DEDICATION

In recognition of their years of continuing archaeological research on Lake Abitibi and their friendship, advice and helpful aids, this dissertation is respectfully dedicated to Marjorie M. Jordan and Justin C. Jordan.

ABSTRACT

The major purpose of this thesis is to extend beyond the traditional boundaries of stone tool analysis to explore a new theory and method of lithic analysis. The search for new methods and theories of lithic analysis has been somewhat neglected by archaeologists in recent years. The method utilized and developed here is a cognitive based experimental approach. Modern lithic craftsmen, through controlled experiments, are used to define the specific attributes and morphology produced by a unique behavior unit (i.e., substantial percussion thin with billet) on an individual experimental flake scar or series of scars. These morphological units then, serve as a reference collection which is used to help interpret the behavior responsible for the morphology of prehistoric stone tools.

Not only are the specific behavior units used to manufacture the prehistoric specimens reconstructed, but the purpose and sequencing of these units are inferred. It is this sequencing of specific production units which we feel is closely tied to the cultural context in which the artifact was produced. Manufacturing techniques tend to be culture related as flintknapping skills require a lengthy apprenticeship and learning period. Studies of modern craftsmen have also confirmed that once a certain method of stone tool making and problem solving is learned with their associated motor movements, craftsmen tend to follow this learned pattern or repertoire quite closely. Thus, it is entirely possible that techniques and sequencing of techniques used in producing stone tools is much more culture specific than shape or size considerations used in more traditional lithic analysis.

The prehistoric stone tools analyzed in the thesis are from two archaic sites on Lake Abitibi in northeastern Ontario. The study area straddles the Ontario/Quebec border and lies on the edge of the James Bay/Hudson's Bay lowlands. The analysis used is deemed to be particularly suited to these sites which, due to erosion and high water levels, lack much of the normal data found on archaeological sites such as stratigraphy and faunal remains. This lack of other standard archaeological data therefore places a greater burden on the stone tool analysis to produce meaningful culture historical information.

The results of the cognitive processual analysis employed here has produced such information in that the sites have been shown to be technologically independent, therefore indicating the presence of two different archaic groups. It has also demonstrated that one site, the Jordan site, thought to be, perhaps, multicomponent due to the presence of extremely large bifaces, is not multicomponent. The large bifaces have been shown to be manufactured by the same techniques and by the same sequence or process as the smaller bifaces at the site. This suggests that size alone is not a good basis upon which to base a stone tool typology.

In regards to shape typology, three specimens from each of the two sites have very similar shape and size (metric) attributes. The technological analysis, however, indicates that despite the same shape and size, the bifaces from each of the two sites can be clearly distinguished on the basis of how they were made. Thus, a technological analysis allows us to see similarities and differences among artifacts in a way that would be impossible if a more traditional approach were used. This is significant in that the reconstruction of culture history

ACKNOWLEDGEMENTS

This thesis is dedicated to Marjorie M. Jordan and Justin C. Jordan who first introduced the writer to the wonders of Lake Abitibi archaeology. The Jordans for many years were alone in their efforts to carry on the pioneering work of Mr. Frank Ridley.

Many thanks is also due to the Archaeological Committee of the Ontario Heritage Foundation which funded the initial 1979-1980 work by means of an Archaeological Research Grant.

A special thanks is due the personnel of the Northern Regional and Cochrane District Offices of the Ontario Ministry of Natural Resources who very generously provided equipment and assistance for the 1979 season work. Mr. Rick Hollingsworth deserves special mention for his assistance in the field during the 1979 season.

Thanks is also due to Dr. Larry Jensen, Geologist with the Ontario Geological Survey, for his help in locating the Mt. Goldsmith Quarry site during 1980-1981.

Work on the thesis project during 1980-81 was supported by a S.S.H.R.C.C. doctoral fellowship (#452-80-2902) and appreciation is sincerely extended for the opportunity this provided to advance the research substantially during this period.

I wish to acknowledge the assistance of Cochrane District, Ontario Ministry of Natural Resources during the following 1982-83 research period, and particularly the 1982 S.E.P. project No. 3211-3197-21V, which allowed the author to collect the majority of the scientific data contained in Section 4.3 of this dissertation. Funds for the remainder of the 1982-83 study were provided under a separate contract

is only as good as the data typologies which underlie it. It is to this question of typological adequacy that this present thesis is addressed.

with the Northern Regional Office of the Ontario Ministry of Natural Resources.

To the following individuals, all of whom aided the writer and/or provided advice and information in ways too numerous to mention, a sincere thanks is extended to: my wife, Heather Pollock, and son and daughter, George and Grace; my parents, Ralph and Melia Pollock; Dr. Ruth Gruhn, Messrs. Helge Mattson, Don Stuart, Gerry O'Reilly, Bill Therriault, Garry Brown, Ms. Ingrid Kritsch-Armstrong, and Dr. W. C. Noble. A special remembrance is due to Mr. Don Crabtree for helping me through a flintknapping course taken at the University of Lethbridge in 1979 to understand and appreciate the complexity and sophistication involved with lithic technology.

Special mention and appreciation is due to Mr. Don Ball (now deceased), who assisted with the 1976 metric analysis of the Jordan site lithics, and Mr. Barry Newton, who assisted with the metric analysis of the Jessup site as well as aspects of the background prehistory. Mr. Newton, over the years, has also contributed insightful comments and ideas on boreal forest archaeology.

Thanks is due to the 1982 field crew, especially Mr. Mike McLeod of Thunder Bay (crew chief) and assistants Messrs. Godfred Plummer, Kelvin Plummer and Lars Hildebrandt of Iroquois Falls.

A special final mention is due to the persons who have worked so closely with me during the final stages of thesis preparation, especially my wife Heather, and Mrs. Carolyn Reid who so ably undertook the keying in of the thesis on her word processor. Mr. Lance Pepper produced the final drafted figures. The excellent artifact photography [illegible]e work of Brian and Marna Noble. A special thanks is due to

Dr. Rob Bonnichsen for preparing and participating in the lithic experiments.

Appreciation is extended to the thesis committee members, Dr. Mark Fenton, Dr. Cliff Hickey, Dr. Donald Clark, and Dr. Rob Bonnichsen, for their helpful suggestions.

Finally, I would like to thank Drs. Alan Bryan and David Young, my principal dissertation advisors, for their extensive guidance and helpful comments. Dr. Young especially, spent endless hours giving me special instruction on methods and procedures so helpful in learning a new and complex analytical approach.

CHAPTER I

THEORY

General Introduction

The purpose of this dissertation is to analyze two prehistoric campsites and a quarry site in the boreal forest region of northeastern Canada in order to delineate technological variation in lithic manufacturing techniques (Figure 1). This procedure should allow analytical separation of these sites in order to resolve several basic archaeological problems suggested by the work of previous area researchers such as Ridley (1956, 1958, 1966), Lee (1965, 1974), Wright (1972d), Pollock (1975c, 1976), Knight (1977), Marois (1975), and Kritsch-Armstrong (1982). Common to all previous work and endemic to the boreal forest region is the problem of mixed assemblages of artifacts deposited on the surface or in a shallow soil matrix with little or no physical stratigraphy. This situation is largely due to the slow rate of soil deposition and formation, massive forest fires which destroy organic matter in the soil, and a concentration of overlapping occupations in favorable micro-environmental areas (or eco-zones).

Previous researchers (Ridley, Knight, Pollock, above) have utilized a chronicling approach which attempted to produce a continuous and detailed cultural chronology for the area. For the purpose of this

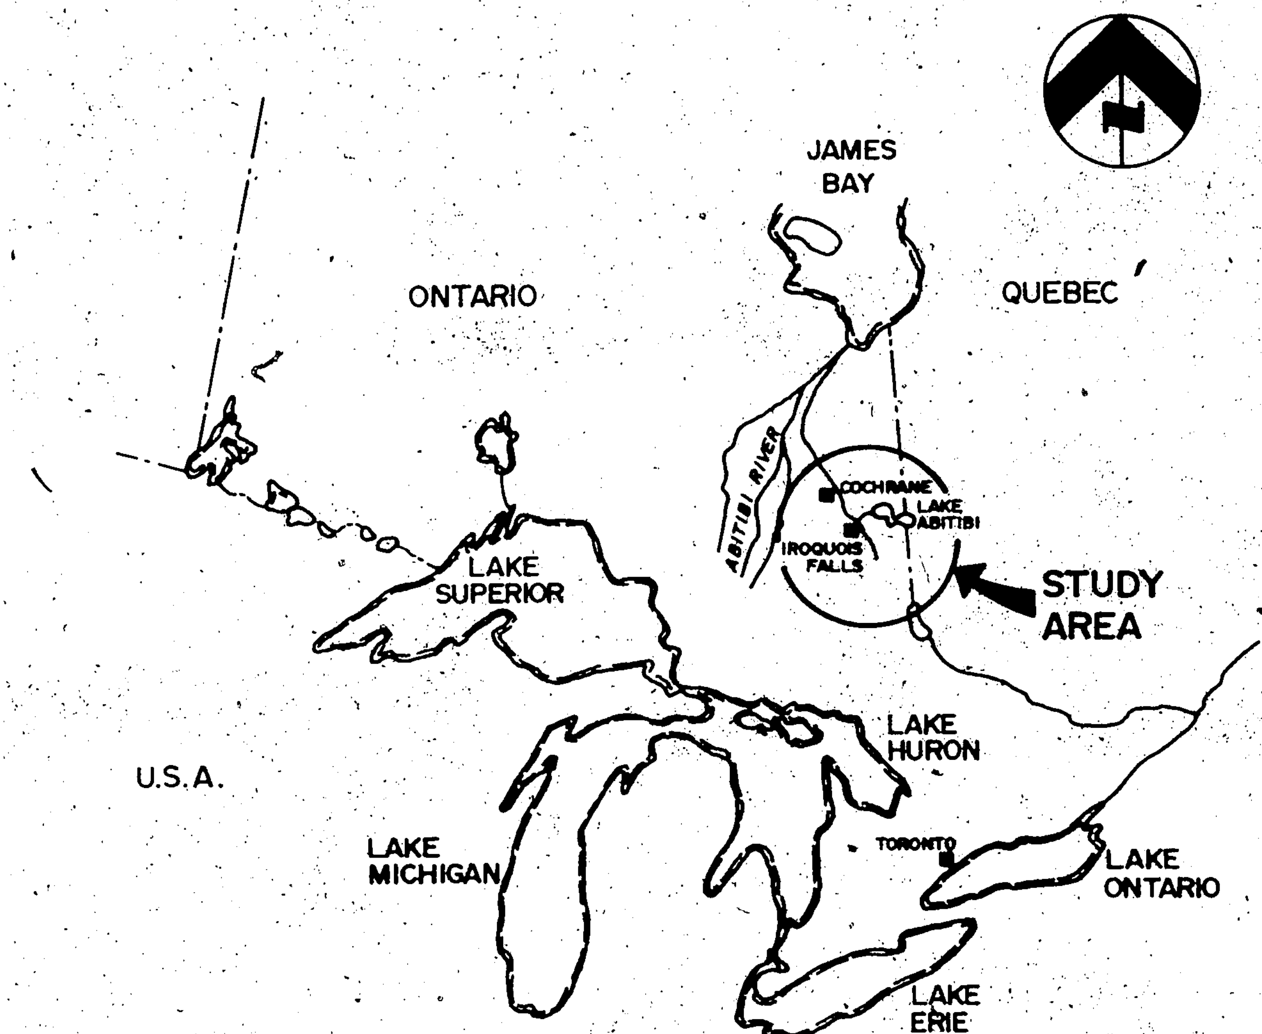

Figure 1: General Location of the Study Area.

dissertation all previous work done in this area of the Boreal Forest can be subsumed under what is generally called the culture-historical paradigm. Furthermore, it should be pointed out that because the ultimate goal of this research is to discover the evolution and variations of human adaptations in the Boreal Forest, this dissertation also has culture history as one of its primary objectives.

Before proceeding, a brief description of the three prehistoric archaeological sites forming the basis of this thesis is in order. The three sites, all located on Lake Abitibi, Ontario, are the Jordan Site (DeHa-8), the Jessup Site (DdGw-2), and the Mount Goldsmith Quarry Site (DdGw-3) located near the Jessup Site.

The Jordan Site, first located in 1973 by Justin and Marjorie Jordan, was surface collected by them during the years 1973, 1974 and 1975. As the site has since been continuously inundated by water it may now have been severely impacted or destroyed by the continuing high water levels and storms. When I visited the site in 1979 it was under water. Extensive subsurface testing of all above water areas near the site failed to produce any cultural materials. The majority of the archaeological specimens, including the important large bifaces, came from a 2 x 2 m cache area. The remaining materials were spread over a 70-metre length of low clay shoreline overlaid by a thin layer of water deposited sand. Flaked materials and numerous fire broken rocks were found among the larger boulders present on the shoreline (Jordan, Jordan and Crockatt 1976:17).

The Jessup Site (DdGw-2) was recorded by Marjorie Jordan, who also recorded and collected materials from the site in 1977. The 1977 investigations revealed the site to be of potential importance for the prehistory of the entire Canadian Boreal Forest. The site is at least 2.5 km long, spread out along a shoreline which varies from a low clay beach with a thin sand covering, to rocky outcrops separated by steep varved clay banks with narrow sandy beaches. A great deal of archaeological materials have been exposed by at least 30 metres of wave cut erosion. The beaches are covered with artifacts, mainly cores, flakes, and biface preforms or rough outs (Jordan & Jordan 1977). The writer first visited the site during 1979 at which time Ingrid Kritsch-Armstrong, as part of her M.A. studies at McMaster University, conducted some excavations at one of the higher terrace localities on the site (Kritsch-Armstrong 1980, 1982). Her excavations of 29 square metres produced over 100,000 flakes in a 6-8 cm layer, amply demonstrating the quarry-workshop nature of the site. However, the actual bedrock quarry and lithic raw material collecting site (as opposed to the Jessup workshop site), although suspected by Kritsch-Armstrong and myself to be nearby, was not located until the following year. During 1980, the writer, accompanied by Larry Jensen, a geologist with the Ontario Division of Mines (who has worked in the area since 1972), did locate the geological formation supplying the lithic raw material, and one bedrock quarry and collecting locale on nearby Mt. Goldsmith called the Mt. Goldsmith Quarry Site (DdGw-3).

All of the prehistoric artifacts under study from the Jordan Site were collected by Mr. and Mrs. Justin C. Jordan of Iroquois Falls, Ontario. They have also kindly loaned the writer a portion of their collection from the Jessup Site which, along with materials collected by the writer in 1979 and 1982, comprise the prehistoric artifact sample from the site used in this dissertation. Additional materials not used in this thesis were collected by Ingrid Kritsch-Armstrong and analyzed in her Master's thesis (Kritsch-Armstrong 1982). As well, some artifacts from the site were analyzed by Thor Conway (Conway 1978) although he did not visit the site.

During September 1982, I undertook some excavations and mapping at the Mount Goldsmith Quarry Site. Details are presented in section 4.3 of this thesis.

Dating (of the above sites) remains a problem (Table 1). Unfortunately the 1979 fieldwork failed to date the early archaic component at the Jessup Site. It should be noted that while both the Jessup and Jordan sites contain primarily pre-ceramic Archaic or earlier materials, a Middle Woodland component is also suspected at Jordan and known for at least a portion of the Jessup Site (see Table 1) (Kritsch-Armstrong 1982:214). Previous work by various researchers in the Boreal Forest regions of Canada has outlined a number of continent-wide problems expressed by Wright (1972d) as hypotheses which require testing:

(1) The Shield Archaic was a cultural tradition that evolved from a late Paleo-Indian or Plano tradition cultural base in the eastern Northwest Territories and probably the northwestern portions of the Boreal Forest - Canadian Shield (Wright 1972d:3). Thus, there was a cultural continuum from late Paleo-Indian into Shield Archaic.

(2) Plant and animal reoccupation of land freed by the retreating Laurentide ice permitted early northwestern Plano-Shield Archaic hunters to expand their territory particularly in an easterly direction into the Lake Abitibi area (Wright 1972d:4).

(3) The relationship between the Shield Archaic and adjacent contemporaneous populations appears to have been both relatively limited

(based on Pollock 1975c:29)

and insignificant in terms of cultural innovation (Wright 1972d:5).

Wright's underlying assumption pertaining to his hypotheses and suggestions is that the above named cultural traditions are prehistoric populations recognizable by defined flake stone artifact types and assemblages. Wright, in his monograph on the subject, "The Shield Archaic" (1972d), utilized a normative approach based on the relative frequency of artifact classes for eleven separate sites (frequency of projectile point varieties, frequencies of large and small scraper varieties, and some technological attributes such as grinding).

Dean Knight's (1977) doctoral dissertation on "The Montreal River and the Shield Archaic," involved a study area immediately south of the Lake Abitibi area. Knight based his thesis on the assumption that cultural adaptations to the environment are patterned behavior and that an evolution of patterned behavior is recognizably reflected in the artifacts (Knight 1977:5). The three major research problems of Knight's thesis were:

> (4) What is the nature of the Archaic occupations of the region; and can these occupations be subsumed under the umbrella term "Shield Archaic"?
>
> (5) Given the fact that there are two or more Archaic phases represented in the area, can reasons be suggested to explain similarities and differences?
>
> (6) Are there cultural dynamics which can explain the noticeable changes in a region through time? Are these changes really changes or is there a cultural continuum between 3000 B.C. and 180 B.C.?
>
> (Knight 1977:6)

Knight found it difficult to solve any of the above questions utilizing standard shape and metric analysis of artifacts. This difficulty clearly points out the limitations of the data obtained from previous analyses of prehistoric materials from Boreal Forest archaeological sites, and suggests the need to squeeze further information from a meagre source.

