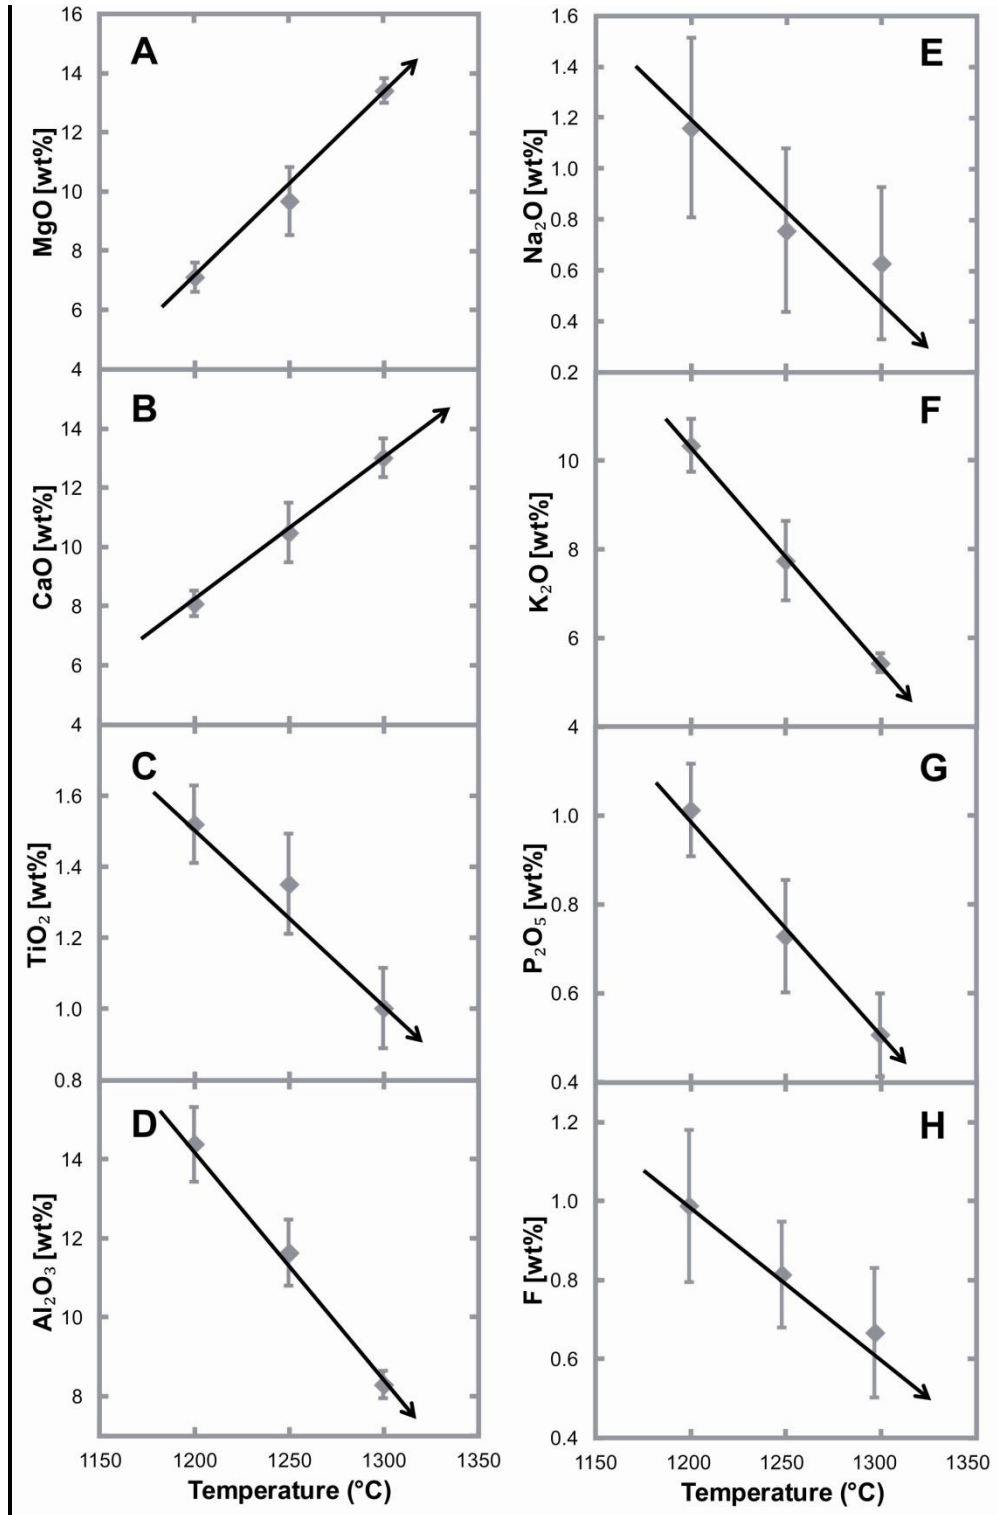

The solidus for DAT4-5 was found to be steep, and located at temperatures above a normal cratonic geotherm. Therefore, mica-clinopyroxenite lithologies in cratons are stable in the investigated pressure range, and melting must be induced by raising the temperature of the surrounding rocks, and/or by introducing hydrous fluids in order to lower the solidus. Because the solidus is steep, melting could also occur at greater depths than the pressures investigated in this study. Comparing our study with the similar study conducted by Lloyd et al. (1985), we found that the presence of accessory minerals in the starting material can change the compositional evolution of the melts with respect to either temperature or pressure. The composition of the glasses analyzed in our experiments are similar to madupitic lamproite magmas from the Leucite Hills, Wyoming craton, studied by Carmichael (1967), and Barton and Hamilton (1978, 1979). Barton and Hamilton proposed that the madupite magmas could have been derived from a source containing phlogopite + pyroxene  $\pm$  olivine. The results of our study are consistent with Barton and Hamilton's hypothesis.