In her 1982 thesis concerning the Jessup Site, Ingrid Kritsch-Armstrong addressed ten specific questions related to her excavation of a portion of the Jessup Site. These involved questions concerning the prehistoric environmental conditions, the source of raw lithic materials and the manufacturing methods and types of tools being produced, at the site. Other questions concerned the nature and seasonality of the site as well as the cultural identification of the site's inhabitants and a comparison to other regional sites (Kritsch-Armstrong 1982:24-5). In her conclusion she states that,

> The Jessup Site was utilized as a lithic workshop and habitation site by Archaic and Laurel peoples over a period of approximately 3000 years. The major attraction to this site was the availability of raw material from nearby sources as shown by the abundance of local raw material in the form of chipping detritus, unfinished tools, broken tools and cores.
> (Kritsch-Armstrong 1982:258)

All previous attempts to solve basic questions such as those outlined by Wright, Knight, and Kritsch-Armstrong have had to contend with problems with the archaeological data base, and the results have been less conclusive than the resolutions obtained in many other prehistoric areas of North America.

In order to compensate for the methodological and data recovery limitations inherent in Boreal Forest archaeology and especially the sites under consideration here, I have applied another approach in order to produce a technologically based lithic typology which is appropriate given the limitations inherent in the data base. The study of variation in lithic production and manufacturing techniques derived from an experimental cognitive approach utilized here is described at length in the theoretical and methodological section of this chapter.

Previous workers concluded that the initial occupation was by Shield Archaic peoples who first occupied the area about 4000 years ago (Pollock 1975, 1976:192; Ridley 1966:4). Although possible, no concrete evidence of actual occupations had been found for Laurentian Archaic (4000 B.C. - 3000 B.C.) or Northern Plano occupations (6000 B.C. - 4000 B.C.).

As a result of these initial archaeological works, several possible chronologies (for a listing see Kritsch-Armstrong 1982:5) and problems as outlined above and in Table 1 were identified. However, the research was clearly at a low level of explanation concerning general anthropological/archaeological concerns including economy, subsistence, and technology. The general artifact classification scheme being used by Wright, Dean Knight, this writer's previous work, and to a lesser extent by Kritsch-Armstrong, was based upon a mixture of shape and assumed functional classes (such as scrapers), and limited metric attributes. Analyzing the attributes utilized a normative approach in that central tendencies were sought in order to segregate artifact "tool kits" (Binford & Binford 1966) and to isolate the lithic artifacts presumably pertaining to specific cultural groups. This approach created real problems, however, because the apparent archaeological assemblages found in the area are not characterized by similarities but by a tremendous diversity of projectile point stylistic forms, raw materials, and a paucity of clear-cut functional classes. Such a situation, with little or no radiocarbon or stratigraphic dating controls, tends to lead to the assumption that the apparent assemblages must have been mixed or are multi-component. Another problem is that

Wright and other researchers (e.g., Dawson 1975) see the Boreal Forest as an area of environmental sameness and postulate that archaeological assemblages reflect this feature by exhibiting broad spatial, temporal, and cultural homogeneity. It was the writer's contention however, after examining the data and conducting research in the region, that cultural variability was present with a number of regionalized cultures located within macro-topographical features such as major river valleys and having slightly differing geographic/ecological environmental zones (Pollock 1975c).

One of the "cultures" around which much debate has centered is the Shield Archaic Tradition (see Hanna 1980:65 for a summary). The debate concerning the Shield Archaic was recently revived by A. P. Buchner (1979:a, b) who makes many of my points above concerning limitations of the boreal forest archaeological data base and suggests that "the comparison of relative frequencies of artifact classes is of little or no utility in distinguishing and/or defining broad cultural traditions" (Buchner 1979:9). He further points out the high degree of artifact variation found on Boreal Forest sites. In regard to shape typological relationships, Buchner points out that, "Closer typological relationships are found with archaic sites outside of the Shield than among most of those which have been attributed to the Shield Archaic Tradition" (Buchner 1979a:7).

In her assessment of the Shield Archaic, Hanna (1980) pointed out that Wright's original 1972 definition of the complex was lacking "methodological validity." This was because the seriation used by Wright to define his artifact category variation was not based on comparable temporal components and the artifact classes used could not be assessed as to their temporal or cultural significance and/or applicability to a single cultural tradition. Further, the sites were from too wide a geographical area and spatial variation was not allowed for despite the fact that a vast geographical area was involved.

Hanna (1980:71-2) also discussed Wright's (1972d) contention that it is the technology of the Shield Archaic that separates it from other archaic traditions. She feels that, "for the majority of the artifact classes discussed, Wright does not demonstrate that their method of manufacture is significantly different from that of other archaic complexes." Of importance to this thesis is Hanna's contention that a "reliance on a percussion technology may be the common technology that binds the diverse regional complexes lumped into the Shield Archaic" (Hanna 1980:72).

The writer believes that one's cultural reconstructions are no better than the taxonomic scheme utilized for handling the data. By adapting aspects of cognitive anthropology to experimental lithic studies, and using the resulting attribute data to study variation in prehistoric archaeological lithics we are building a new typology in a new direction without losing any of the gains made in the past.

Part Two: Specific Hypothesis and Questions of this Thesis

A specific hypothesis and related questions are examined here in order to explain the Lake Abitibi lithic remains in light of the experimentally based flake scar morphology typology used in this thesis. The study of a particular prehistoric lithic manufacturing technology/typology (which may be related to a specific cultural group) can be advanced by first conducting experiments by a modern lithic craftsman utilizing similar raw lithic materials to produce a series of flake scar morphologies on experimental specimens. In this way, the exact manufacturing or technological input is known. Too, once the technology (function, extent of effect, behavior type and tool used) and resulting morphology represented on the flake scars are known for a particular lithic material, it is possible for the prehistoric archaeological artifacts to be analyzed in terms of technologically specific flake scar morphological attributes. It follows then, that this data combined with standard archaeological information (subsistence, settlement pattern, stratigraphy, etc.) can help in the resolution of culture/historical hypotheses and questions.

The method is deemed particularly useful for single-component or suspected multi-component archaeological areas or sites where lithic remains predominate and/or there is poor archaeological data on stratigraphy, within site artifact provenience, etc. Some forms of ploughed surface sites, flooded sites, disturbed sites and many sites in the Boreal Forest regions fit these conditions.

Hypothesis: By creating a technologically based typology (as opposed to an outline shape/size typology) utilizing bifaces from the two site collections, it can be demonstrated that there are technological differences between the Jessup site and the Jordan site artifacts which reflect real differences in the production strategies and manufacturing techniques employed. Specific questions associated with this hypothesis are as follows:

(1) What is the technological significance of the extremely large bifaces from the Jordan site? Are they part of the same technological assemblage as the smaller bifaces found on the same site or do they represent a different manufacturing technique?

(2) Is there any technological evidence to support the assumption that the Jessup site (DdGw-2) is presumed to be a lithic manufacturing or workshop site for the production of biface roughouts or preforms?

(3) Are the biface manufacturing technologies represented at the two sites essentially similar or are they different? Are the similarities close enough to suggest only one cultural group (a specific linguistic-biological population) is represented by the two sites or are there sufficient differences to postulate that two different cultural groups were involved?

It should be noted that because this is a new typology and represents an initial application of the method to prehistoric materials, the sites here are "type" sites and as such there is not at present any body of comparative data which would allow us to answer at this time any definitive questions concerning the Jessup and Jordan sites' relationship to other sites in the Shield Archaic Tradition or their relationship to preceding or succeeding cultural groups. Some non-technological comparisons are however, made in Chapter IV, Part Four of the thesis. However, there are two broad questions arising from this thesis which can be addressed, to some extent, by the data available. These are:

(4) Is there any evidence from this thesis to support Hanna's (1980; 71-2) suggestions that a very heavy reliance on percussion technology may be characteristic of the Shield Archaic and be the common technology that links the regional phases into a tradition?

(5) In regards to the Mt. Goldsmith Quarry site, what are the major methods of raw lithic extraction used? Is the lack of a lithic workshop and finished stone tools at the quarry itself an unusual occurrence or is this common for sites of this type?

Part Three: Theoretical Discussion

It is somewhat obvious from the previous discussions that, in the Boreal Forest at least, the standard approaches utilized in the analysis of lithic materials, while allowing for creation of a basic cultural chronological sequence, have not been overly successful in answering many of the broader anthropological questions regarding the evolution and adaptation of prehistoric cultures. What is clearly needed is a way to build in a new direction while using what has been done previously in the area. I believe that the study of lithic manufacturing technology offers such a way. Before discussing this approach derived from cognitive anthropology however, other relevant theoretical approaches, particularly the normative, culture historical and systems approaches, should be discussed in regard to their adequacy in handling the classification of stone artifacts. Especially in dealing with sites such as those in the Boreal Forest where contextual information is often minimal, classification of the lithic remains are "of necessity the foundation of data analysis . . . as it is largely on the basis of the classification of the data — that inferences are made" (Read 1974:216).

Because all theoretical approaches in archaeology are ultimately dependent on artifact typology, let us begin with a brief review of earlier concerns with typology. Krieger (1944) states that "ideally, an archaeological type should represent a unit of cultural practice equivalent to the culture trait of ethnography." Krieger goes on to discuss procedures, types, subtypes, classification schemes, and application of the formal typological method based primarily on shape. In the conclusion of the paper, Krieger states that:

1. Arrangement for descriptive orderliness and symmetry is equivalent to analysis for the discovery of cultural relationships.
2. Any grouping in a classifactory outline is automatically a type.
3. There are basic characters underlying the products of human workmanship which, if they can be discovered, will provide the means for more uniform and standardized classifications.

(Krieger 1944:28)

Other attempts to deal with typology include "mode" analysis (Rouse 1960), "attribute analysis" (Spaulding 1953; 1960), classification of artifacts in terms of production stages, and the concept of the "tool kit" (Binford & Binford 1966). Tool kits were constructed by "the use of factor analysis carried out on a matrix of correlation coefficients calculated between various pairs of tool types using data on the relative abundance of tools within assemblages" (Ammerman and Feldman 1974:610). Put more concisely, the aim was to isolate groups of tools utilized for a common function (such as hide working). Still other methods involve looking for assemblage-types and artifact-types as outlined by Desmond Collins (1970). Such types are identified by "constantly recurrent traits."

With this brief background on the development of typology in archaeology, let us turn to a consideration of how data retrieved from artifacts has been used to reconstruct the larger picture, examining first the culture-historical approach. The culture-historical approach grew out of the association by North American archaeologists with departments of anthropology and was thus heavily influenced by ethnology (Flannery 1972:100). Like early ethnologists, archaeologists were concerned with material culture and the description of space-time cultural sequences. This early and important paradigm was based on the concept of culture as a body of shared ideas, and research was aimed at discovering the norms for each culture.

Although the culture-historical approach was successful in regards to analysis of such processes as diffusion, parallel and in situ cultural development, as well as establishing chronological sequences, in the writer's opinion the approach suffers from certain limitations. First, judgmental assessments of the data base sometimes flow from an ethnocentric world view of the particular archaeologist. In other words, judgments are often highly subjective and procedures poorly spelled out. Second, while the majority of conclusions of culture-historical research may be valid, some aspects of material culture such as manufacturing technology have not been dealt with in depth. Rather than an emphasis on manufacturing techniques, the approach has relied heavily on "stylistic" (shape) considerations. Third, the culture-historical approach has lacked a dynamic capacity to handle variation due to its reliance on a normative approach. The normative approach has been described for archaeology by Binford (1965). In his view the normative approach has led to the dependence on index fossils (e.g., projectile points) and a focus on diagnostic artifacts in order to construct cultural chronological sequences within a geographical and temporal framework. Because a normative view of the universe allows one to organize and describe large amounts of data, it is productive. It has, however, created a picture of assemblage uniformity by focusing on central tendencies. Finally, as mentioned in the early pages of this chapter, the culture-historical approach often ends with a chronicle of unique events rather than leading to the isolation of general cultural adaptations such as changes in lithic manufacturing techniques.

The processual or systems approach, generally known as "The New

Part Four: The Cognitive Approach to Prehistoric Artifact Analysis

Several years ago David Young (cognitive anthropologist) and Robson Bonnichsen (archaeologist and lithic technologist) came to the conclusion that it was essential for anthropologists to begin an active search for common ground between cultural anthropology and archaeology.

This research concerning stone tools, which has now been in progress for several years, has concentrated on working with living craftsmen in order to understand how a craftsman uses his knowledge and skills to solve specific production problems, and how his decisions are reflected in the morphology of the finished artifact. The method involves videotaping the entire production process and eliciting information about the range of alternative solutions to technological problems perceived by the craftsman, his reasons for choosing specific alternatives over others, and how he translates these decisions into behavior by the application of different kinds of force to the material. Using this kind of information, it becomes possible to study the relations, for example, between particular flaking behavior and resulting morphological attributes on experimental artifacts. Knowledge of such technological cause and effect relations (i.e., relating "dynamic processes" to "static patterns") not only preserves vital information on dying crafts but provides analogues for the classification and interpretation of prehistoric artifacts in terms of manufacturing procedures, rather than on the basis of outline shape and/or technological attributes whose meaning and significance may be undemonstrated.

Previous to this research, the cognitively derived experimental work has been expended to date, few "laws" relating to prehistoric cultures have been discovered and it would appear that other than the promotion of significant inter-disciplinary studies and the increased awareness of the need for greater environmental, subsistence, and raw material procurement data, etc., the systems approach school has exhausted some of its more aspiring goals and techniques (Thomas 1978:23).

In regard to my Boreal Forest data, the emphasis of the systems school on subsistence and within-site distribution, and their concern with mathematical models involving large numbers of attributes, does not seem suitable for my purposes. Not only are excavated contexts lacking for the Boreal Forest materials, but subsistence and other subsystem data are non-existent. The lithic studies conducted under the systems paradigm appear to be based on a large number of metrical and technological attributes, few of which can be clearly defined as being of significance. Indeed, it is seldom clear what specific attributes such as artifact length or edge angle actually represents in terms of the technology used by a specific prehistoric group.

The writer believes that artifact based reconstruction of past cultures is no better than the typology for handling the data. Given that the culture-historical and systems approaches may have reached close to the limits of their productivity, there is a need to try a new approach to lithic studies. Such a way is provided by the cognitive approach upon which this thesis is based.

Archaeology," is, at least in part, a response to the culture-historical approach. Many different scientific methods under this banner have been tried by researchers in an attempt to generate scientific explanations or 'covering laws' for archaeology (Watson et al. 1971; but see critique by Morgan 1973). The main initiator of this paradigm was Lewis R. Binford (1972), following the anthropologist Leslie White, who views culture as an "extra-somatic adaptive system . . . employed in the integration of a society with its environment and with other socio-cultural systems" (Binford 1965:205). In a functionalist manner the approach sees society (and prehistoric cultures) as a number of subsystems including not only cultural subsystems such as religion, language, trade, technology, etc., but also interrelated environmental subsystems such as geology, flora, fauna, climate, etc., all maintained within an equilibrium. Theoretically, all the components of the system can be studied as variables in precise relationships to one another (Dumont 1975:7, 8). In contrast to the normative view, a systems approach to culture holds that variability in artifact styles is associated and correlated with specific social groups and their concurrent environmental settings, with no precise relationships to time and space. That is, a great deal of variability could be contained within one cultural group in a short time frame due to factors such as subsistence shifts.

Many researchers studying variation in lithic assemblages have used a number of models such as the Hempel-Oppenheim model of deductive-nomological explanation (Fritz and Plog 1970), or R-mode analysis which can be expressed as statistical or mathematical models aimed toward the goal of obtaining 'covering laws.' Although a great deal of lithic approach has been applied only in a very preliminary fashion to the analysis of artifact assemblages from the Cypress Hills of Alberta, the Munsungun Lake area of Maine, and the Pryor Mountains of Montana (David Young: personal communication). Several students are currently applying this analytical approach to a variety of prehistoric data. The theoretical foundations of the cognitive approach have been presented in several unpublished papers by Young and Bonnichsen, and in a 1984 monograph, 'Understanding Stone Tools: A Cognitive Approach.' Also of interest is Bonnichsen's Ph.D. dissertation (1977). The cognitive approach to lithic analysis offers a methodology for the analysis of each individual artifact, and provides a way to describe meaningful variation; most importantly it allows one to study differences as well as similarities in an artifact assemblage.

By utilizing an experimental approach, the method demonstrates the nature of the connection between decisions, behavior and resulting morphological attributes. It is important to stress that the cognitive approach offers a dynamic process approach to typology. <u>It does not simply add a new series of attributes</u> for archaeologists to analyze. Arbitrary selection of attributes and the statistical manipulation of such attributes are useless from the beginning if one does not understand precisely how that attribute was formed on the stone tool, and more importantly, the overall relationships to other attributes. The cognitive approach offers a way of developing a better typology based on processual analogues. The typology developed is based upon a series of attributes grounded in the observation of craftsman's production processes not found in shape or earlier attribute typologies. The main reason this kind of approach has not been tried before is because aboriginal flintknappers are no longer available for observation in North America, and until recently there was also lack of modern flintknappers from which to develop analogues. That is, the real basis of the cognitive approach in regard to lithic studies is the study of the 'behavior behind the attribute' within a strictly controlled experimental situation (in lieu of ethnographic or ethnoarchaeological observation). The use of modern craftsmen to replicate prehistoric technology allows one, where the technological input is known (e.g., billet percussion flaking on a specific material), to describe the resulting flake scar attributes. This is quite different from a purely intuitive or essentially arbitrary attribute selection process.

The cognitive approach as it applies to the study of prehistoric technology can now be examined in detail. The approach consists of the following major components:

A. Basic Process Studies

1. Studying how living craftsmen use their production codes to generate specific production strategies and how these strategies are translated into behavior.
2. Studying the kind of morphology unit, (such as a flake scar) that is produced on an artifact by the application of a specific kind of "behavior unit" (e.g., hard hammer percussion).

B. Classification of Prehistoric Artifacts

1. Using process analogues developed in basic process studies to analyze individual prehistoric artifacts in terms of the behavior units responsible for the morphology exhibited by flake scars.
2. Constructing artifact techno-types in terms of similarities and

differences in manufacturing technology.

C. Archaeological Reconstruction

This involves an assessment of artifact types in terms of variation in lithic production strategies plus related archaeological data, and resolving problems such as whether technotypes reflect different cultural traditions or varying adaptive strategies within a single tradition. This stage involves intuitive and subjective evaluations of the data; however the basis for conclusions in respect to the flaked stone assemblage is precisely documented at each step of analysis and replicable by other researchers.

Basic Process Studies

As a result of intensive studies over the past few years, the goals of the first component of "Basic Process Studies" — to come to a better understanding of the relation between cognition and behavior and to isolate a master list of behavior units (see Table 11) (Young and Bonnichsen (1984:43) which can be used to describe the behavior of different flintknappers — has largely been met.

The second component of "Basic Process Studies" still requires further work. The goal of this component is to provide a photographic reference collection illustrating the morphological results of specific kinds of behavior units to a variety of lithic materials. This reference collection should help archaeologists who are not themselves lithic craftsmen better understand the technological decisions and behaviors represented on artifacts under study. Briefly, the method of building this reference collection (which was also used for the experiments in this thesis) is as follows.

A number of preforms are prepared from a given material and dyed in a color which contrasts with the color of the rock so that flakes removed during the experiments leave clearly visible scars (the Lake Abitibi Welded Tuff material was dyed white). An accomplished lithic craftsman is then requested to use a specific behavior unit (such as moderate percussion thinning with a hammerstone) along one edge of the preform to provide an idea of the range of variation produced by the repeated use of the same unit. All of the most common behavior units are used in this way and the entire set of experiments videotaped and coded to insure that the craftsman used the specified set of input conditions for each behavior unit (such as support system, angle of force, amount of force, etc.).

Each of the resulting "experimental artifacts" is then photographed in stereo pairs and the photographs enlarged on 3 x 5, 5 x 7 or 8 x 10 prints so individual flake scars and morphological features can be studied with ease. When desired for analytical purposes, multiple copies of experimental specimen photographs can be cut in two lengthwise and combined in a variety of ways so morphological differences resulting from the application of different behavior units can be systematically studied. This is referred to as a morpho-contrast set.

A preliminary list of morphological attributes (Table 2) can then be used to describe each flake scar. Using these attributes we have been able to distinguish among the eight general kinds of production activities shown in Table 3, on the basis of flake scar morphology alone. It should be noted that these eight distinguishable activities were first studied in reference to Georgetown Flint, a material which provides a relatively clear morphological record. Not all these activities were equally as well represented or visible on some other materials such as the Welded Volcanic Tuff from Lake Abitibi.

In summary, the first component of experimental cognitive lithic studies described above, is used to define the behavior units employed by lithic craftsmen in natural technological production sequences; the second component involves having skilled craftsmen use these "natural units" in a controlled experimental situation where the connection between the application of a given unit and the resulting morphology can be isolated and studied. It is important to emphasize that this kind of basic research does not simply add a new series of technological attributes for archaeologists to add to existing lists. The cognitive experimental lithic approach tries to avoid the indiscriminate selection of as many attributes as possible and the statistical manipulation of these attributes in the search for patterning. Utilizing all the attributes which can be visually discriminated introduces too much "noise" into the system and tends to be used as a substitute for a genuine understanding of the processes responsible for flake scar morphology. Individual attributes are not nearly as important as the way in which groups of attributes are combined on an individual flake scar as the result of the application of a particular kind of production activity. The relation between behavior input and morphological output must be understood before moving on to the classification and interpretation of prehistoric artifacts.

Table 2. Preliminary Morphological Attributes Used to Describe Individual Flake Scars*

A. Sharpness of Proximal Edge (based on tactile test):

1. Sharp
2. Intermediate
3. Dull

B. Ribs (waves extending toward distal edge from platform):

1. Absent
2. Indistinct
3. Moderately distinct
4. Pronounced
5. Variable on same flake scar

C. Rib Spacing:

1. Not applicable
2. Relatively far apart and fairly evenly distributed across flake scar
3. Relatively far apart and found primarily near flake scar termination (distal edge)
4. Relatively close together and fairly evenly distributed across flake scar
5. Relatively close together and found primarily near flake scar termination (distal edge)
6. Other

D. Scales (semi-detached, incipient microflakes which may occur anywhere on the fracture surface):

1. Absent
2. Limited
3. Moderate
4. Extensive

E. Imbedded Flaking (secondary flake scar(s) imbedded in the primary scar; produced by the same action that removed the primary flake; generally found on margin of proximal edge):

1. Absent
2. Limited
3. Moderate
4. Extensive

Table 2 continued.

F. Microflaking on Proximal Edge (a series of tiny edge indentations produced by the same action that removed the primary flake):

1. Absent
2. Limited
3. Moderate
4. Extensive

G. Flake Scar Shape at Distal Edge:

1. Scar terminates in relatively straight distal edge
2. Scar terminates in rounded distal edge
3. Scar terminates in irregular distal edge

H. Flake Scar Size (based on a ratio between length of flake scar and width of artifact, measured from point of force application):

1. Almost imperceptible
2. Very minimal
3. Minimal
4. Moderate
5. Substantial

I. Morphology of Proximal Edge of Flake Scar (resulting from type and extent of force applied when flake is removed):

1. Edge relatively straight
2. Distinct U-shaped notch
3. Notch is either a flat curve or bell-shaped
4. Edge is rough but not distinctively notched
5. Other

* The specific list of attributes used for analysis in this dissertation can be found in Table 13.

Table 3. Representation of Production Activities Distinguishable on the Basis of Individual Flake Scar Morphology

Distinguishable Types of Production Activities

Indirect Percussion	Percussion flaking		Pressure Flaking	Shearing (twisting motion across edge of artifact with flat tool surface)	Edge rubbing		
	Hard hammer (such as a hammer-stone)	Soft hammer (such as a billet			Rub/Buffet (dragging the flat side of a tool across the edge of the artifact)	Abrade (rubbing the flat surface of a tool such as a grinder or hammer-stone parallel to the edge)	Pressure rub (using the tip of the pressure flaker to gently push off small projections on the edge of the artifact or to create small notches in the process of isolating a platform)

<u>Note</u>.

The term "production activity" is restricted in use; it refers to general activities such as percussion flaking or shearing which may encompass a variety of behavior units.

Classification of Prehistoric Artifacts

As previously mentioned, in the Boreal Forest it is seldom safe to assume that an archaeological assemblage represents the work of a single group of people or even a single cultural tradition. Since an assemblage may be mixed, it is essential to describe each artifact in the assemblage. Because different kinds of artifacts may have different technological grammars, it is necessary to sort an assemblage into general artifact functional classes such as unifaces, stemmed bifaces, non-stemmed bifaces, flake tools and cores. It is important to note that each functional class (e.g., bifaces, scrapers, projectile points) should be analyzed separately.

Describing a single artifact involves examining the range of morphological features on an artifact and documenting how meaningful features are patterned on each flake scar. An informed judgment (using the attributes and morpho-contrast sets from the experimental studies) can then be made about the production activity responsible for each flake scar on prehistoric specimens. If the lithic materials represented in the assemblage (such as the Lake Abitibi Volcanic Tuff) are not adequately represented in the "on-hand" photographic and experimental artifact reference collection, the second component of "Basic Process Studies" previously described should be employed. This method involves having a skilled craftsman apply the most common behavior units (Table 1) on a lithic raw material similar to that represented in the assemblage. If possible, these materials should be collected from the same rock formation or a very similar one to the aboriginal quarry sites. Experimentation with techniques should be conducted until a good match between flake scars on experimental specimens and flake scars on prehistoric artifacts is achieved. As usual, the experiments are videotaped and the resulting experimental artifacts are photographed for inclusion in the photographic reference collection. Information on the Lake Abitibi lithic experiments is contained in Chapter V of this thesis.

After representative and complete (as opposed to overlapping and failed) flake scars have been classified, and sequencing of flake scars has been established in an attempt to recover the production strategies, it is possible to make some process inferences. For example, it might be possible to conclude that on one face the craftsman took off a series of edge strengthening flakes with a pressure flaker and then removed a final sequence of thinning flakes, using a pressure and an indirect percussion technique. This type of description is considerably different than describing artifacts in terms of form, shape measurements, or selected technological attributes.

In addition to this technological description, more standard types of archaeological data can also be analyzed in regards to artifact shape, size, use-wear patterns, and basic metric measurements of the specimen.

It is important to note here that part of the cognitive analysis involves an awareness and an accounting for, of any use-wear morphology on the prehistoric artifacts, especially the implications of use-wear morphology and attributes.

Use-wear studies inspired by Semenov's classic (1964) monograph, Prehistoric Technology, have become of increasing interest. Other milestones in the development of use-wear studies were monographs edited by Swanson (1975) and Hayden (1979). Most recently Lawrence H. Keely (1980) has summarized the current state-of-the-art of microwear analysis. Use-wear techniques involve the use of two different approaches. The most used one involves examination of wear traces with a low level magnifying stereo microscope. The alternative technique, of which Semenov and Keely are the major proponents, uses magnifications of greater than 80x to study polishes and striations.

It is interesting to note that use-wear researchers agree that the microwear analysis of archaeological specimens can only proceed by means of controlled experimental studies (Keely 1980:3). Although many researchers such as Hayden (1979) do not discuss it directly, there is a major need in use-wear studies for control over technologically based use-wear traces that may be confused with user caused morphology (Olausson 1980:52, Keely 1980:4). This point was also strongly made by Tringham et al., who stated that attributes relating to retouch and method of manufacture must be studied in combination with use-wear attributes in order to gain the fullest possible knowledge from stone tools (1973:173).

Almost all use-wear studies, like the cognitive approach to manufacturing technology, have been, to date, time consuming and limited in size and extent with emphasis on methodological and technical problems (Stafford and Stafford 1983:351).

The prehistoric specimens in this thesis were examined by means of low magnification and stereo photographs. This did not reveal any use-wear striations or other forms of use-wear apart from some abrasion from water tumbling. Edge damage and microflaking caused by use-wear is a potentially difficult problem as use-wear might produce small flake scars that could be confused with or obscure identification of morphology resulting from manufacturing techniques. No attempt was made however, to undertake a complete and detailed use-wear study.

Most of the specimens being studied here have also been found in water eroded deposits and some minor abrading effects have been caused by water tumbling or wear on a few specimens. This process, I believe, has obscured any use-wear traces (especially micro-wear) to a much more serious extent than it has affected the manufacturing traces as these are on a much larger or macro-morphological level.

It is clear that any comprehensive approach to lithic studies must include use-wear and function, and the cognitive approach is no exception. It is also apparent that the systematic and experimentally based study of use-wear morphology, although not at an advanced state, is indeed farther advanced than the study of manufacturing morphology. Despite its lack of any direct contribution to use-wear studies this thesis should be of assistance to such studies by identifying some types of edge morphology which are directly attributable to manufacturing techniques alone.

Returning to the technological analysis, once the basic analysis is completed for a particular artifact class (such as bifaces), these can then be grouped into "techno-types" on the basis of degree of overlap in production activities and how the resulting flake scars are sequenced on an artifact. In other words, because technological considerations are paramount, bifaces similar in shape or size may be put in different techno-types, and vice versa. Why are technological considerations considered more important than shape? Shape is a visual concept which can be communicated readily by copying from an example or a model. The idea of a particular hafting technique for example, would not be difficult to explain to others, once the original idea had occurred. Clovis fluted points provide a good exampe of a style based on a hafting technique which evidently caught on and spread like a fad across an entire continent within a relatively short period of time.

The reason lithic manufacturing technology is more conservative and less easily communicated than an outline shape is because manufacturing technology is a complicated process involving extremely complex knowledge and motor skills. Acquiring the necessary knowledge and skills requires up to twenty years of experience — often in an apprenticeship context. Once these skills have been acquired they become second nature to the craftsman. He may copy a new shape from a neighboring group but is unlikely to borrow the technology that goes with it. He will simply replicate the shape using his own fundamental techniques. It is this very conservative (because it is fundamental) nature of lithic manufacturing technology which makes it diagnostic and therefore of use to the archaeologist attempting to define new typologies leading to techno-types and techno-patterns, forming a basis for associating (on a judgmental or assumptive basis) prehistoric archaeological sites with particular cultural traditions or groups of people.

A constraint is in order before returning to the discussion of analytic classification steps. Not all aspects of manufacturing technology are diagnostic of specific technological traditions. Given the constraints provided by the raw material, there are only limited ways to break open a cobble and to remove flakes. Lithic craftsmen tend to perform some of these activities in very similar ways. It is therefore critical to discover those areas in which the craftsman has options open to him; it is these areas of "free choice" (Young 1976) which are most important for isolating cultural groups in time and space; they need to be weighed most heavily in classifying artifacts. These areas of free choice can only be isolated by working with living craftsmen. It remains to be learned how such "choices" are or can be culturally defined.

After artifacts have been sorted into "techno-types," it may be possible to cluster a set of techno-types exhibiting significant technological overlap into "techno-patterns," a more abstract unit of analysis which may include all the members of a given class (such as projectile points) within an assemblage.

Clustering artifacts on the basis of shared technology also makes it possible to link within-site artifact classes or to link different sites. For example, even though a stemmed and non-stemmed biface may differ considerably in shape and be from different prehistoric sites, if they are produced by similar production techniques, it is possible to encompass them in a single techno-complex. The totality of production techniques and associated rules for applying and sequencing these techniques can be referred to as a "production grammar." A study of morphological similarities and differences may indicate that more than one production grammar is represented in an assemblage. If so, it becomes possible to ask whether these differences in production grammar are due to the presence of different cultural groups, whether they reflect different sorts of activities within the same group, whether trade items are present, etc. Answering this question requires the addition of other kinds of data as outlined below.

Archaeological Reconstruction

After the typology has been formulated, it is possible to move to a more general analysis by evaluating a production grammar in terms of its distribution through time and across space. The production grammar can also be correlated with use-wear data and environmental data, including the flora and fauna with which the artifacts are associated. Whenever possible, an attempt is made to identify specific cultural traditions and reconstruct their adaptive strategies. This latter aspect of the research design is not unique as reconstructing prehistoric adaptive patterns, groups, and cultures is the professed goal of most archaeologists. The uniqueness of the cognitive experimental lithic approach lies in the way controlled, meaningful attributes are selected and used in a detailed analysis of individual flake scar morphology to produce a typology for describing and classifying stone tools.

Part Five: Summary-Discussion

The relevance of cognitive anthropology for the study of material culture was noted as far back as 1964 in a classic article by Sturtevant:

> Material culture resembles language in some important respects: some artifacts — for example, clothing — serve as arbitrary symbols for meanings . . . and occur in a limited number of discrete units whose combinability is restricted. Possibly complex phenomena of esthetics would yield to a similar approach. Studies in these areas are potentially of much importance for ethnography, and it seems wise not to restrict the meaning of ethnoscience to the study of <u>terminological</u> systems.

Despite this admonition, in almost all studies undertaken to date, cognitive anthropologists have generally limited their investigation to the cultural structuring of kin terms, disease terms, color terms, etc. A major goal of this thesis is to attempt to break this barrier and apply cognitive insights to material culture and prehistoric archaeological artifacts. This is no easy task, however, as many archaeologists are pessimistic in regards to cognitive archaeology, arguing that it may be impossible to attribute cognitive significance to the patterning of attributes on artifacts when this patterning may simply be due to conditions imposed upon the cratfsman by the rock or to the requirements of function. This issue was dealt with briefly previously. It is handled more fully in <u>Understanding Stone Tools: A Cognitive Approach</u>, in which Young and Bonnichsen (1984) demonstrate that despite the fact that craftsmen tend to overlap in their use of behavior units, the way that behavior units are strung together to solve technological problems provides opportunity for significant craftsman (and perhaps cultural) variation.

It is important to note that many archaeologists are suspicious of "cognitively derived experimental archaeology" for less sophisticated reasons; they mistakenly assume that the cognitive approach must be a type of "paleopsychology" — the study of prehistoric cognitive structures and motivations. It should be strongly emphasized that the so-called "cognitive approach" should not be described as psychological in the normal sense. Rather it is based on the simple observation that archaeologists should not classify prehistoric artifacts without taking manufacturing processes into account. To do this requires either speculating about the technological information available to the aboriginal craftsman and how the artifact was used, or making more informed inferences on the basis of experimental data derived from recording technological decisions made by living craftsmen. In either case, the technological strategies employed by the craftsman are basic to the analyses employed by the archaeologist.

Although the cognitive approach to the study of variation in lithic production strategies is not intended to replace other more traditional typological approaches, it is hoped that archaeologists will come to see it as a useful way to decode the stone tool technology left by prehistoric peoples. The method is especially applicable to archaeological sites where recovery of normal range archaeological data is not possible and where, by necessity, a heavy reliance has to be placed on stone tool analysis to reconstruct culture history.

In the past, a typology based on general outline shape or stylistic attributes has been used to identify prehistoric site assemblages. These "type" projectile points have been dated, and time ranges estimated for each point style. The writer believes that this has been successful in defining broad time horizons as represented by these stylistic trends. However, I also believe that many of these broad geographic and temporal horizons as represented by single or co-existing projectile point styles are multi-cultural, and the more geographical spread and temporal depth, the greater the possibility of multi-cultural use of a single point style. A good example would be Oxbow points which have been found throughout the Northern Plains, east to the Boreal Forest and north to the edge of the Sub Arctic regions. It is my contention that these stylistically similar or identical Oxbow projectile points were made by many different cultures — peoples of different linguistic and biological backgrounds (Pollock 1981:153). A case can be made that stylistic influence is readily transferrable cross-culturally as evident by the spread of western clothing styles, etc., throughout the world. Projectile point shape or stylistic outline form would also be readily transferrable either by copying an example or even by drawing a simple picture. How then can one separate the projectile point stylistic types into specific cultural groups on a regional basis? The answer, I believe, lies in manufacturing technology. It has become apparent, as more sites are excavated, that the archaeological record is much more complex than many of us ever imagined, and considerably more varied. In my opinion, it has become increasingly difficult to fit a given site neatly into many of our pre-existing cultural phases, especially in the boreal forest areas.