The composition of our lowest-degree partial melt (~37%) at 1.77 and 2.21 GPa were compared with the compositions for the RAB90 Au24-1 minette and representative populations of mantle orthopyroxene and olivine. We found that the minette lies on a linear trajectory between our experimental melt and mantle orthopyroxene. This supports Buhlmann et al.'s and Funk and Luth's hypotheses.

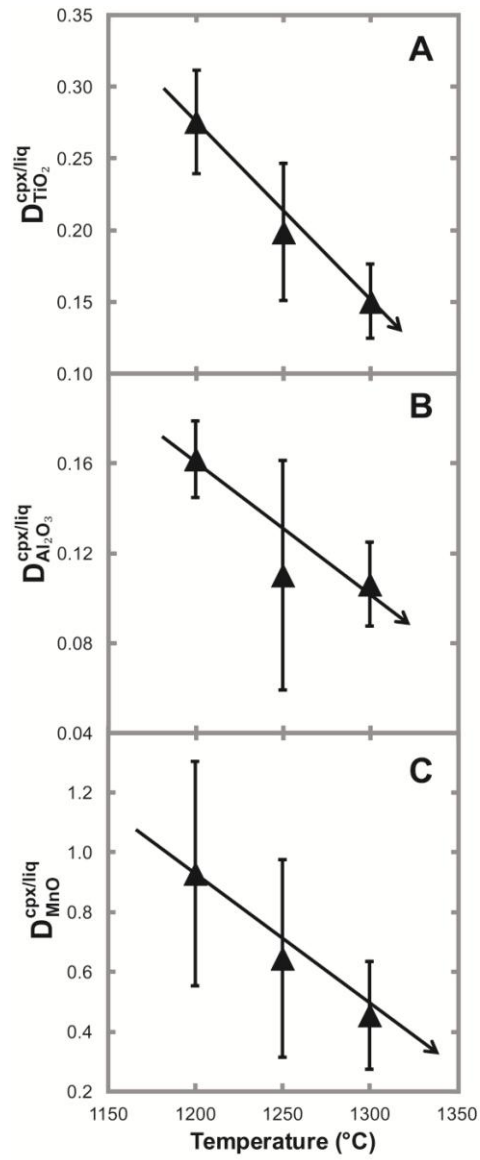

**Figure 3.1:** Phase relationships for DAT4-5. The black solid line marks the inferred solidus and the apatite-out reaction. The dark grey line marks the boundary where olivine is observed and is an upper bound for the solidus. The light grey solid line marks the upper limit of phlogopite stability. ol? = unobserved olivine in capsule; liq? = the liquid phase was unable to be quantified

**Figures 3.2a-h:** Compositional evolution of melt as a function of temperature at 1.33 GPa. Black arrows show the best-fit melting trend. Errors plotted are  $2\sigma$