The inherent complexity of stone tools in their own right was readily apparent to me the first time I attempted to analyze them as a novice archaeologist at the University of Toronto many years ago. I had a great deal of difficulty at that time until I was taught to sort them into size, shape and artifact classes. This shape-functional approach was effective and allowed one to produce a coherent description of assemblages quickly. Using this technique of style and artifact class, plus some metric attributes, allowed myself and others to produce regional cultural chronological sequences. Stone tools have been especially important in the boreal forest regions where there is a paucity of ceramics, bone preservation and stratified sites. This places a heavy reliance on stone tools for cultural reconstructions. Further complicating boreal forest archaeology is the problem of the generally small numbers of stone tools recovered, and the tremendous diversity found in these small samples in terms of shape and stylistic forms. If stone tools were ever to be used to answer many questions regarding cultural evolution and development in the boreal forest, a different typological method was needed. What was especially frustrating to me, utilizing the more traditional normative approach, which looks for central tendencies in the data, was that one had to make a large jump from one's basic observational and descriptive stone tool data directly to propositions and inferences regarding specific cultures. There was no middle ground or middle range theory allowing one to understand and ask the right questions of the tremendous variation in the boreal forest archaeological lithic record. In terms of the cognitive approach, middle range theory means not just the study of site formation processes but a set or continuum of data transformation procedures from the most basic levels to increasingly higher levels of generalization (Table 4).

The concept of middle range theory was initially developed by sociologists Talcott Parsons and Robert K. Merton, who, in order to

(4) General Theory:
cultural evolution, culture process and culture change.

(3) Culture History Level:
propositions and inferences regarding specific prehistoric cultures.

(2) Inferential Level:
no middle range theory, no systematic steps of data, instead, educated inferences used to interpret basic lithic data. Inferences made are not easily replicable by other researchers.

(1) Empirical Level:
basic level lithic data consisting of descriptive metrical data, stylistic or shape typology, artifact classes, projectile point identifications and other forms of non-lithic archaeological data.

CHRONICLING APPROACH

(2) Middle Range Theory Level:
middle range cognitive theory of technology used to provide a series of systematic steps whereby data is transformed from the empirical level to increasingly higher levels of generalizations. Results and inferences are replicable and testable by other researchers.

(1) Empirical Level:
dynamic and processual basic level lithic data consisting of some descriptive metrics but mainly technological data obtained from first hand observation of artifact production procedures undertaken by a skilled craftsman - behavior units, production units plus other relevant non-lithic archaeological data.

COGNITIVE APPROACH

Table 4. Comparative Theoretical Orientations

explain society, utilized structural-functional theories which led to a general category of equilibrium and systems theory (Firth 1955:255, Appelbaum 1970:10-11). By providing a framework for a number of diverse observations and social system components, the structural-functionalist and subsequent variants such as systems theory, served to advance the understanding of social systems.

As was the case with sociology, the purpose of middle range theory in archaeology is to provide a framework for ideas and hypotheses about how the archaeological record is formed. As such, middle range theory attempts to gather together many diverse elements such as manufacturing, use-wear, and site formation processes. Binford has stated that "middle range research results in the production of knowledge and understanding that may grow, serving as the research based paradigmatic underpinning of science" (1982:128). Furthermore, he states that,

> What we are seeking through middle range research are accurate means of identification and good instruments for measuring specified properties of past cultural systems. We are seeking reliable cognitive devices . . .
> (Binford 1982:129)

Middle range theory is dynamic and processual being based on observations and experiments giving rise to principles which can be applied in many situations. One of the goals of my thesis is to summarize the initial outlines of a general theory of cognitive based experimental approach to artifact manufacture. A more specific goal is to demonstrate through an actual case study how the general cognitive theory and method can be applied to specific situations. I believe the cognitive approach to archaeology by combining three approaches to lithic artifacts, i.e., the artifact as an object to measure and observe (outline form and metrics), the artifact as an object to be interpreted through use of experimental cognitive data, and the artifact as a functional tool (i.e., how it was used), will eventually lead to the development of a general theory of archaeological lithics and their role in cultural evolution.

It should be noted that this thesis is not a duplicate or parallel study to previous research, but represents the very first systematic application and test of the cognitive approach to prehistoric site collections. As such, it contains new theoretical and methodological developments in regard to the analysis of prehistoric artifacts.

Turning to culture history, it has been of concern to me in recent years that the application of stone tool studies to culture-historical problems has not been a growing area of interest or interpretive productivity. This is despite the fact that interest in lithics at the fracture mechanics use-wear and experimental replication of techniques levels has been strong. One explanation is perhaps due to the fact that such studies which also include this thesis are all in a developmental stage. Appropriate research theory, techniques and methods need to be developed before regional lithic studies can be undertaken and applied to culture historical problems and hypotheses. New approaches such as the cognitive approach found in this thesis are at present time consuming and require a great deal more effort than traditional typologies. However, I am confident this initial disadvantage can be overcome by building up appropriate raw material reference collections, mechanical attribute coding and computer matching of morphological sets, thereby making the approach of greater practical application. Because this thesis is a prototype, all aspects of the approach must be explored and explained. Some of this detail, no doubt, can be eliminated from future studies.

CHAPTER II

ARCHAEOLOGY OF LAKE ABITIBI AND ADJACENT REGIONS

Introductory Note

The following three chapters (Chapters II to IV) are intended to provide background information on the study area and the prehistoric sites involved in the thesis research. These chapters will be of interest to those involved in studying the cultural history of north-eastern Ontario. Those more interested in the methodology of the cognitive approach may wish to proceed directly to the analysis undertaken in Chapter V.

Part One: General Environment and Ethnology of Lake Abitibi

The Lake Abitibi area is characterized by two different topographical expressions. One is the upland shield country as exemplified by the Ghost Mountain Range, while the other comprises the rolling Cochrane Clay Plain (Putnam 1952:296) laid down as bottom deposit from glacial Lake Barlow. The upland or bedrock shield areas have been called the Abitibi Uplands by Bostock (1970:16). The greater part of the Uplands lies between 900 and 1200 feet above mean sea level (Bostock

1970:16). Thus, two major landforms dominate the Lake Abitibi area. One is the sandy and rocky upland Shield with its low hills and ridges; the other is a gently undulating clay plain laid down by glacial lake deposits.

Presently, the major plant species of the region include jackpine, black spruce and mixed forest typical of the boreal forest (Baldwin 1958, 1962). Some small remnants of the Great Lakes - St. Lawrence forest type persist, although many of these species are at their far northern limit.

In regard to fauna, 23 species of mammals are currently known for the area. From previous archaeological work in the area (Pollock 1975c, 1976) it is known that beaver, moose, caribou, porcupine and dog or wolf were important prehistorically. Fish were also an important dietary element for prehistoric peoples of Lake Abitibi, especially at the spring/fall spawning runs when they were obtained at the mouths of tributary streams flowing into Lake Abitibi. Today, important species include pike (Esox lucius), walleye (Stizostedion vitreum) and suckers (Catostomas commersonii).

In regard to climate, Chapman and Thomas (1968:58, see Table 5) delineate three separate climatic regions for the Kirkland Lake District. They encompass the Northern Clay Belt to the north, the Height of Land, and the Timiskaming Clay Plain. The Lake Abitibi area is situated in the Northern Clay Belt climatic zone (Table 5).

Table 5. Lake Abitibi Area Climatic Zones

	Timiskaming	Height of Land	Northern Clay Belt
Altitude (feet above sea level)	600-1000	1000-1600	700-1000
Mean annual temperature (F°)	36	34	34
Mean annual minimum temperature (F°)	-35	-45	-40
Mean date of last frost in spring	June 10	June 15	June 8
Mean date of first frost in fall	Sept. 13	Sept. 2	Sept. 7
Mean annual frost-free period	96	80	92
Start of growing season	Apr. 27	May 5	May 7

Ethnology of Native Peoples Since European Contact

Although native people have no doubt resided around Lake Abitibi since the last deglaciation, for a few brief years in the 1970s there were no native peoples permanently resident on the Ontario portion of Lake Abitibi. However, as in the past this situation has since changed and Indian peoples are again (1982-83) living year round on the lake.

Previously, the Abitibi Dominion Band and the Abitibi Ontario Band (now located near Amos, Quebec and sometimes on Lake Abitibi), were traditionally connected with our area of study (MacPherson 1932; Jenkins 1939). John T. MacPherson (1930:7) considered the Abitibi to be "an off-shoot of the Ojibway Indians . . . some writers believe they sprung from a common base southwest of Lake Superior. . . ." but, MacPherson also mentioned that "the casual observer would have difficulty in detecting the difference between the Abitibi and the neighbouring Cree" (MacPherson 1930:7).

Prior to 1939, the Abitibi occupied a hunting territory of 148 miles wide and 160 miles long, comprising some 22,400 square miles (Jenkins 1939:2) (Figure 2). Jenkins (ibid.) mentions that the Abitibi "are bounded on the west by the Ojibway, on the north by the Cree, on the east by the Montagnais, and on the south by the Timiskaming Algonquin." Jenkins clearly did not wish to assign a dialect or language grouping to the Abitibi.

The Abitibi are mentioned for the first time in the Jesuit Relations of 1640. They appear again in the Relation of 1660 in connection with a raid by the Iroquois (Orr 1921:26).

Others have associated the Abitibi with the Tetes de Boule (Orr

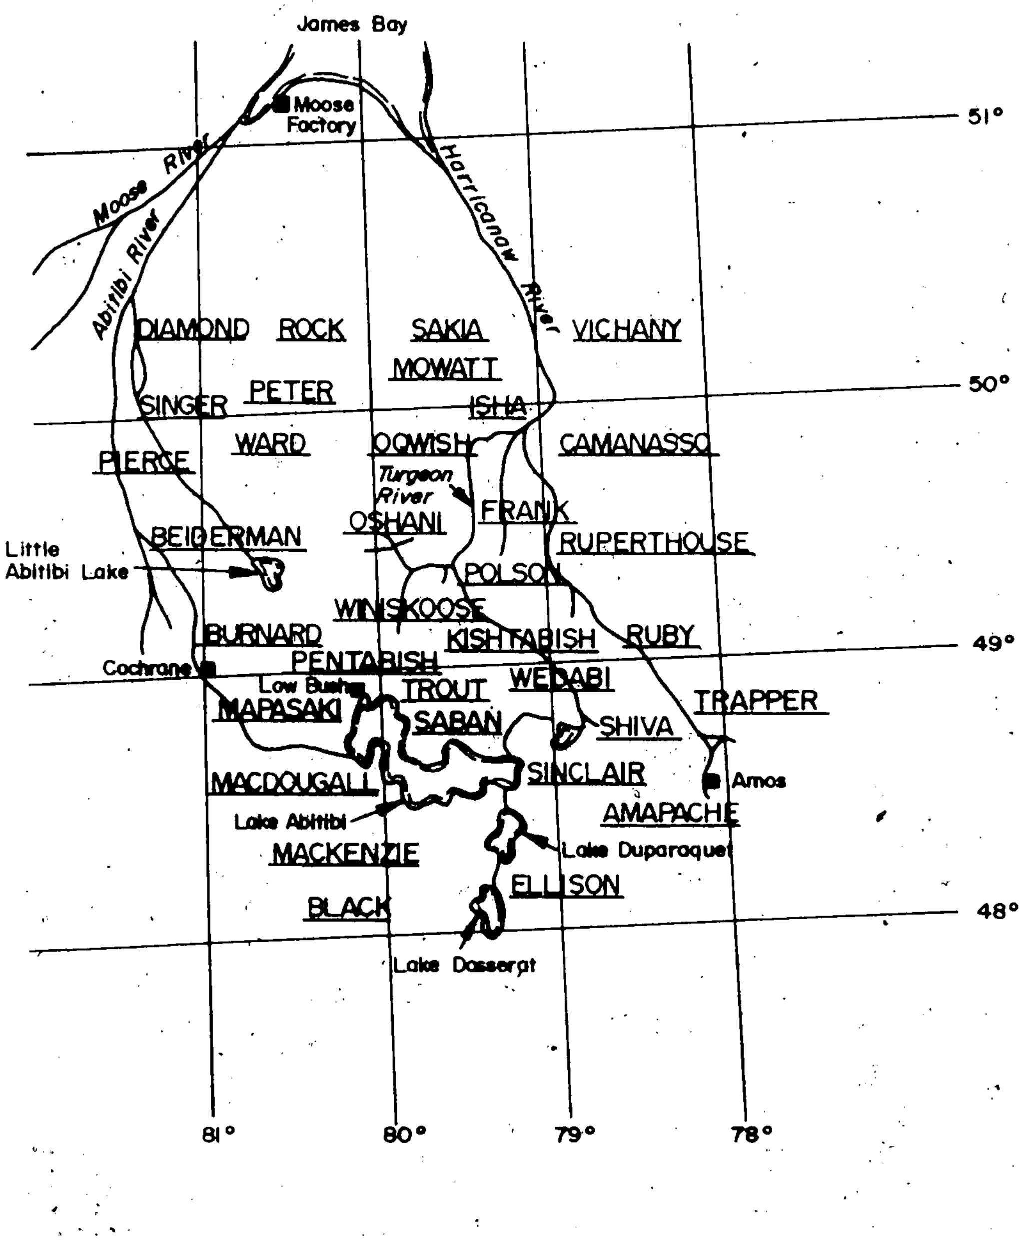

Figure 2: Approximate family hunting territories of the Abitibis - Ontario and Quebec (Jenkins 1939; Figure 28).

1921-22:26). According to Orr (1921-22:26) there is a clear relationship between the Tetes de Boule, Timiskamings and the Abitibi. Speck (1915:13) also mentions that these people (the Timiskamings and Abitibi) consider themselves to be of the same culture and dialect grouping.

It is possible that Tetes de Boule in this case represent various Algonquin bands of the Ottawa River. It seems from the evidence that the Abitibi are most closely related to the Algonquin peoples and that the Direct Historic Approach for this area must begin with historic Algonquin sites (as these people represent the prehistoric archaeology).

Apparently, the Abitibi, during early historic times, lived for the most part in conical lodges and had definite hunting territories (MacPherson 1930:8). With regard to their social organization, MacPherson says that there was little recognition of social bonds in 1930 apart from the family unit. Too, at that time even the oldest band members had no knowledge of totemic clans (MacPherson 1930:8).

Of material culture, even in 1930 the Abitibi still occasionally used bone and flint knives as well as wooden spoons and plates of birch bark (MacPherson 1930:35). For hunting, the Abitibi used a fairly long bow with an arrow headed by flint. Small game and waterfowl were shot with bone-tipped arrows, while blunt arrows were used for partridge (MacPherson 1930:38-39).

As previously mentioned, sites of the early historic Abitibi should prove immensely valuable in trying to apply the Direct Historic Approach. Frank Ridley (1966:42) has located such sites on Lake Abitibi, namely: the Ghost River Garden site, the Ghost River Island site, and the Abitibi River Point site. The Ghost River Garden site is located on a promontory at the mouth of the Ghost River, where Ridley excavated 475 square feet (Ridley 1966:34).

Thomas E. Lee (1965) excavated historic materials on the Quebec side of Lake Abitibi. His Louis and Iroquoian Point sites at the mouth of the Duparquet River are helpful in establishing the nature of the historic acculturation in this region.

Part Two: Northern Ontario Prehistory

In order to maintain a continuity with the cultural-chronological sequence currently being employed by northern Ontario researchers (Table 1), the following chronological outline will be used in discussing northern Ontario prehistory and history:

(a) Late Paleo-Indians - circa 7000 - 5000 B.C.

(b) Shield Archaic - circa 5000 - 500 B.C.

(c) Initial and Middle Woodland - circa 500 B.C. - 900 A.D.

(d) Terminal Woodland - circa 900 A.D. - 1700 A.D.

The Late Paleo-Indian Period (circa 7000 - 5000 B.C.)

The Early Paleo period equated with Clovis style points has not been identified in northern Ontario to date; however, there is ample evidence indicating the presence of Late Paleo peoples particularly in northwestern and northcentral Ontario and related developments along the north shore of Georgian Bay and on Manitoulin Island. The Late Paleo complexes are characterized by extremely well made "Plano" points similar in form to the Agate Basin points of the western plains. In northern Ontario and especially around Thunder Bay, complexes are found in direct association with fossil glacial lake beach lines, well inland from present day lake levels.

In northwestern Ontario, Late Paleo campsites are found along the Glacial Lake Agassiz strandline several kilometres inland from the present shoreline of the Rainy River and Lake of the Woods. The projectile points are characteristically lanceolate (leaf-shaped) in form, with ground bases and edges and a diagnostic pattern of shallow parallel flake scars running either diagonally or horizontally across both faces of the point (Reid 1980:3, 4).

In northcentral Ontario, a major Late Paleo occupation has been documented and dated in association with the Glacial Lake Minong beach line in the vicinity of the city of Thunder Bay (Fox 1975, 1977a, 1977b) (Newton 1975, 1977). This Late Paleo occupation termed the Lakehead Complex represents a primarily littoral (lakeshore) settlement pattern consisting of a series of small secondary campsites generally located at a point where the Minong beach line has been cut by rivers or streams draining into the lake (Fox 1975:34). In addition to these secondary sites, however, the Lakehead complex also known from a series of major quarry workshop sites (particularly the Cummins site), is associated with taconite and jasper taconite outcrops.

A second area of Late Paleo quarry/workshop activity has been identified on Knife Lake on the Boundary Waters in Quetico Provincial Park. Only one Paleo site has been located on Knife Lake to date. However, as this lake is the source of a second raw material type, felsite, which occurs in small frequencies on sites in the Thunder Bay area, the site is important as it indicates a direct association between these inland Paleo sites and the coastal Lakehead Complex sites (Fox 1977a:2).