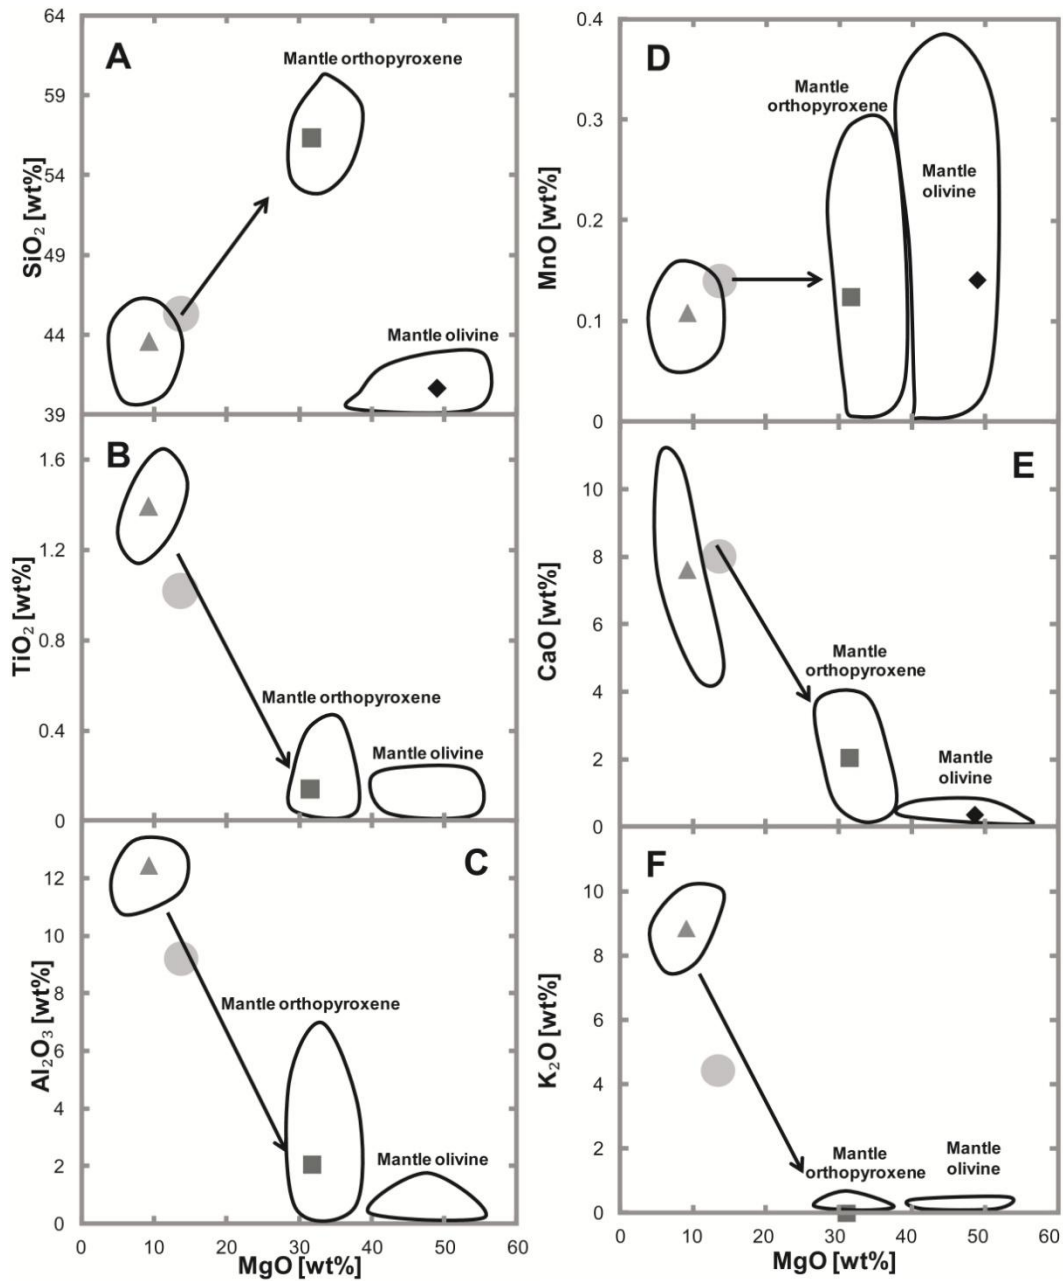

**Figure 3.3a-c:** Partitioning coefficients of cpx/liq for  $\text{TiO}_2$ ,  $\text{Al}_2\text{O}_3$  and  $\text{MnO}$  as a function of temperature at 1.33 GPa. Errors plotted are 2 $\sigma$

**Figure 3.4:** Partitioning coefficient for ol/liq for MnO as a function of temperature at 1.33 GPa.

Errors plotted are  $2\sigma$

**Figures 3.5a-f:** Variation diagrams of SPF52X melt (dark grey triangle), RAB90 Au24-1

minette (light grey circle), and mantle orthopyroxene (dark grey square) and olivine (black diamond) compositions. Black ovals denote the compositional variation of each population. Arrows are drawn from the 52X melt population toward orthopyroxene. Oxides <d.l. for olivine not shown

**Figure 3.6:** Comparison of the solidus of DAT4-5 (black curve) with a cratonic mantle geotherm (dark grey curve; Chapman and Pollack 1977). The solidus was extrapolated (black dashed curve) in accordance to the Clapeyron equation ( $dP/dT = \Delta S / \Delta V$ ) and constrained using the experimental study of Luth (1997). The extrapolated solidus approaches the cratonic geotherm at higher pressures. See text for discussion

**Table 3.1** Composition of starting material

<b>Sample</b>	<b>DAT4-5</b>	<b>Volatile-Free</b>
SiO <sub>2</sub>	47.67	48.77
TiO <sub>2</sub>	0.72	0.74

Experiments at 1.33 GPa are precise to  $\pm 0.1$  GPa; higher pressures are precise to  $\pm 0.05$  GPa. Temperatures are precise to  $\pm 15^\circ\text{C}$ . "X" denotes single-stage experiments, "XX" denotes double-stage experiments. Calculated modal abundances of mineral phases are given in parentheses (#); sum of residual squares ( $\sum R^2$ ) given on the right. Inferred modal abundances are in square brackets [#]; phases inferred to exist, but with no microprobe data, are in bold. Proxy compositions for olivine and melt were used in order to calculate model abundances of those phases in experiments where they were inferred to occur. Abbreviations: cpx = clinopyroxene, phl = phlogopite, ap = apatite, ol = olivine, liq = liquid

SPF91X	0.32	0.33
SPF49X	0.33	0.27
SPF65X	0.33	0.33

Calculations for the exchange coefficient are based on the reaction  $\text{Mg (mineral)} + \text{Fe}^{2+} (\text{melt}) \leftrightarrow \text{Mg (melt)} + \text{Fe}^{2+} (\text{mineral})$ . General formula:  $K_D(\text{Fe-Mg})^{\text{min-melt}} = (X_{\text{FeO}}^{\text{min}} X_{\text{MgO}}^{\text{melt}}) / (X_{\text{FeO}}^{\text{melt}} X_{\text{MgO}}^{\text{min}})$ , where  $X_z^y$  = mole fraction of oxide z in phase y

## Chapter 4: Geotectonic Model and Future Research:

The kimberlite corridor (KC) (**Figure 1.1**), as defined by Heaman et al. (2003; 2004) and Currie and Beaumont (2011), stretches southward from the Slave craton in the Northwest Territories, Canada, through the Wyoming craton and Colorado Plateau in the United States, approximately 1000 km inland from the west coast of North America. The main emplacement ages for these alkali-rich magmas occurred from ca. 110 Ma to ca. 45 Ma, trailing to ca. 25 Ma in some locations (see Currie and Beaumont 2011 for a review). Many authors who have studied the Montana and Wyoming high-potassium magmas suggest that an ancient lithospheric cratonic mantle, an asthenospheric mantle (mantle wedge), and a younger component (usually interpreted to be subducted oceanic crust) are involved in the generation of these magmas (Fraser et al. 1985; Dudas et al. 1987; Eggler et al. 1987; Meen and Eggler 1987; Mitchell et al. 1987; Hyndman et al. 1988; Scambos and Farmer 1988; Irving 1990; Dudas 1991; O'Brien et al. 1991, 1995; Macdonald et al. 1992; Buhlmann et al. 2000; Downes et al. 2004; Facer et al. 2009; Smith 2010). Many of these authors, to varying extents, invoke the dehydration of the subducting Farallon plate in the genesis of the alkaline magmas in western North America.

In Chapter 2, I report the results of liquidus experiments on the most primitive minette from Milk River (RAB90 Au24-1), which found that this composition was in equilibrium with orthopyroxene and olivine at 1.77 GPa and 1350°C. Notwithstanding, I argue that the composition of the minettes (e.g. 8.02 wt% CaO; 4.44 wt% K<sub>2</sub>O; 1.02 wt% P<sub>2</sub>O<sub>5</sub> for RAB90 Au24-1) is best explained by partial melting of a vein assemblage comprising phlogopite + clinopyroxene + apatite. Based on the work of Navon and Stolper (1987) and Foley (1992), I suggested that the primary minette magma re-equilibrated with the wall-rock during ascent via dissolution of orthopyroxene and olivine. The multiple saturation point is at a high temperature

for cratonic mantle (~600-700°C), and it is unlikely that the craton rose by >500°C to induce partial melting. Rather, I propose that melting likely occurred at greater depths (base of craton?), possibly requiring the introduction of hydrous fluids. The trace element (HFSE-depleted and LILE-enriched) composition of the minettes supports a subduction-related origin, and therefore it is likely that hydrous fluids derived from the subducting slab were involved in triggering partial melting (Buhlmann et al. 2000).

For any numerical model to be realistic, it must support the known geochemical and geochronological constraints. Recently, geodynamical simulations (Liu et al. 2008; Currie and Beaumont 2011) have tested the possibility that the Farallon plate was involved in the genesis of the alkaline magmas in western North America. In Currie and Beaumont's numerical model, the hydrated Farallon plate subducts underneath a thick, cool Archean craton, already embedded with metasomatic veins (in this discussion we will assume mica-clinopyroxenite veins) (**Figure 4.1a**). The subduction of the Farallon plate during the Cretaceous period (~100 Ma) was originally steep, resulting in typical arc magmatism (Currie and Beaumont 2011). Currie and Beaumont demonstrated that rapid subduction of the Farallon plate coupled with westward motion of the North American plate resulted in a progressive decrease in subduction angle (**Figure 4.1b**). A consequence of shallowing subduction is the landward movement of the asthenospheric mantle wedge (Currie and Beaumont 2011). Sixty million years after the onset of low-angle subduction (~40 Ma), the Farallon plate would be sub-parallel to the lithosphere. The shallow-angled, old oceanic slab would remain cool, allowing hydrous minerals (e.g. phlogopite, amphibole, serpentine, chlorite) to persist  $\geq 1000$ -1500 km away from the trench. This placed the "wet" region of the Farallon plate underneath the Wyoming craton (Currie and Beaumont 2011).