Southeast of Sault Ste. Marie, along the north shore of Georgian Bay and on Manitoulin Island, another northern Late Paleo complex utilized a fine grained high quality quartzite. The Sheguiandah site on Manitoulin Island represents an extensive quarry/workshop operation where prehistoric peoples have been mining quartzite from the primary deposits and manufacturing stone tools from it since at least the Late

Paleo-Indian period. A series of Late Paleo-Indian sites have also been located on the mainland of Georgian Bay, which have produced stone tools attributed to a Late Paleo occupation which were manufactured Sheguiandah quartzites from Manitoulin Island. These sites are located on post-Algonquian strandlines and are assumed to represent Late Paleo occupations (Storck 1979:72; Lee 1957).

The Shield Archaic (circa 5000 - 500 B.C.)

The term Shield Archaic was initially defined by Wright as representing:

> . . . a widespread stone tool complex characterized by biface and uniface blades, lanceolate and side-notched projectile points, a wide range of scraper varieties, crude chopping and scraping-cutting tools and a paucity or absence of stone grinding.
>
> (Wright 1968a:57)

The Shield Archaic stage in northern Ontario is comparable to the Archaic period in southern Ontario in terms of its longevity, representing as it does some 5000 years of northern Ontario's prehistory; and in the fact that although it is one of the least comprehended prehistoric stages in terms of its distribution, however, it represents the most widespread prehistoric occupation in northern Ontario, stretching from the Manitoba border on the west to the Quebec border on the east and north along James and Hudson's Bays.

The Shield Archaic appears to evolve directly out of the preceding Late Paleo occupations, although this evolution remains to be demonstrated conclusively. The presence of Shield Archaic quarry/workshop and habitation sites on the Nipissing beach line (the next glacial lake stage below Minong in the Thunder Bay area), combined with an emphasis on the same raw materials as used in the preceding Paleo-Indian period and a similar technology centered on the production of large bifaces and somewhat less refined lanceolate points, supports Wright's hypothesis of a continuation. However, more work in other areas is required to demonstrate conclusively the transition. Following what appears to be the initial Shield Archaic period which is characterized by large bifaces and lanceolate points, there is an apparent proliferation of point styles including various forms of stemmed and notched points, however the lack of stratigraphic separation of these point styles have precluded establishment of a chronological order (Newton 1977).

Reid (1980:5) has identified a definite Shield Archaic occupation in the northern portions of northwestern Ontario with what has been called a Plains Archaic occupation in the southern portion. All sites are represented by a variety of notched plains point styles including Oxbow and McKean.

In northeastern Ontario, during previous research projects I identified the Abitibi Narrows Phase on Lake Abitibi, and assigned it a tentative date of circa 6000 - 3000 B.C. The Jessup site (DdGw-2) analyzed in this thesis, is a component of this phase. The phase is characterized by:

> . . . large percussion flaked (predominantly greywacke) implements, large bifaces, ovate blades, leaf-shaped bifaces, predominantly large crescentic end scrapers (over 10 grams), some small end scrapers, bifacial core chopping tools, core derived lanceolate and stemmed points.
>
> (Pollock 1975c, 1976)

The results of a recent analysis by Ingrid Kritsch-Armstrong of excavated materials from the Jessup site have demonstrated that the site is a Shield Archaic site (1982:238). Previous analysis of collections from Lake Abitibi (including the Jessup and Jordan sites) have indicated the presence of another form of artifact which may be diagnostic of the Shield Archaic period; the trihedral adze (Fox 1977c). Trihedral adzes are presumed wood working tools which are manufactured primarily from siltstones or greywackes. The adzes are roughly triangular in section, pointed at the butt end, ground to a cutting edge at the bit end, rounded on top and flat on the bottom, and flaked all over the upper surface. Similar artifacts have been recovered from northcentral Ontario from lakes adjacent to the Knife Lake greywacke deposits, from Dog Lake north of Thunder Bay, and from several other locations east of Thunder Bay (Newton 1975, Fox 1977, McLeod 1981).

I have also defined what might be a terminal Shield Archaic phase (the Mattawan Phase) dated to 970 +/- 300 B.C. on Lake Nipissing in northeastern Ontario. This phase is characterized by:

> . . . lanceolate, stemmed, and expanding convex based side-notched points, with small end scrapers, leaf-shaped biface blades, ovate bifaces, side scrapers, chipped bifacial core choppers and small retouched random flakes.
>
> (Pollock 1975c:12)

Shield Archaic occupations were also recognized from associated projectile points at the Sheguiandah site on Manitoulin Island, associated with the quartzite deposits and workshop operations (Fox: pers. comm.). There are also indications of Shield Archaic peoples in the southern Shield Extension into the eastern part of southern Ontario, particularly along the Ottawa and Mattawa River Systems (Wright 1978:24).

One of the more significant developments to occur during the Shield Archaic period was the beginning of metal working associated with native copper deposits around Lake Superior. Copper was mined, heated and hammered into a variety of artifacts, including knives, projectile points, spear points, beads, bracelets, gaff hooks, axes, adzes and chisels to name but a few types, and these artifacts formed the basis of an exchange system between the Upper Great Lakes region and groups to the south, east and west. Although there are no dates available from northern Ontario to indicate when copper began to be used, we can infer from the radio carbon 14 date obtained for the Morrison's Island site on the Ottawa River, that the industry was well underway at least as early as 2750 B.C. +/- 150 (Kennedy 1967:114, Ritchie 1969:91).

Reid notes that around 5000 B.C. the climate of northwestern Ontario became warmer and drier ". . . possibly changing the southern portion of the region into a prairie or parkland environment" (Reid 1980:5). Associated with this warming trend was a change in animal and plant populations (bison, prairie plants, etc.) and a shift in subsistence patterns. Presumably, at this time, elements of Plains Archaic culture would have begun to appear in the region. A similar warming trend is also hypothesized for northcentral Ontario, associated with a change in plant and animal communities. It has been suggested that in reaction to this change in the environment there was a corresponding change in the artifact assemblages which included ". . . a reduction in the size of projectile points and the appearance of fishing technology" (Arthurs 1979:5).

After temperatures gradually cooled and the climate and environment assumed the pattern normally associated with northern Ontario today. The subsistence patterns traditionally attributed to northern hunting/gathering groups were probably established during the la stages of the Shield Archaic Period, as indicated by the predominance of moose and beaver in the faunal assemblages associated with various prehistoric components in the region (Pollock 1975c:50).

Initial Woodland Period

Laurel (circa 500 B.C. - 900 A.D)

The term Laurel was first applied by Wilford to ". . . Middle Woodland burial mounds in extreme northern Minnesota. . . ." (Wright 1967:1). Wright, on the basis of the analysis of sixteen Laurel components in northern Ontario, lists the following as being the ". . . most characteristic traits of the Laurel Tradition . . .: ceramics sherds, scrapers, paintstone nodules, linear flakes, biface blades, projectile points, abraders, copper beads, net sinkers, ceramic wastage and copper nuggets" (ibid. 97). Wright's trait list agrees in part with that given by Stoltman for Laurel sites in northern Minnesota. Stoltman more specifically indicates that the Laurel culture is characterized by an artifact assemblage that includes:

> . . . the earliest ceramics in the area, a lithic industry typified by numerous end-scrapers and stemmed and notched projectile points, and a bone-antler industry whose hallmarks are cut beaver incisors and socketed and perforated antler harpoons. . . . Native copper was commonly worked into awls, beads and other simple forms in sites of the Lake Superior Basin. . . . and traded into adjacent areas.
>
> (Stoltman 1973:3)

Stoltman adds that:

> Evidence of contact with the Hopewellian 'Interaction Sphere' might be seen in the occasional appearance of obsidian at some sites. . . . and in the practice of mound burial in Minnesota and adjacent Ontario.
>
> (ibid. 3)

Laurel ceramics have been characterized by Stoltman as being:

> . . . tempered with crushed rock, had their exterior surfaces smoothed but rarely if ever cord marked, and had the upper rim area decorated mainly with a variety of dentate stamps, often applied in a push-pull or stab-and-drag fashion.
>
> (ibid. 3)

In northern Ontario, Laurel ceramics are quite often decorated with a pseudo-scallop shell motif; a motif held in common with Middle Woodland cultures of southern Ontario including Saugeen and Point Peninsula, with whom they interacted (Wright 1967).

The origins of Laurel are still somewhat equivocal, with some archaeologists maintaining that Laurel developed at least in part out of preceding Archaic cultures (Kritsch-Armstrong 1982, Pollock 1975), while others suggest a southern origin for Laurel peoples, who moved into the Upper Great Lakes area from a southern base (Salzer 1974, Steinbring 1974, Stoltman 1973).

Settlement data determined through excavations in northwestern Ontario indicate that, "Most Laurel sites in the region are small encampments with the remains of no more than two lodges for one or two extended families (about 25 people including grandparents, aunts, uncles, parents and children). The outline of Laurel house structures were uncovered during excavation and consisted of . . . oval lines of stones surrounding the remains of cooking hearths, the stones probably serving to weigh down the lodge coverings" (Reid 1980:9).

Laurel is widespread throughout northern Ontario, stretching east from Lake of the Woods along the Boundary Waters, along the north shore of Lake Superior and into northeastern Ontario (Newton 1975, Pollock 1975, Reid 1980).

Laurel peoples maintained the same hunting and gathering type of subsistence pattern established during the Archaic period. Stoltman (1973:113) notes that a variety of large and small game were hunted ". . . with moose and beaver being especially important." Stoltman also emphasizes the importance of fish and wild rice resources in the Laurel diet, indicated by a "pronounced seasonality that involves the intense exploitation of fish in the warmer months of the year" (ibid. 113). The presence of moose remains along with net sinkers and bone harpoons from Laurel sites in Ontario indicates a similar hunting/fishing subsistence pattern to that demonstrated in Minnesota (Newton 1974, Pollock 1975, Wright 1967).

Terminal Woodland

Blackduck (A.D. 900 - Historic Period)

Once again the origins of Blackduck are heatedly debated by archaeologists; as Arthurs notes: "We do not know yet whether they were the descendants of the earlier Laurel peoples or moved into the region from the south or a combination of both" (in Reid 1980c:13-14). The cultural affiliation of Blackduck also remains in question, some researchers attributing it to Cree or ". . . another Algonquian speaking group related to Cree," while others suggest that they are Ojibway or even Assiniboine (ibid. 14-15).

Blackduck artifact assemblages typically include:

> . . . triangular projectile points, long-bone fleshers, unilateral barbed bone points, bird bone whistles, antler flakers and side scrapers of several varieties. Ceramics are distinctive in that cord marked bodies, punctates, oblique lines on rim and lip and horizontal or herring bone lines on the neck predominate.
> (Pollock 1975c:16)

from the preceding Shield Archaic and Laurel traditions. These phases are found on the upper Ottawa/Lake Timiskaming and Lake Abitibi/Abitibi River drainage basins. An early Duncan Lake phase has been described, followed by a terminal Woodland Ghost River phase. This later phase is distinguished by the complete acceptance by Northern Algonquin peoples of the Ontario Iroquois pottery complex, including the local manufacture of Iroquois ceramics (Pollock 1975c:26).

The task of connecting prehistoric assemblages on Lake Abitibi and elsewhere is made difficult by the fact that during the early historic periods a form of Pan-Algonquian culture developed due to large scale migrations precipitated by the mid-seventeenth century Iroquois wars, the disruption of traditional movements due to the economic influence of the fur trade, which also no doubt encouraged migration; and an expansion of traditional hunting and subsistence areas. The influence of disease, the central economic attraction of the trading posts, and the new European material culture often caused a blending of cultural groups in a more homogeneous culture than in prehistoric times when the groups may have been more geographically separated, perhaps closely associated with a particular drainage system (i.e., the Moose River or Ottawa River system in northeastern Ontario). Contact between groups would have taken place but incentive for contact, travel and trade may have been much less during prehistoric times.

I believe that the late prehistoric peoples of the Lake Abitibi region were neither Cree nor Ojibway but formed part of a northern extension of the Ottawa Valley "Algonquin" peoples which were closely connected to the Lake Timiskaming Algonquin. The Timiskaming Algonquin were situated on the northeast shore of Lake Timiskaming and numbered

211 persons in 1911 (Speck 1915). They were a modified cultural group due to contact with their neighbours at Bear Island, Lake Temagami (ibid. 1915:2). Speck (ibid. 3) also mentioned that these people considered themselves to be most closely connected to the Lake Abitibi "Bluewater Peoples," and the Mattawa and Ottawa River Algonquin bands (Pollock 1976:21-41). As discussed in the preceding section, the historic confusions as to the linguistic and biological/cultural groupings can be at least partially attributed to the Iroquois raids during the 1600s, which caused considerable movement and relocation of inhabitants throughout Ontario. As a result considerable blending took place and a further blending of cultures developed during the fur trade era. This blending makes reconstruction of prehistoric peoples from ethnographic data alone an exercise fraught with confusion and error.

Part Three: Previous Archaeological Work, Lake Abitibi and Vicinity

Prehistoric sites on Lake Abitibi are both numerous and rich in artifactual remains. Evidently the area was a major centre for people since the retreat of the last glaciation and ranks in terms of numbers and density of sites among the richest within the boreal forest environment of Canada. The entire story of prehistoric peoples for northeastern Ontario from 6000 B.C. to fur trade days is present on Lake Abitibi. This complete archaeological record is rarely found in one geographical area, and greatly increases the archaeological importance of the area. Prior to 1982 some twenty-four archaeological sites were known for the lake. With the thirty-three additional sites recorded by Pollock and McLeod during 1982, the total documented prehistoric sites for the Ontario portion only of Lake Abitibi is fifty-six (see Table 4 and Figure 5).

The pioneer archaeologist on the Ontario portion of Lake Abitibi was Mr. Frank Ridley (1956, 1958, 1966). During the years from 1954 to 1962, Ridley undertook archaeological surveys and excavations which resulted in the location of archaic, middle woodland, terminal woodland, and historic sites. No further work was again undertaken until 1970. Subsequently, Justin and Marjorie Jordan undertook numerous "search and survey" expeditions continuously throughout the years 1970 to 1982. Accompanied by Bill Therriault and Bob Stewart of the Ontario Ministry of Natural Resources, I first visited Lake Abitibi during August 26 - 27, 1975. At that time I was the regional archaeologist for the Northern Region of the Ontario Ministry of Natural Resources. Later that same year, a short trip was made with the Jordans and Thor Conway, long time regional archaeologist based at Sault Ste. Marie, Ontario. It is entirely due to the foresight and initiative of the Jordans that archaeology on Lake Abitibi was carried on. Their work made possible the writer's thesis research and that of the other current area researcher, Ingrid Kritsch-Armstrong (1980, 1982).

On the Quebec side of the lake, pioneering fieldwork was undertaken by Thomas E. Lee in 1962 and 1964, the results of which were published in a 1965 monograph (Lee 1965). Since 1970, Roger Marois, of the Archaeological Survey of Canada, has excavated several mainly late woodland sites along the eastern shore of Riviere Duparquet on the Quebec side of Lake Abitibi (Kritsch-Armstrong 1980).

As well, during 1977, W. E. Noble continued the writer's 1973 excavations at the Pearl Beach Site on Larder Lake, and demonstrated occupation of the area from Shield Archaic and Laurentian Archaic times to the historic period (Noble 1980).

During 1979, 1980, 1981 and 1982, the writer undertook further fieldwork on the Ontario side of Lake Abitibi and also analyzed portions of the existing Jordan's collections from the Jordan (DeHa-8) and Jessup sites (DdGw-2). All known sites for the Ontario portion of the lake are listed in Table 6 of this thesis and illustrated on Figure 3.