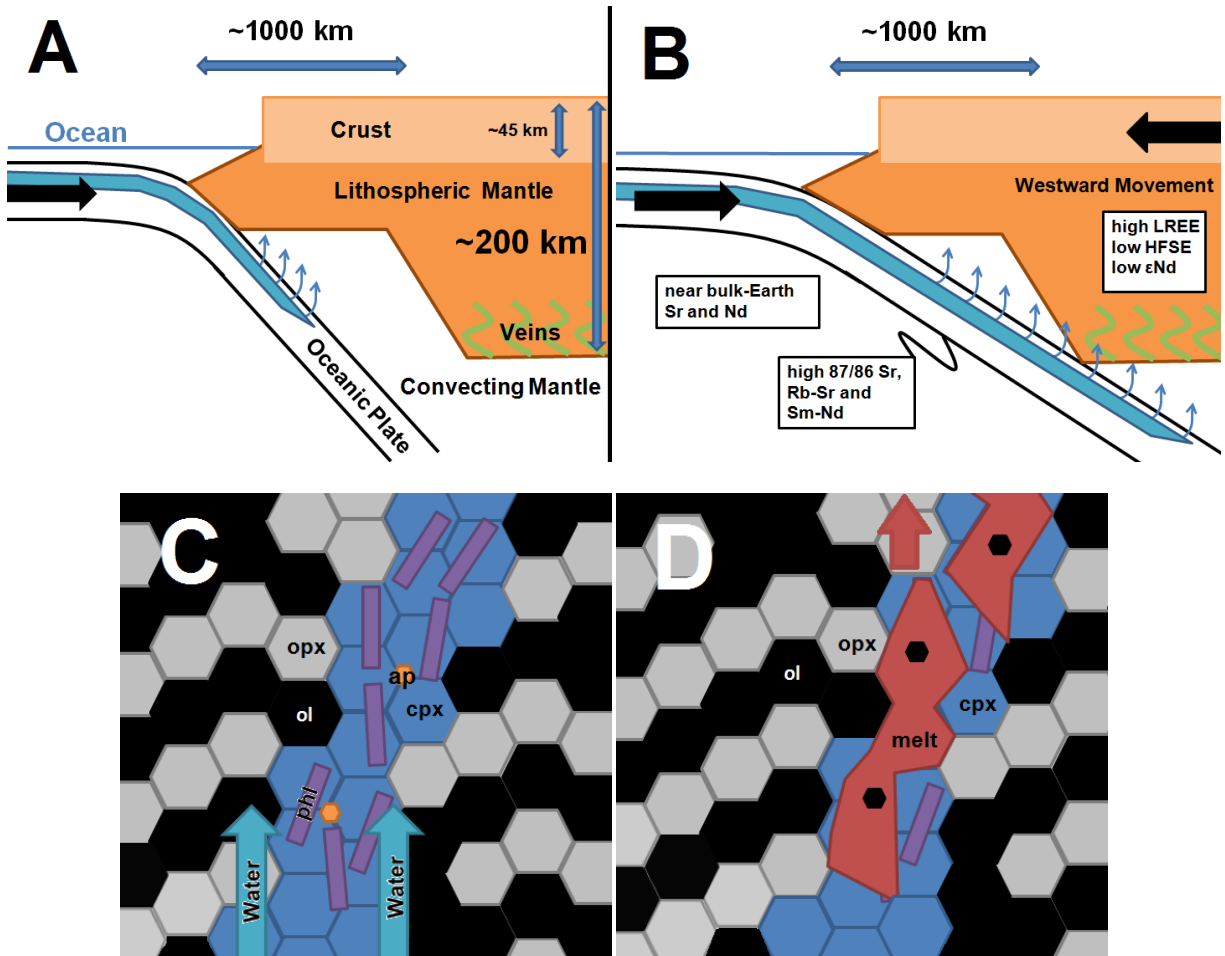

Currie and Beaumont argued that the devolatilization of the Farallon plate triggered alkali magmatism in the region (**Figures 4.1c, d**).

Facer et al. (2009) studied the spinel dunite xenoliths from the Bearpaw Mountains, Montana, USA, and found that the xenoliths were serpentinized and had high B, Cl and H<sub>2</sub>O contents. They argued that the presence of serpentine and the concentrations of B and Cl in the xenoliths were consistent with metasomatism by hydrous fluids derived from a subducting slab, likely the Farallon plate. Smith (2010) conducted a similar study on antigorite peridotite, Cr-magnetite dunite, chlorite harzburgite, and other ultramafic rock fragments from the Colorado Plateau, United States. He argued that the serpentinization of these rocks was consistent with hydrous fluids acting as metasomatic agents infiltrating the mantle underneath the Colorado Plateau. Smith also suggested that these fluids were likely derived from the Farallon plate.

The presence of xenoliths in the minettes at Milk River are consistent with the hypothesis that these magmas rose to the surface rapidly, likely through pre-existing cracks and fissures in the lithosphere (**Figure 4.1e**) (Sparks et al. 1977; Spera 1984). A consequence of rapid ascent rates, coupled with slow cooling rates, is that the primary melt derived from partial melting of the vein assemblage would preserve the high (near-liquidus) temperatures of melting (Sparks et al. 1977; Spera 1984). Based on the multiple saturation point found in Chapter 2, the primary melt likely stalled at ~58 km (~1.77 GPa) (**Figure 4.1f**), where it re-equilibrated with the surrounding harzburgite wall-rock via dissolution of orthopyroxene (**Figures 4.1g, h**).