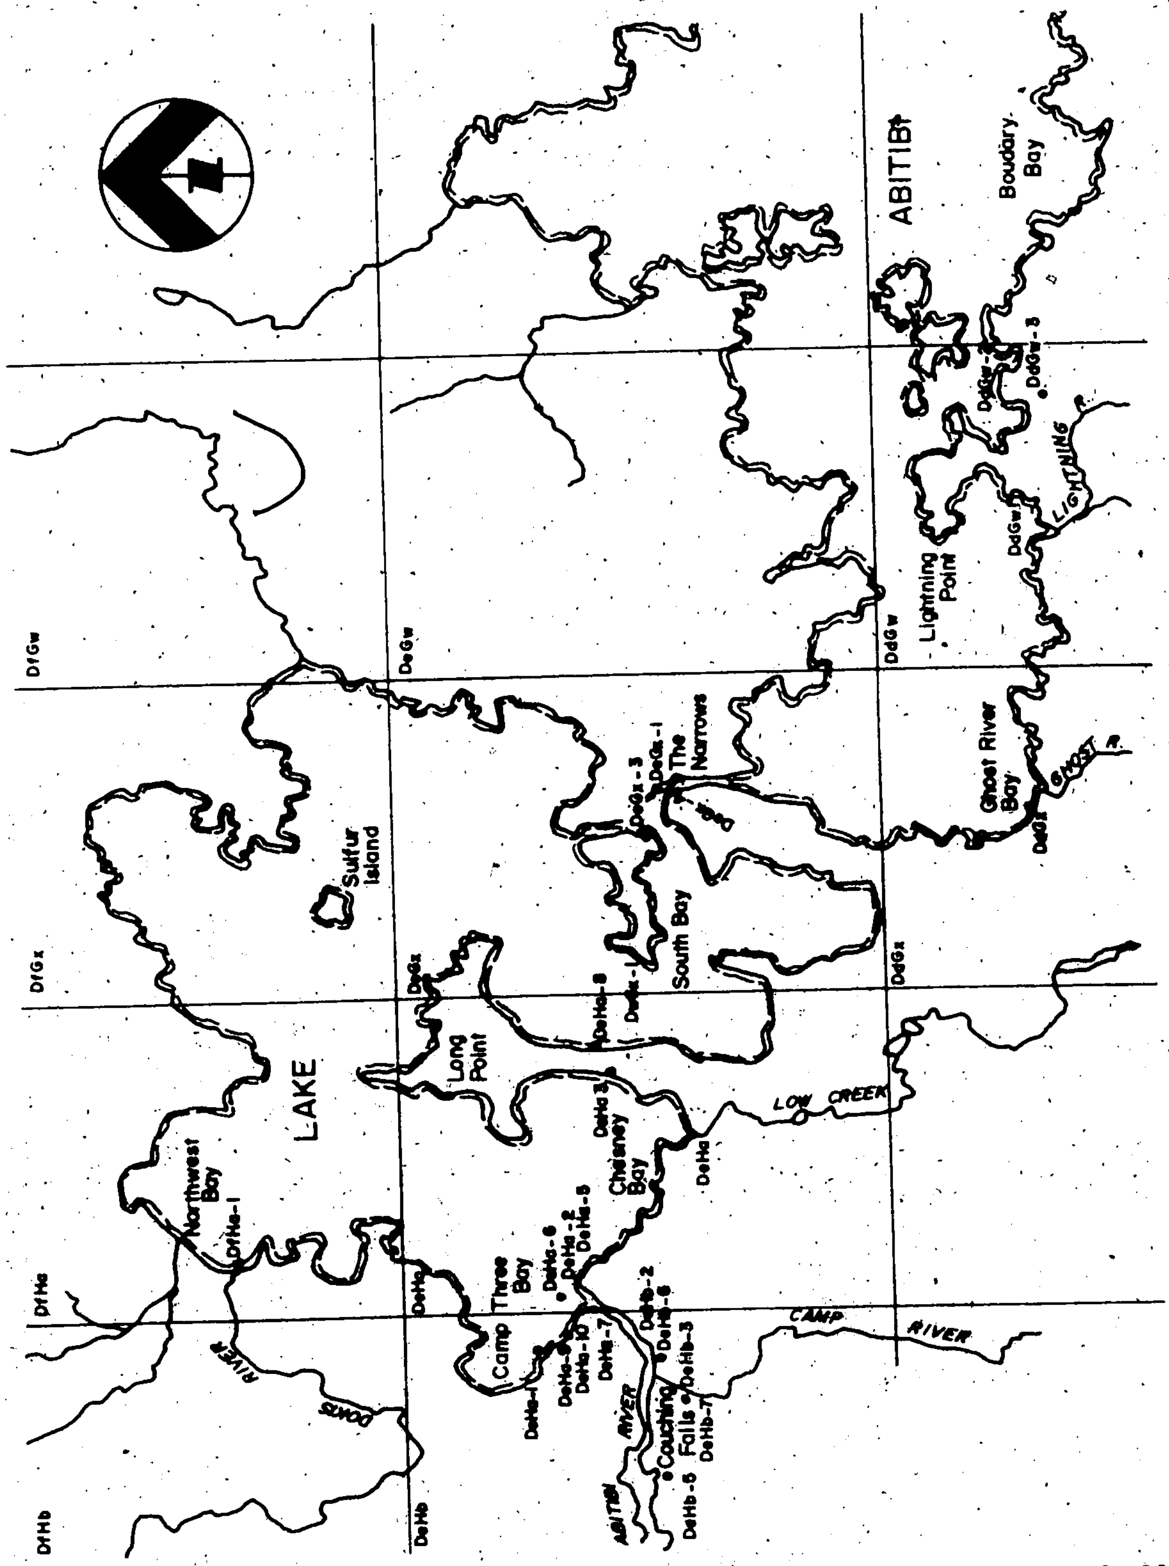

Figure 3: Map of the Abitibi River/Abitibi Lake showing location of all known archaeological sites to 1982.

Table 6: Distribution and Description of All Recorded Prehistoric Archaeological Sites on Lake Abitibi up to 1982

DeHb-15	Abitibi River shore, small rocky point	six flakes	McLeod, 1982
DeHb-16	south shore Camp 3 Bay	seven flakes	McLeod & Pollock 1982
DeHb-17	small embayment north of Bartlett Point	seven flakes	McLeod & Pollock 1982
DeHb-18	long curved sand spit	core, end scraper, Lalonde High Collar pottery - site is excavatable	McLeod & Pollock, 1982

to prehistoric Cree (The Moose River Cree Tradition, 1200 A.D. - 1650 A.D.), and northern Algonquin groups (The Northern Algonquin Tradition, 800 A.D. - 1650 A.D.) in northeastern Ontario (Pollock 1975:20-25).

The Moose River Cree Tradition represents an occupation in the western Moose River and eastern Albany River basins by indigenous Cree groups from approximately 1200 A.D. to 1650 A.D. The Northern Algonquin Tradition (Northern Ottawa River drainage system) consists of two phases, the Duncan Lake Phase (800 A.D. - 1300 A.D.) which shows ". . . clear developmental traits from the preceding Laurel Tradition and the Ghost River Phase (1300 - 1650 A.D.), with the latter exhibiting a complete sharing of the Iroquoian pottery complex" (ibid. 23). Also, I have stated that:

> This tradition geographically corresponds to the area (Lake Timiskaming - Northern Ottawa River) occupied in the early historic period by Algonquian speaking people known as Algonquins and thus, the prehistoric assemblages are deemed to relate to these people.
> (ibid. 23)

The groups now known as Ojibwa, Cree, and Algonquin may have been formed from the late prehistoric Blackduck and Selkirk as well as other late prehistoric Algonquian speaking cultures influenced by the Iroquois. I believe that the hypothesized Algonquian speaking prehistoric cultural sequence on Lake Abitibi extends back to the Abitibi Narrows phase of the Shield Archaic tradition or earlier, and is directly ancestral to historic Northern Algonquian groups and may also be specifically ancestral to Cree and other Algonquian speakers. Thus the Shield Archaic phase presents intriguing possibilities for the initial occupation and diffusion of early peoples in northeastern Ontario and adjacent Quebec (Pollock 1975c:26). As well, I have suggested that two phases of the Northern Algonquin tradition evolved

Reid suggests that Blackduck peoples in northwestern Ontario:

> . . . probably wintered in small groups of about 20 - 40 people but gathered together in large villages of several hundred people for the fall ricing and spring sturgeon runs. . .
>
> (Reid 1980c:14)

Blackduck sites have been identified from Manitoba east along the Boundary Waters and along the north shore of Lake Superior to Sault Ste. Marie where Blackduck wares appear in only very small frequencies on sites such as the Whitefish Island site. I have also identified Blackduck material in Missinaibi Provincial Park to the east of Lake Superior, and some possibly Blackduck-like wares have also been reported from the Shield area of eastern Ontario (Pollock 1975c:16-19; Phil Wright: personal communication).

Selkirk

Selkirk represents a second indigenous Terminal Woodland culture which developed at the same time as Blackduck. The two cultures overlapped in northwestern Ontario and along the coast of James Bay and Hudson's Bay. Selkirk is found to the north of Blackduck in north-central Ontario, Blackduck being located predominantly in the vicinity of the Lake Superior watershed. The major difference between Blackduck and Selkirk material culture is in the ceramics, Selkirk pottery being fabric impressed as opposed to cord impressed. Aside from this feature, the two cultures share similar patterns of subsistence and habitation. Also in northwestern Ontario there is a strong preponderance of Iroquoian pottery styles during the late prehistoric period. Selkirk is believed to represent prehistoric Cree groups. I have identified a number of separate cultural traditions in northeastern Ontario relating

CHAPTER III

GENERAL GEOLOGY OF LAKE ABITIBI AND THE MOUNT GOLDSMITH QUARRY SITE (DdGw-3)

Introduction

The geology of the Lake Abitibi region (see Figure 4) is important to the archaeological problems raised in this thesis for several reasons. Firstly, the deglaciation of Wisconsin ice puts a time limit on the earliest occupations of the area. Also important in regards to early settlement are two Pleistocene events, namely the Cochrane readvance of Wisconsin ice; and the formation of glacial Lake Barlow-Ojibway, which lasted for some 2,000 years. The Mount Goldsmith Quarry site may have been on an island in this glacial lake. A final and extremely important factor is the Precambrian bedrock. A unique formation of cherty tuff situated between ancient Archean lava flows provided a source of lithic material for aboriginal stone tool manufacture.

In this chapter a general discussion of the glacial and early history of the area is presented in section one, followed by a general bedrock geology discussion in section two, and finally in section three, details of the geology at the Mount Goldsmith Quarry Site (DdGw-3).

DdGw-2 Jessup Site	at the bottom of Lower Bay next to the east base of Lightning Point site extends for circa 2.5 km. Other than at extremely low water levels, most of the site is submerged	there are literally tons of artifacts on this major lithic workshop site. Most materials remain under water. The Jordans have a large collection used for John Pollock's dissertation research	first located by the Jordans and Jessups in 1976 (see Jordan & Jordan, 1977 report). Extremely low water levels in 1977 allowed for a large collection of materials to be made by the Jordans (see their 1977 report). In 1978 the site was flooded and, has been from 1978 to 1982. During 1979 Ingrid Kritsch-Armstrong excavated a small portion at the extreme eastern end. J. Pollock visited the site in 1979 (see Pollock's 1981 report) and again in 1982.

Part One: Glacial History of Lake Abitibi and Quaternary Geology.

The Late Glacial period begins with the Wisconsin ice retreat from the area. Once thought to have been about 10,000 B.P. (Terasmae & Hughes 1960:a & b;, Terasmae 1962:4), recent evidence has indicated an earlier time frame. During deglaciation large meltwater lakes were impounded between the northward receding glacier and the former Arctic Ocean/St. Lawrence River drainage divide. Subsequent isostatic uplift has shifted this divide northward. The levels of the various impoundments which ended with glacial lake Barlow-Ojibway were determined by "differential isostatic uplift and fluvial downcutting of these outlets" (Vincent & Hardy 1979:1). Previous research had placed the existence of Glacial Lake Barlow-Ojibway from 9,000 to 7,000 B.P. with final drainage taking place by 6,000 B.C. (Terasmae 1962:37).

More recent research by Vincent and Hardy has indicated that at the time of deglaciation the water level in the glacial lake was about 355 to 380 metres (1,164.4 feet) above sea level. A height of 355 metres would mean that only the uppermost reaches of Mount Goldsmith at a height of 396.8 metres (1301 feet) would have been an island in the glacial lake, at times completely submerged when levels reached the 380 metre level (Jensen 1978:27 in Kritsch-Armstrong 1982:31). Vincent and Hardy (1979:17) feel drainage of the glacial lakes took place some 7,900 years ago. This then would set the earliest date for occupation of the lake bed by prehistoric peoples. Of importance to regional early man studies is the fact that much earlier, Lake Barlow had become separated from Lake Ojibway by the water free Angliers sill (Vincent & Hardy 1979:Fig. 36, p. 15). As mentioned, it is important to date the

drainage of the glacial lakes in the region in order to date the earliest possible age of occupation for sites on the former lake beds. However, it is also a distinct possibility that man was living along its shorelines and on islands in the area before drainage of the glacial lakes. Thus, there are two critical geological dates; the initial retreat of the ice from the land and the final drainage of the post-glacial meltwater lakes. According to Hillaire-Marcel and Vincent (1980:48) the date for initial deglaciation of the Lake Abitibi area is between 9,500 - 9,000 years B.P., with the Cochrane readvance of ice (just north of Lake Abitibi) dating to 8,500 - 8,000 years B.P. Glacial Lake Ojibway existed in the area for about 1,600 years, with final drainage taking place about 7,900 B.P. Thus, the Jordan and Jessup sites located on the bed of the proglacial Lake Ojibway should not date earlier than 7,900 yrs. B.P. Any possibility of earlier sites would depend on a few restricted localities, such as Mt. Goldsmith which may have been islands in the glacial lake. Sites on these restricted areas could date as early as 9,500 yrs. B.P. Also of concern would be fluctuations in the level of modern Lake Abitibi. Hughes suggested (1955:39) that at some time in the past modern Lake Abitibi may have existed at a higher level. The terraces of this lake, if they can be identified, may be of use as well in dating archaeological sites. A summary of the glacial chronology is provided in Table 7. The dates listed above are about 1,000 years earlier than those formerly postulated for the area (see Pollock 1976:11).

There are conflicting data regarding paleo-environmental flora and climate. Northeast of the Abitibi area in Quebec a transect of five radiocarbon-dated pollen diagrams from lake sediments showed that the

Table 7: Glacial Chronology

Time	Event	Climate	Flora
8000 - 7000 B.C. (10,000 - 9,000 B.P.)	Retreat of ice north of Lake Abitibi	arctic and sub-arctic	predominantly aspen
7000 B.C. (9,000 B.P.)	Glacial Lake Ojibway forms	sub-arctic	aspen with black spruce and jackpine
6500 - 6000 B.C. (8,500 - 8,000 yrs. B.P.)	Cochrane I & II Glacier ice readvance (does not cover Lake Abitibi	sub-arctic	dominated by aspen as above
5900 - 5250 B.C. (7,900 - 7,250 yrs. B.P.)	Draining of Glacial Lake Ojibway	close to modern climatic conditions?	black spruce, jack-pine, balsam fir and white birch
5250 - 4000 B.C. (7,250 - 6,000 yrs. B.P.)	Water levels lower than modern level?	warmer and drier than present	Great Lakes Forest, closed forest beginning and climax of white pine (Pinus strobus)
4000 - 1250 B.C. (6,000 - 3,250 yrs. B.P.)	more open vegetative cover	warmer & drier than present	Great Lakes & Boreal Forest, open forest with juniper (Juniperus) and alder (alnus crispa)
1250 B.C. to Present (3,250 yrs. B.P. to Present)	modern drainage systems	modern climatic conditions (see Table 3)	Boreal Forest with a few remnant Great Lakes species in sheltered areas

initial landscape following deglaciation was a quasi desert rapidly followed by an Aspen Parkland (Populus) and an open spruce (Picea mariona), alder (Alnus crispa) and dwarf birch (Betula glandulosa) woodland. About 2,700 B.P. the present day forest stabilized (Hillaire-Marcel and Vincent 1980:133). As the above area, situated between latitudes 53 and 55 degrees, is considerably north of the study area (between latitudes 45 and 50) and is located to the east of the James Bay lowlands in contrast to Lake Abitibi located south of the lowlands, the climate and flora could have been quite different in the Lake Abitibi region.

Of considerable importance are early paleo-environmental data collected by Marois from pollen cores obtained at Lake Cleo and Yelle, 10 km south of Lake Abitibi, and analyzed by Pierre Richard (Kritsch-Armstrong 1982:33). Data from this study indicates that trees were growing along the southern shore of the glacial lake even as the north shore was a solid wall of retreating glacial ice. The early colonizers were predominantly aspen (Populus tremuloides) along with black spruce (Picea mariana) and jackpine (Pinus divaricata). These species, together with balsam fir and white birch, spread over the freshly drained glacial lake bottom and covered it for a 500 year period following glacial lake drainage about 7,900 yrs. B.P.

As indicated in Table 7, during this short period climatic and flora conditions may have been close to modern day circumstances, although during this short early period (7900 - 7200 yrs. B.P.) megafauna such as mastodon (Mammut americanus) may have found this to be a refugium area. Mastodons in North America lived in cool temperate conifer and mixed forest zones along with caribou and moose.

Following the initial establishment of vegetation on the exposed glacial lake bottom, a warmer and drier period is indicated by the establishment of a white pine (Pinus strobus) forest on suitable sites from 7,200 - 6,000 yrs. B.P. followed by a more open forest cover with climatic conditions around 3,250 yrs. B.P. (Richard 1979 in Kritsch-Armstrong 1982:35). In contrast to Kritsch-Armstrong's statement that the warmer and drier period lasting some 4000 years from circa 7,200 - 3,250 B.P. probably did not cause environmental changes that would force environmental adjustments on prehistoric peoples (Kritsch-Armstrong 1982:36), one could take the alternative view that these changes may have had a very great effect.

In summary, the late glacial and post-glacial history and chronology dictates not only the earliest date for initial occupation of the area by aboriginal peoples but also indicates a number of environmental shifts that may have been reflected in the culture of peoples resident in the area. There may be a possibility then, that these environmental shifts are reflected by technological differences in the prehistoric lithic tool kits.

As dating of the glacial events in the area becomes more refined, the trend is clearly toward an earlier rather than later initial deglaciation of the study area. A recent minimum deglaciation date for the Larder Lake area just south of Lake Abitibi, taken on a sample of organic material at the base of a four-metre section, shows the area to be ice free at 9,990 +/- 260 yrs. B.P. (Cameron Baker, Ontario Geological Survey: 1980 map sheet 2381). With a minimum date for deglaciation of 8000 B.C. there is ample time to postulate late Paleo-Indian or Plano occupations in the area. Clearly, further paleo-environmental work is needed, especially radiocarbon dated pollen cores, so that the dates for potential occupation by man, plants and animals and their environmental contexts can be precisely delineated and related closely to the archaeological record.

Quaternary Geology - Surficial Deposits

Pioneering work on the surficial geology of the area (Figure 4) was undertaken by Owen L. Hughes (1955) and A. N. Boissonneau (1965). More recently, E. D. Frey (1975, 1976) and Cameron Baker (Baker et al. 1980) have continued research into the Quaternary geology of nearby Shield and lowlands areas. To date, however, Hughes is the only researcher to have undertaken field research within the specific area under discussion (Figure 4).

Although the final known re-advance of the Wisconsin glacier occurred just to the north of the study area and may even have reached the north shore of Lake Abitibi (Larry Jensen: personal communication), as yet, no evidence has been found for Cochrane till (see Table 8) of the North Driftwood Formation (Hughes 1959 & 1965, INQUA 1977) dating to the Driftwood Stadial (time of the last ice re-advance) existing on the south shore of the lake. Thus, it is entirely possible that early aboriginal sites and post glacial Lake Barlow-Ojibway deposits were not disturbed by the Cochrane re-advance, dated at circa 8,000 years B.P. The re-advance of the ice sheet is thought to have a duration of about 300 years (Terasmae & Hughes 1960, Hughes 1965, Skinner 1973).

One of the most important depositional factors affecting surficial deposits in the study area was the proglacial Lake Barlow-

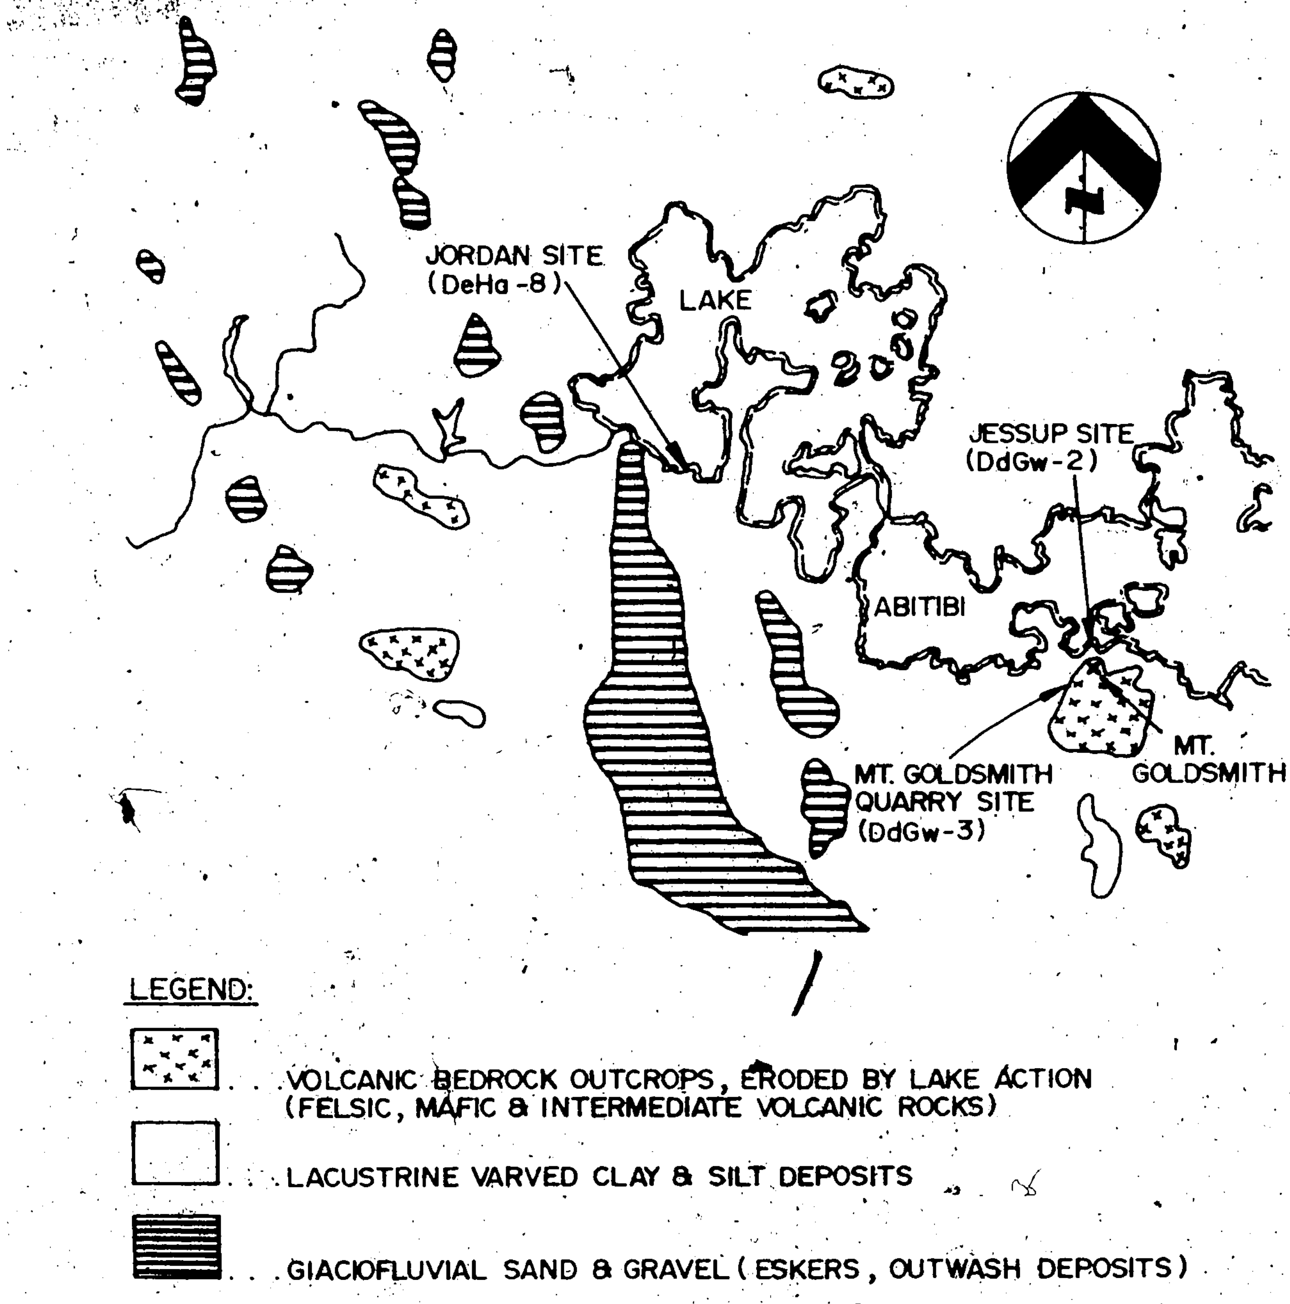

Figure 4: Generalized surficial and bedrock geology of study area.

Frecheville Township and Area, Lake Abitibi

CENOZOIC

Postglacial and Recent

Colluvium (slope deposits)	–	sand, gravel, cobbles
Alluvium (includes beaches on Lake Abitibi)	–	silt, fine sand, storm beaches present day Lake Abitibi
Organic sediments (bogs)	–	peat, carbonaceous mud

Pleistocene

Barlow-Ojibway Formation:

Glaciolacustrine Sediments	-	(1)	varved clay deposited on the lake bottom.
		(2)	shore and near shore deposits, sand, boulders and cobble beach deposits, etc., stratigraphically higher than unit one above. North-south trending.
Glaciofluvial Sediments	-		sand and gravel eskers; cobbles, outwash plains.

Matheson Formation:

Till Deposit	-	sandy with assorted boulders, pale blue-grey, weathering to pale grey-brown, friable flakey texture; lens of silty gravel near top. Forms an almost continuous sheet in the region.
	-	lenses of gravel and sand in till.

- Unconformity -

* There is no evidence at present that the area was ever covered by the Cochrane readvance (Hughes 1950:42), or also known as the Driftwood Stadial (Dreimanis & Karrow 1972); the last major southward readvance of the Wisconsinan Continental glacier.

Table 8 continued

Unnamed Formation:

Till	- unconfirmed remnant tills from other glaciations may be present in deeply buried valleys.

- Unconformity -

PRECAMBRIAN

Early Precambrian (ARCHEAN)

Felsic Intrusive Rocks	- feldspar porphrydikes - hornblende - feldspar porphrydikes - lamprophyre

- Intrusive Contact -

Mafic and Intermediate Intrusive Rocks	- gabbro and quartz gabbro diorite.

- Intrusive Contact -

Felsic Volcanic Rocks	- massive rhyodocite and rhyolite - rhyolite breccia - rhyolite tuff - rhyodocite and rhyolite with quartz phenocrysts * - cherty bedded rhyodocite and rhyolite - rhyodocite and rhyolite dikes
Intermediate Volcanic Rocks	- andesite and dacite, pillow flows, tuffs - argillite and graphitic sedimentary rocks - andesite and dacite dikes
Mafic Volcanic Rocks	- massive basalt and andesite, pillow lavas, basalt and andesite tuff-breccia

(The above Table is taken from: Frey 1975, 1976; Hughes 1955; Lumbers 1962; and L. S. Jensen 1972).

* Source of aboriginal lithic material for stone tool manufacturing.

Ojibway which existed for some 2,000 years from inception to drainage (Terasmae and Hughes 1960:1446). During that time the lake laid down major bottom deposits of glaciolacustrine sediments, mainly thick accumulations of varved clays and silts. Hughes noted that where the Barlow-Ojibway varved clay is exposed, varves are not always recognizable in the upper metre or so of the deposit, because they were obliterated by soil forming processes and/or wave action (Hughes 1965:38).

Remnant beach ridges of sand and cobbles are also present. These would be of interest for early man sites in the area. It is quite possible that the Ghost Range and specifically Mt. Goldsmith (elevation 396.8 m; 1,301 feet) (Figure 4) was an island in the glacial lake. Therefore, early man sites may be located along former shorelines of the island at some distance from present day Lake Abitibi. As the chert source is located on these islands and Mt. Goldsmith specifically, possibly early peoples (travelling by water) utilized these flakable rocks.

Also of significance are the glaciofluvial sand and gravel eskers and broad outwash plains or sand deltas. Several eskers (steep sided ridges of sand and gravel) are present west of Mount Goldsmith and south of Lake Abitibi (Figure 4). Eskers have a distinctive profile characterized by undulating high nodes and low saddles with nodal crests high above the surrounding topography (Frey 1976:13). These landforms would have served as possible travel routes for early peoples and large ungulates such as moose and caribou.

A stratigraphic sequence is available for the south shore of Lake Abitibi, between the Jordan and Jessup sites on the west side and 1.93 km (1.2 miles) south of Long Point. From the lake level up there is sandy clay, greasy blue-grey clay, and dark grey clay containing shells of freshwater mollusks. These are overlain by 17 feet (5.2 m) of Barlow-Ojibway sand and gravel (Hughes 1955:38). Hughes comments that the massive post-glacial clay "appears to record a somewhat later stage than does the unvarved silty clay . . . perhaps a stage in which Lake Abitibi existed as a separate glacial lake but at a level above the modern one" (Hughes 1955:39). The foregoing is significant as regards early sites and settlement patterns in the area. Again, if Hughes is correct very early sites could be situated on high terraces around the lake. Thus, not only may former shorelines of the glacial Lake Barlow-Ojibway yield early human occupation sites, but former shorelines of a much larger Lake Abitibi may also be present, with sites situated on an intermediate shoreline between the early glacial lake shoreline and more recent modern shoreline. Such terraces or shorelines have not yet been recorded for the area and therefore, precise identification of these features (if they are present) awaits further geological research.

The oldest tills in the study area, lying below the glacio-fluvial sediments are tills of Wisconsin age including the Matheson Formation (Hughes 1965:10), the oldest known surficial unit in the study area. It "occurs as an almost continuous sheet in the region at the surface or beneath younger deposits, except for local discontinuities over bedrock hills" (Hughes 1955:11). In many areas the Matheson Formation lies beneath the varved clays of the Barlow-Ojibway Formation. The Matheson Formation in places contains large boulders and rocks derived from underlying Precambrian bedrock. It is also possible, but not confirmed, that some still older tills may be present in buried valleys.

As mentioned, Hughes is the only geological researcher to have undertaken extensive field work in the surficial geology of the immediate study area (Figure 4), and therefore the available surficial data is largely restricted to this one reference source.

Part Two: Bedrock Geology of Lake Abitibi

The Canadian Shield is one of the world's largest exposures of Precambrian rock, and one of the oldest and most stable bedrock areas in existence. The Canadian Shield, centered around Hudson's Bay, is comprised of seven structural provinces and thirty-four subprovinces (based on differences in folding, structural, and age aspects) (Stockwell et al. 1970:45, 46).

The geological study area of this thesis (Figure 4) is located in the Superior Province and more specifically in the Abitibi Belt Subprovince. The Archean rocks in the area include metavolcanic, metasedimentary and plutonic rocks accompanied by minor Proterozoic Sediments and igneous rocks (see Table 8). The area is noted for its large and rich mineral deposits centered near the present day mining communities of Timmins, Kirkland Lake and Rouyn-Noranda (Goodwin 1980:44).

One of the earliest geological descriptions of Lake Abitibi is provided by Walter McQuat of the Geological Survey of Canada, who conducted a micrometer survey of the lake in July 1871. His description of the lake is of some interest, for it dates before the waters were artificially raised .91 m (3 feet) by the Abitibi Pulp and Paper Co. dam on the Abitibi River at Iroquois Falls. According to McQuat, the lake at that time was thirty-three miles long and two to eight miles wide,

> . . . except a little to the eastward of the middle, where a bay extends eight or ten miles to the north, and another bay directly opposite increases the width of the lake two or three miles southward, giving the upper lake a total width here of about seventeen miles. . . . The shoreline in both lakes is exceedingly irregular and the number of islands in all parts is very great.
>
> (McQuat 1873:126)

In describing the rock formations of the area he mentions that:

> The rocks belong to the same two classes met with farther south. Gneissoid and granitic rocks occur all along the north side of the upper, and on the southeast side of the lower lake, while the other portions of both are occupied by micaceous, hornblendic, and chloritic schists, fine grained hard quartzites, diorites, and dioritic schists, with serpentines.
>
> (Ibid. 126)

Also of note relative to this dissertation are the hills of "light greenish-grey compact diorites" mentioned by McQuat (1873:128). These are no doubt the hills of the Ghost Range (Figure 4). In regard to these hills he mentions that,

> They are precisely similar in appearance, and from one of them which was ascended, and which rises to a height of about 400 feet above the lake, the country was studded with them as far as the eye can reach, looking southward as well as east and west.
>
> (Ibid. 128)

The rocks of the Abitibi region are entirely Precambrian in age (Table 8) (Lumbers 1962:6). According to Lumbers (1962:6, 7), they "comprise a complex of metavolcanic and metasedimentary rocks intruded by sills, dikes, stocks and batholiths that vary widely in composition and age." The volcanic rocks in the area are related to individual volcanic eruptions which were close-spaced fissure controlled vents (Goodwin 1980:46). The rocks are typically basalt lava and associated gabbro intrusions, overlain by more andesitic flows, tuffs and breccias. Felsic volcanic rocks such as rhyolite and dacite are common in upper lava flows. Interflow material is generally sparse but in certain areas such as the Mt. Goldsmith quarry site, chert and iron formation sediments are present between the flows (Goodwin 1980:44; Jensen 1972). These rocks though of limited areal extent (Plates 1 and 2) are most important because they contain a lithic raw material suitable for prehistoric stone tool manufacture.

In regards to the specific bedrock geology in the vicinity of the Mount Goldsmith and Jessup archaeological sites, the bedrock consists of the Kinojevis Group volcanic bedrock formation, comprising:

> . . . mafic and intermediate volcanic rock intercalated with thin units of jaspilite and graphitic chert and argillite. Gabbro and dorite intrude the volcanic rock . . . and a few dikes of feldspar porphry cut the volcanic rock near the southern shore of Lake Abitibi . . . along the southern shore of Lake Abitibi . . . the rocks are altered to upper green-schist facies of metamorphism along narrow shear zones and near feldspar porphry dikes.
> (Jensen 1972: Preliminary Map p. 823, and 1978:234)

Within the above formations, the specific occurrence of the cherty or welded tuffs suitable for aboriginal tool manufacture has been also described by Jensen as follows:

> . . . finely laminated cherty tuffs were noted between the lava flows. In the north, in the lower parts of the volcanic sequence, the cherty tuffs are associated with magnetite and jasper. Higher in the volcanic sequence, the cherty tuffs are associated with argillite and graphite.
> (ibid. 1972)

Jensen also states that three volcanic rock sequences are present in the area. The archaeologically important Kinojevis Group (4000 metres thick) contains, within its lower 1000 metres, "interflow units of tuff breccia, crystal tuff and cherty tuff of cale-alkalic dacite and rhyolite composition, as well as chert, argillite, graphite and cherty oxide iron formation" (Jensen 1981:234 in Kritsch-Armstrong 1982:45). The term "cherty" or "welded tuff," can also be used as a composite term to include other possible materials for prehistoric use such as andesite and dacite tuff, cherty bedded rhyodacite and rhyolite. These are about 2,719,000,000 years old (Kritsch-Armstrong 1982:47). All the above are found relatively close together within the Kinojevis volcanic group.

The significance of the bedrock geology to the prehistoric peoples is explored in the following and final section of the chapter.