Assuming the composition of the metasomatic veins at the base of the craton is appropriate, Currie and Beaumont's model accounts for the major- and trace-element, and isotopic composition of our minettes and accurately predicts the age of formation. However, a

key feature of Currie and Beaumont's model is that melting was induced by fluid fluxing, directly implicating the Farallon plate in the genesis of the alkaline rocks. To test this key feature of their model, experiments would need to be conducted where 1) water is added to our mica-clinopyroxenite xenolith, and the depression of the solidus is characterized; and 2) the pressures are extended to depths approaching the base of the craton (~150 - 250 km). By comparing the water-saturated, depressed solidus with a cratonic mantle geotherm, we could see if melting could be induced simply by introducing hydrous fluids or if external heating is also required.

**Figures 4.1a-d** Tectonic and petrogenetic model for the minettes at Milk River, southern Alberta. **a)** the basic geometry of the Farallon plate (oceanic plate) and the North American plate (crust plus lithospheric mantle and veins) at ca. 100 Ma. **b)** westward movement of the North American continent, coupled with rapid subduction of the Farallon plate, causes the oceanic slab to shallow, ca. 50 Ma (Buhlmann et al. 2000). The "wet" region of the slab now extends >1000 km inland, allowing hydrous fluids to infiltrate the base of the cratonic lithospheric mantle. Also shown are the isotopic and some trace-element characteristics of the three components needed in the petrogenesis of the minettes (O'Brien et al. 1991, 1995). **c)** close-up of the harzburgite wall-rock imbedded with an apatite-bearing mica-clinopyroxenite vein. The vein assemblage is assumed to be at or close to the base of the craton (~200 km depth) and at an ambient temperature (based on a  $40 \text{ mW m}^{-2}$  geotherm) of ~1400°C. Hydrous fluids derived from the dehydration of the Farallon plate are assumed to be the trigger for partial melting. **d)** partial melting is focused on the vein because it has a lower solidus temperature relative to the surrounding refractory harzburgite. Based on the studies of Yoder and Kushiro (1969) and Modreski and Boettcher (1973), olivine is produced during the melting of phlogopite. The red arrow indicates that once the primary melt reaches a critical buoyancy, it will rise through pre-existing fractures in the lithospheric mantle

**Figures 4.1e-h *continued*** Tectonic and petrogenetic model for the minettes at Milk River, southern Alberta. **e)** the primary melt rises rapidly through the cratonic lithospheric mantle, preserving a near-liquidus temperature of  $\sim 1350^{\circ}\text{C}$  (based on the multiple saturation point found in Chapter 2) (Sparks et al. 1977; Spear 1984). **f)** based on the multiple saturation point found in Chapter 2, the primary melt likely stalls at a depth of 58 km ( $\sim 1.77$  GPa), where it forms a magma chamber. **g)** close-up of the magma chamber (possibly containing entrained clinopyroxene and/or phlogopite) surrounded by a harzburgite wall-rock. **h)** the primary melt begins to dissolve the surrounding orthopyroxene in an attempt to establish equilibrium (Foley 1992).

## Chapter 5: General Summary and Conclusions:

Minettes from southern Alberta, Canada, crop out as dykes near the Milk River area. Coarse-grained xenoliths composed of phlogopite, clinopyroxene and apatite were carried up in the minette dykes. Buhlmann et al. (2000) previously studied these rocks, and proposed that the minettes were formed from a source region composed of phlogopite and clinopyroxene, at depths  $\geq 1.7$  GPa. Their hypothesis is supported by many experimental (e.g.: Esperanca and Holloway 1987) and geochemical (e.g.: Macdonald et al. 1992) studies on similar mafic, alkali-rich magmas. We conducted our study to test Buhlmann et al.'s hypothesis experimentally.

Our first series of experiments involved locating a multiple saturation point along the liquidus of a primitive minette (RAB90 Au24-1). Experiments were conducted between 1.33-2.21 GPa, and 1300-1400°C. We found that olivine was the sole liquidus phase at 1.33 and 1.55 GPa, whereas orthopyroxene was the liquidus phase at 2.0 and 2.21 GPa. We discovered a multiple saturation point at 1350°C and 1.77 GPa where olivine and orthopyroxene coexists with liquid. Clinopyroxene and phlogopite are not liquidus phases. Our findings are not consistent with Buhlmann et al.'s hypothesis and the general consensus of previous studies. We argue that the whole-rock composition (e.g. 8.02 wt% CaO; 4.44 wt% K<sub>2</sub>O) of the minette is best explained by partial melting of a source containing phlogopite and clinopyroxene. To reconcile our experiments with studies such as Esperanca and Holloway (1987), we turned to the models proposed by Navon and Stopler (1987) and Foley (1992), where our multiple saturation point is interpreted as the re-equilibration of the minette with the surrounding harzburgite wall-rock during ascent.

Our second series of experiments simulated possible melting processes that may have occurred in the cratonic mantle. We chose a mica-clinopyroxene xenolith that was "representative" of a mantle lithology, and conducted melting experiments between 1.33-2.21 GPa, and 900-1350°C. We found that the solidus was steep and at temperatures above a normal cratonic geotherm. Therefore, melting must be induced by either raising the temperature of the surrounding wall-rocks or by introducing hydrous fluids. We found that the composition of our melts were similar to other mafic alkali-rich magmas (e.g. madupitic lamproite from Carmichael 1967). Using variation diagrams and a binary mixing model, we plotted the composition of one of our experimental glasses (SPF52X shown) along with the RAB90 Au24-1 minette and representative populations of mantle orthopyroxene and olivine. We found that the minette was on a linear trajectory between the 52X melt and mantle orthopyroxene, consistent with the wall-rock dissolution model proposed by Foley (1992).

We conclude that the RAB90 Au24-1 minette likely formed by partial melting a source containing clinopyroxene, phlogopite and trace amounts of apatite at a pressures  $\geq 1.7$  GPa, and that the minette likely re-equilibrated with mantle orthopyroxene during ascent via dissolution.

## Appendix B: Additional Iron Loss Data:

To check for iron loss in our experiments we also analyzed the platinum capsule. Standards for both platinum metal and iron metal were used. The accelerating potential was 15 kV, with a current of 20 nA; the beam diameter was <1  $\mu\text{m}$ . Line analyses were taken perpendicular to the Pt capsule at locations likely to experience iron loss. Totals <97 are attributed to analysing part of the graphite capsule. The data acquired from the electron microprobe were corrected using the PRZ program provided by JEOL.

**Table B1:** Line analyses along the bottom of the Pt capsule for SPF87XX

## Appendix C: Alkali Migration:

Alkali migration is the physical diffusion of alkali elements (typically sodium and potassium) in a hydrous glass away from the electron beam because of heating (Vassamillet and Caldwell 1969). This phenomena has been a previously studied (Varshyneya et al. 1966; Borom and Hanneman 1967; Goodhews and Gulley 1974; Goodhews 1975; Jercinovic and Keil 1988; Nielsen et al. 1995; Spray and Rae 1995; Morgan and London 1996, 2005; Borisov 2009) and is known to affect the resultant signal of Na or K to the spectrometers. Resultant X-ray signals from other elements, notably Si, Al, and possibly Ca, artificially increase (Morgan and London 2005). Vassamillet and Caldwell (1969) noted that the rate of alkali migration under the electron beam increases with decreasing accelerating voltage, at a constant beam current, because the excitation volume decreases with decreasing accelerating voltages. Therefore, the resulting thermal energy per unit volume is greater at lower accelerating voltages, leading to faster alkali migration.

Morgan and London (2005) performed a detailed analysis on a hydrous and anhydrous haplogranitic glass, and systematically detailed the effect of beam diameter, beam current, and the resultant beam current density (in units of  $\text{nA } \mu\text{m}^{-2}$ ) on sodium migration. All analyses performed in their study were with a 20 kV accelerating voltage, using beam currents varying from 2 - 50 nA, and fixed beam diameters ranging from 2 - 20  $\mu\text{m}$ . Morgan and London (2005) found that for current densities  $<0.006 \text{ nA } \mu\text{m}^{-2}$ , there is very little ( $<2.7\%$  relative) loss of sodium signal. In general, sodium loss increases with increasing current densities. With a current density up to  $0.1 \text{ nA } \mu\text{m}^{-2}$ , minor (7 - 9% relative) sodium loss is observed, while becoming severe at current densities  $>0.5 \text{ nA } \mu\text{m}^{-2}$  (Morgan and London 2005). They also found that

sodium loss is far more pronounced in hydrous glasses relative to anhydrous glasses (Morgan and London 2005).

Borisov (2009) also performed a systematic study on alkali loss, this time including Rb and K with Na, as a function of beam diameter on the electron microprobe. He noted that the effects were dramatic when the beam diameter was  $<1\mu\text{m}$ , and less so as beam diameter increased, consistent with Morgan and London's findings. At  $20\mu\text{m}$ , the alkali signal was nearly constant, indicating that the alkali elements were stable.

Morgan and London (1996) suggested that in complex multi-component systems, use two separate beam conditions and an accelerating voltage of 20 kV, in order to properly analyse hydrous glasses; first: a beam current of 2 nA and a beam diameter of  $20\mu\text{m}$  be used to analyse alkalis and aluminosilicate components, and; second: a 20 nA and  $20\mu\text{m}$  beam for all other components. These conditions should reduce the effect of alkali migration induced by heating from the beam, and minimize gains in Si and Al, while providing consistent measurements for all other components. However, these conditions were unusable in our analyses because we have both solid phases and melt. Instead, we used a beam diameter of  $10\mu\text{m}$ , and a current of 10 nA, with an accelerating voltage of 15 kV. This was chosen in order to help mitigate alkali loss in the hydrous glasses, as well as to keep the oxidation volume of my analysis roughly the same as the mineral analyses.

Time-dependant analyses were performed on our hydrous glasses in order to quantify the relative proportion of alkali loss due to heating from the incident beam. Eighty to one hundred analyses were performed on a single spot on the glass. An accelerating voltage of 15 kV, with a current of 10 nA, and a beam diameter of  $10\mu\text{m}$ , was used (current density:  $\sim 0.12\text{ nA }\mu\text{m}^{-2}$ ).

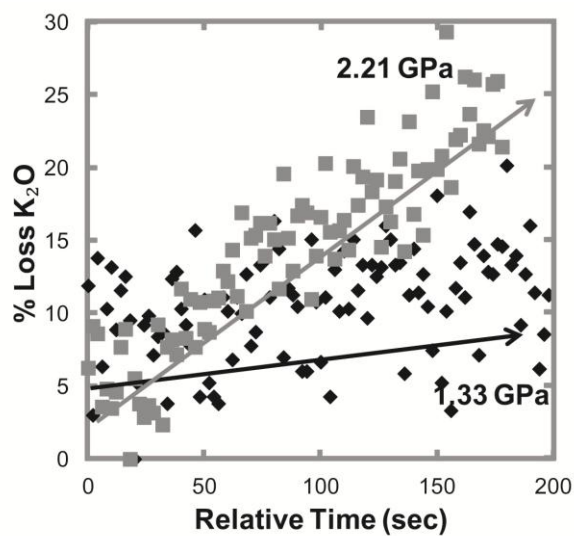

Because we counted only the peak and not the background, the absolute counts are useful only to monitor changes with time. **Figure C1** shows the percentage of  $K_2O$  loss with respect to temperature, while **Figure C2** shows this effect with respect to pressure. The extent of potassium migration, at constant pressure, in these glasses decreases with increasing temperature of the experiment (**Figure C1**), similar to the findings of Morgan and London (2005). The extent of isothermal potassium migration increases with increasing pressure (**Figure C2**). We conclude that both trends reflect the relative proportions of water in the melt. In experiments with relatively low fractions of partial melt ( $\sim 37\%$ ), there seems to be a "grace period" lasting  $\sim 20$ - $30$  seconds, where the signal of potassium appears nearly constant ( $1200^\circ C$  and  $1250^\circ C$  at  $1.33$  GPa, **Figure C1**;  $1300^\circ C$  and  $2.21$  GPa, **Figure C2**), after which, heat from the beam decreases the resultant potassium signal (i.e. increases the %  $K_2O$  loss). This is consistent with the findings of Vassamillet and Caldwell (1969), who argued that a critical temperature exists, after which alkali migration proceeds. This was also seen in Morgan and London (1996) and Borisov (2009).

We found it difficult to properly assess the extent of Na loss in our glasses. This is likely due to the low concentrations of  $Na_2O$  in the glass, relative to  $K_2O$ , and the short spot-time during our time-dependant analyses. In general, we found that Na loss does increase with increasing time (**Figure C3**), consistent with the studies of Hanson et al. (1996) and Borisov (2009), but the scatter in the data is larger than what was observed in the K loss.

If alkali migration did occur, it would be more prominent in experiments with low melt fractions. However, because K and Na (along with Si and Al) were analysed first, and the time of each analysis takes place during the "grace period", we argue that alkali migration was not a significant factor that affected the concentrations of these elements.

**Figure C1:** % Loss of  $K_2O$  versus time of analysis at constant pressure (1.33 GPa). Curves with arrows show approximate trends. Symbols: black diamond = 1200°C; grey square = 1250°C; grey triangle = 1300°C.

**Figure C2:** % Loss of  $K_2O$  versus time of analysis at constant temperature (1300°C). Curves with arrows show approximate trends. Symbols: black diamond = 1.33 GPa; grey square = 2.21 GPa.

**Figure C3:** % Loss of Na<sub>2</sub>O versus time of analyses at 1.33 GPa and 1200°C. The black arrow indicates the trend of the sodium loss.

## Appendix D: Substitution mechanisms in phlogopite

Determining the substitution mechanism of Ti in phlogopite was more involved. Two possible substitution mechanisms for Ti in phlogopite have been proposed, one by Forbes and Flower (1974; reaction 4), and the other by Robert (1976; reaction 5):

where  $\text{Mg}^{[\text{VI}]}$ ,  $\text{Ti}^{[\text{VI}]}$  and  $\square^{[\text{VI}]}$  represents magnesium, titanium and vacancy on the octahedral sites, respectively, and  $\text{Si}^{[\text{IV}]}$  and  $\text{Al}^{[\text{IV}]}$  represent silicon and aluminum in the tetrahedral sites, respectively. Using the graphical methodology outlined in Arima and Edgar (1981), both substitution mechanisms occur in the phlogopite in these experiments (**Figure D1**). This conclusion is supported by the cation totals in the octahedral sites  $< 6$  (**Table 3.6**), interpreted as vacancies, and Al in the tetrahedral sites  $> 2$  (**Table 3.6**), consistent with reaction 5.

**Figure D1:** Ti in phlogopite vs. Octahedral site occupancy. The black lines indicate the substitution reactions. Symbols: black diamond = 1.33 GPa, dark grey squares = 1.77 GPa, light grey triangles = 2.21 GPa.