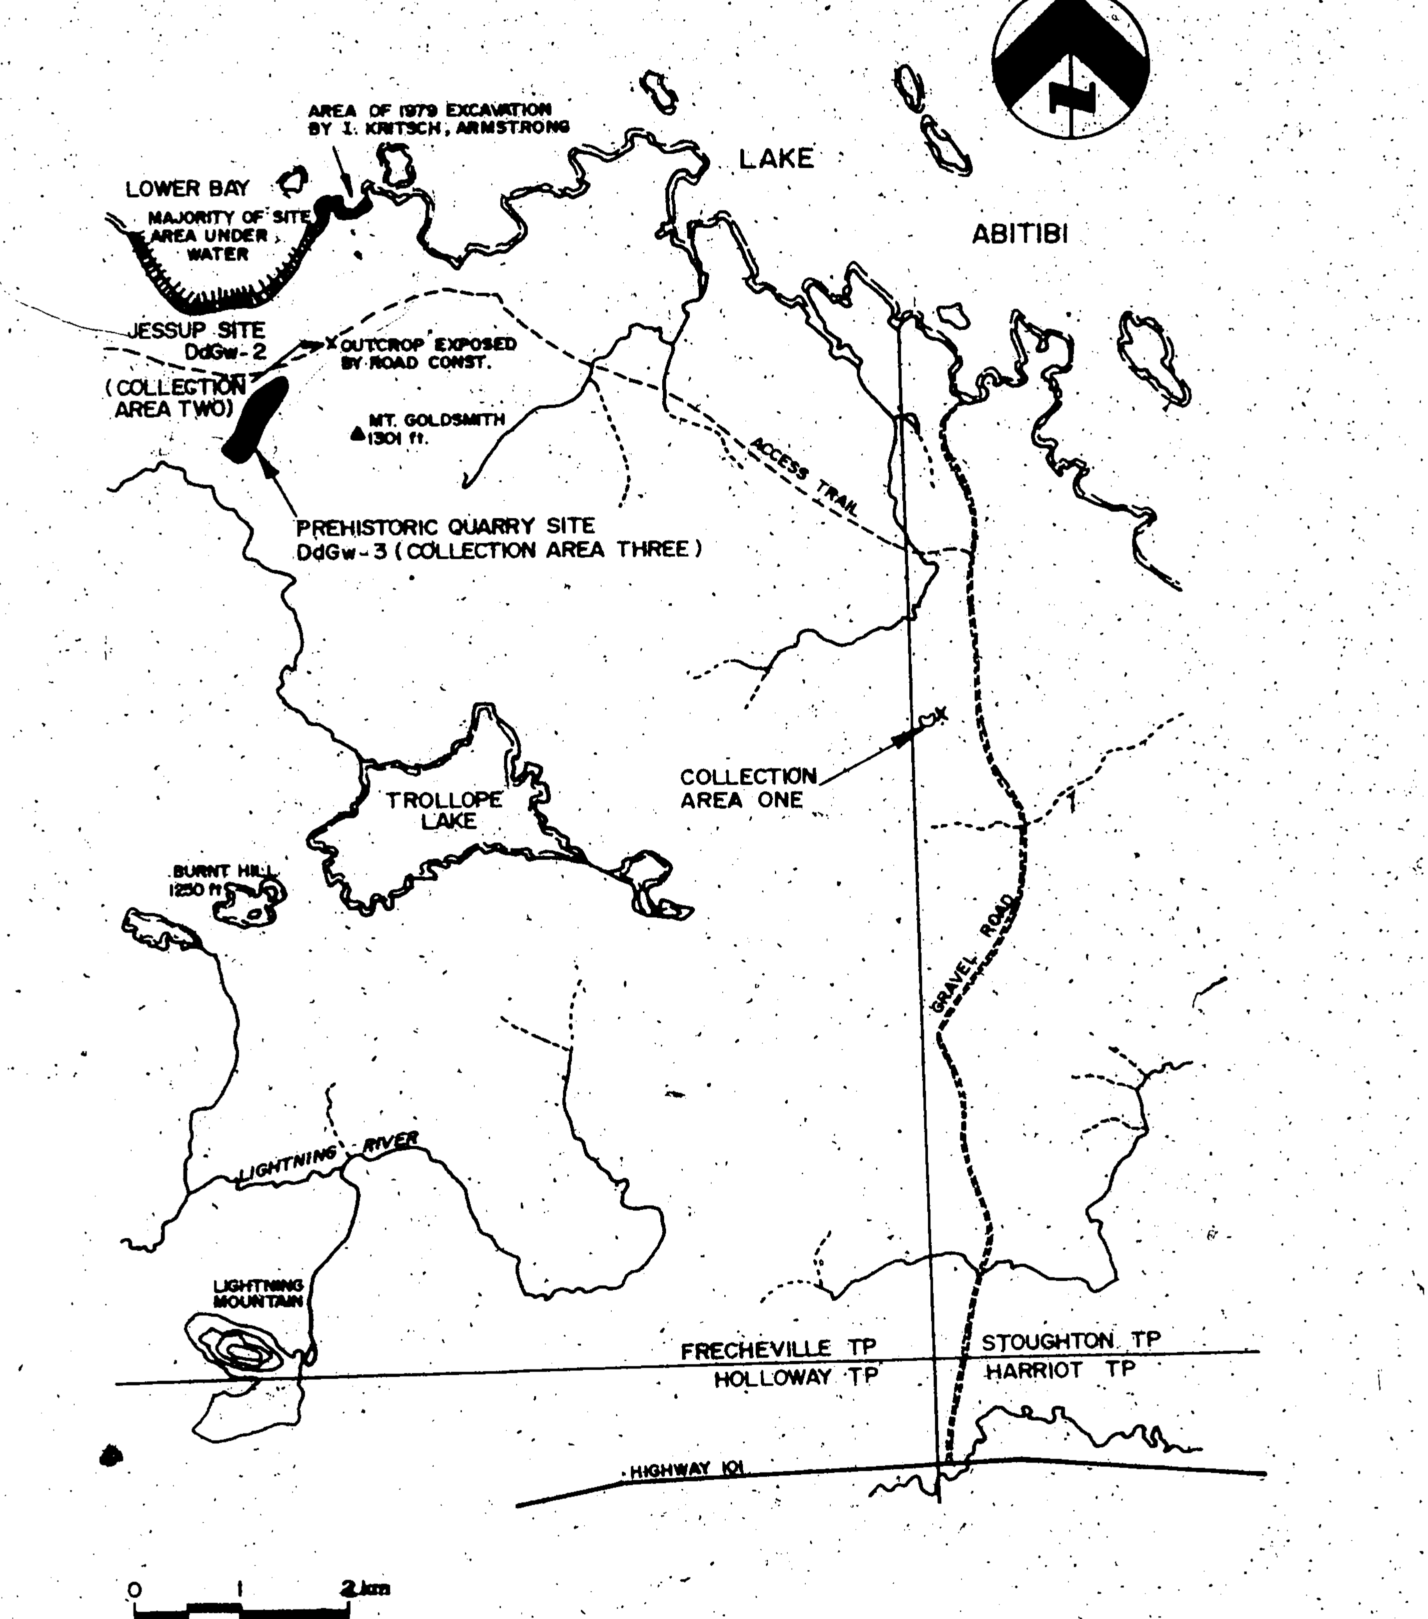
Part Three: Geology of the Mount Goldsmith Prehistoric Quarry Site (DdGw-3)

Of importance to this dissertation is the previously described Kinojevis formation which supplied the aboriginal flintknappers of the area with a source of raw material for stone tool manufacturing.

During August 1980, I was fortunate to meet Mr. Larry Jensen, a Geologist with the Mines Division of the Ministry of Natural Resources. Mr. Jensen conducted geological mapping in Stoughton and Frecheville Townships during 1972 (Figure 5), and completed his Ph.D. thesis on the area during 1981. With the assistance of Mr. Jensen and his field crew we were able to relocate in the field the "cherty welded tuff" rock formation that extends for about 12 km in a 'V' configuration through Stoughton and Frecheville Townships and outcrops at only seven places on the surface (Larry Jensen: personal communication) (see Figure 8). This deposit is composed of silicious volcanic ash deposited in graded beds (not thicker than one or two metres and averaging much less). The ash was deposited between lava flows, and now has the physical properties of a medium to fine grained green chert. The formation forms a 'V' shape with the bottom of the 'V' extending to within 2,000 feet (610 m) of the lake. Close to the lake, the "welded tuff" is associated with a thin (10 cm thick) band of magnetite and red jasper. The laminated chert formation is unique to this one small area and indeed rare even on a world wide basis (Larry Jensen: personal communication).

The formation containing the welded (laminated) tuff comes closest to the lake at the Mt. Goldsmith quarry site outcrop (Figure 5). There are no exposures closer to the lake. During 1982, we checked the

Figure 5: Map of Mt. Goldsmith and area showing the Prehistoric Quarry Site (DdGw-3).



outcrops between the Mt. Goldsmith quarry and the lake, but no further outcrops of welded tuff (green laminated chert) were located and none of the rock formations between the quarry and the lake contain material suitable for stone tool manufacture. It is the writer's opinion that other aboriginal quarry locales may exist in the area but that these are at a greater distance from the lake.

During 1980, for the purposes of conducting the cognitive lithic experiments utilized in this thesis, three outcrops were examined and a large collection of raw material was made from two non-aboriginal utilized outcrops and loose pieces of non-utilized material from the actual quarry site area (see Table 9 and Figure 5) for replicative experimental lithic work. Larry Jensen assisted the writer in collecting these samples.

The third group of three outcrops visited (Figure 5) was the Mount Goldsmith Quarry Site (DdGw-3) close to the flank of Mount Goldsmith (elevation 1,301 feet) on a high outcrop and within visible distance of the Jessup lithic workshop site (Plate 3). During the 1980 examination, I did not have sufficient time to conduct extensive sub-surface testing nor were any archaeological specimens collected. Some surface raw material for experimental purposes was taken from non-aboriginal altered portions of the rock outcrop as documented in Table 9.

In order for rock materials to be suitable for tool manufacture or for experimental flintknapping, they must possess a number of characteristics such as a concoidal fracture. For the prehistoric knapper, aside from favoured materials obtained by trade, the vast majority of materials were obtained locally or regionally. Thus,

depending on the area, prehistoric peoples used chert, flint, argillite, silicified siltstone (greywacke), quartzite, chalcedony, obsidian, basalt, quartz or any other hard, fine grained, siliceous rock exhibiting a concoidal fracture. An important distinction has been made, however, by R. Bonnichsen who states:

> . . . there are two major classes of brittle solids: crystaline and amorphous . . . . Amorphous materials used in tool making such as obsidian, are isotropic and have the same properties in all directions . . . crystalline materials (such as quartzite) have different properties in different directions (i.e., along bedding planes) and are called anistropic. (Importantly) . . . the same body of theory can be used to explain fracture features in both isotropic and anisotropic materials.
> (Bonnichsen 1977:94)

The welded (cherty) tuff used by the prehistoric peoples of Lake Abitibi and also used for the experiments undertaken as part of this thesis is an anisotropic material in that it has very distinctive bedding planes. Within the cherty interflow formation and in related andesite, dacite and cherty rhyodacite zones there are, however, a number of distinct grades of material in regards to grain size, degree of silica present and ease of working. At the centre of the laminated chert formations are thinly bedded laminates (see Plate 2) of a pale to dark green fine-grained elastic chert.

In regard to prehistoric exploitation of the chert formation of the quarry site, the quarry is located within visual sight of the Jessup lithic workshop site (Plate 3, Figure 5) as speculated upon long before discovery by the Jordans, Kritsch-Armstrong, and the writer. Although the surface materials collected by the writer and used for our experiments were somewhat fractured (Plate 4), aboriginal peoples could have obtained better materials by quarrying the bedrock. Other raw materials were available to prehistoric peoples as along the edges of the chert are coarser andesite and dacite tuff and/or cherty bedded rhyodacite and rhyolite (Jensen 1972). Although the finer grained, more elastic and easily worked green chert was preferred by aboriginal peoples, use was also made of the less elastic, harder to work and coarser grained materials mentioned above. For experimental purposes a range of materials was collected during the writer's 1980 geological expedition into the area led by Larry Jensen. On a lithic materials scale from 5.5 to .5 (Callahan 1979:16) the fine grained laminated chert rates a 3.5 while the coarser rhyodacite, andesite and dacite peripheral materials rate only 4.5 to 5.0.

The artifacts from the Jordan site include very large bifaces, numerous other bifaces, extremely large crescentic end scrapers, trihedral adzes, unifaces, flake scrapers, and uniface blades made from large crescentic flakes (see Plates 6 and 7). This assemblage in some respects is comparable to the Caribou Lake complex found on the east side of Lake Winnipeg (Steinbring & Buchner 1980:25-29).

Dating the Jordan site materials remains a problem. A few small pieces of bone (10 grams) are available from the site, and these will be saved for radiocarbon-14 accelerator dating when it becomes available commercially in a few years. The problem of dating the site is also complicated by the possibility of minor mixture from some later components.

There are other similarities between the Jordan site and the Caribou Lake complex. The Jordan Site is situated, like the Caribou Lake complex, on the shore of a very large water body. The Jordan site is situated in an area of extremely low elevation on lacustrine clay and has been inundated by flooding. Even allowing for modern flooding levels due to the dam on the Abitibi River, the fact that the entire site is under water and is still partially covered even when water levels reach close to natural levels, indicates that the site was occupied during the prehistoric period of lowest water levels. This surmise is further supported by the fact that the sandy terrace not far to the rear of the site was never occupied, as this terrace was extensively subsurface tested during my 1979 fieldwork at the site. As outlined in Table 5, paleoenvironmental evidence shows that the warmest and most arid period was the time span between 5250 B.C. to 4000 B.C. (7,250 - 6,000 yrs. B.P.). The fact that the site is situated on

JORDAN SITE

CHAPTER IV

PREHISTORIC SITE DESCRIPTIONS AND METRIC ANALYSIS OF THE ARCHAEOLOGICAL/PREHISTORIC ARTIFACTS

Part One: Jordan Site (DeHa-8)

Before proceeding further with the thesis, a preliminary description of the three prehistoric archaeological sites forming the archaeological basis of this thesis is in order.

The Jordan Site, a prehistoric campsite, first located in 1973 by Justin and Marjorie Jordan of Iroquois Falls, Ontario, was surface collected by them during the years 1973, 1974, and 1975 (Figure 6). As the site has been continuously inundated since 1975 it may have been destroyed by the continuing high water levels and storms. During a visit to the site by the writer in 1979 the site was completely under water (Plate 5). Extensive subsurface testing of all above water areas near the site failed to produce any cultural materials. The majority of the archaeological specimens, including the important large bifaces, came from a 2 m x 2 m feature area. The remaining materials were spread over a 70-metre length of low clay shoreline overlaid by a thin layer of water deposited sand. Materials were found among the larger boulders present on the shoreline, along with numerous fire broken rocks (Jordan, Jordan, and Crockatt 1976:17). All of the prehistoric artifacts under study from the Jordan site were collected by Mr. and Mrs. Jordan.

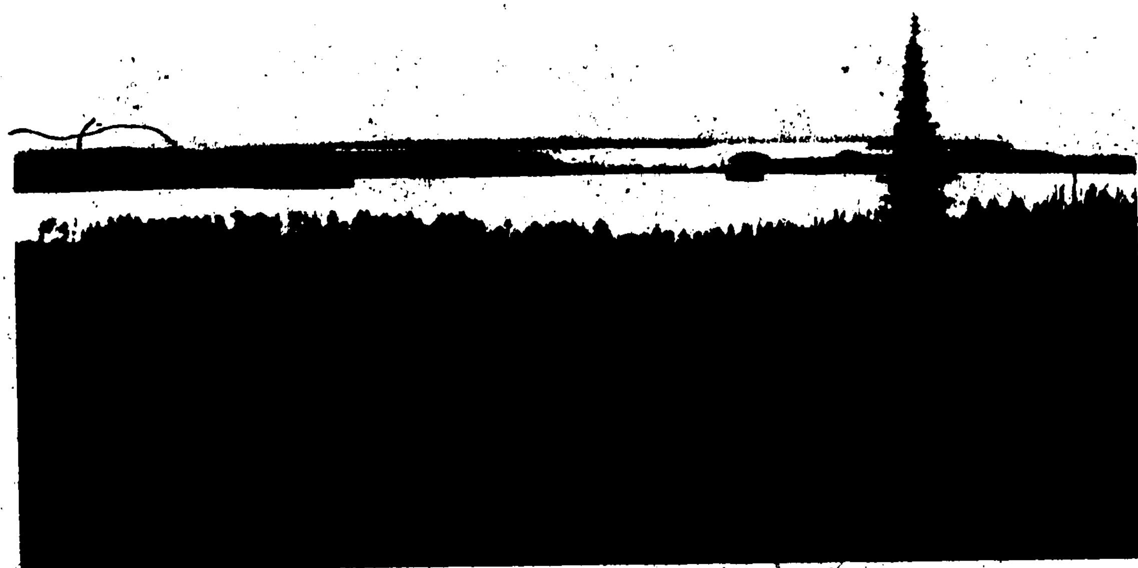

Plate 3: View toward Lake Abitibi and the Jessup Site from the Mount Goldsmith Quarry Site. (1980 photo).

Plate 4: Highly fractured (but fine grained) lithic material available on surface at Mount Goldsmith Quarry Site. (1980 photo).

Plate 1: The welded (cherty) tuff formation outcrops in centre of photo. Outcrop exposed at base of Mt. Goldsmith near former logging road. (1980 photo).

Plate 2: Close up of thinly laminated chert beds at centre of formation. A thinly bedded iron and jasper unit is also associated. Both chert and iron formation units average about 10 cm in thickness. (1980 photo).

lacustrine clay places a maximum date for the site at the time of the glacial lake draining 5900 B.C. (7,900 yrs. B.P.). The warmer and drier post glacial hyperbissal period lasted until 1250 B.C. (3,250 yrs. B.P.) but a possible break occurred during the 4000 B.C. to 1250 B.C. period (6,000 - 3,250 yrs. B.P.) when a trend towards more modern conditions may have become established. From this paleoenvironmental and settlement pattern evidence, the writer concludes that the Jordan site was occupied during the maximum of warm temperature and aridity in the Lake Abitibi region, a dating which would place it in the period immediately following glacial lake drainage from 5250 B.C. to 4000 B.C. (7,250 to 6,000 yrs. B.P.). This time frame corresponds well with the suggested time frame for the Caribou Lake complex dated by similar evidence to between 5500 and 4500 B.C. (7,500 to 6,500 yrs. B.P.) (Steinbring & Buchner 1980:33).

The primary purpose of the investigations during the 1979 field-work at the Jordan site (DeHa-8), was to investigate the potential sub-surface artifact occurrences at the site. This work was not possible due to high water levels. In fact the site has been continuously under water since 1975 (M. Jordan: personal communication). However, all areas in the general vicinity of the site were extensively tested by single shovel hole testing (0.25 m square) with entirely negative results. Special attention was paid to the remnant esker behind the site some 30 to 60 metres back from the present shoreline. Although one might expect to find archaeological materials here, none were located despite forty 0.25 x 0.25 metre test pits placed at random along the rim of the sand topographic feature. As mentioned, this work strongly supports the premise that the site was occupied during times of extremely low water levels. The fieldwork phase of the project extended from July 10th to July 27th, although before and after that time considerable effort was expended on examining the existing collections from the Jordan site (owned by Justin and Marjorie Jordan) and preparing the material for shipment to the University of Alberta, Edmonton, where it was subsequently analyzed.

Unfortunately, the Jordan site (DeHa-8) also remained under water throughout subsequent fieldwork undertaken by the writer during 1980, 1981, and 1982. Therefore, important subsurface testing or attempts to obtain radiocarbon datable materials or additional specimens have not been possible to date. Hopefully, in the future an unusually dry year will result in extremely low water levels that may expose the site for further research and allow the collection of radiocarbon datable materials.

Lending further support for an early occupation of Lake Abitibi is a radiocarbon date obtained from a component 250 km (155 miles) south of the Abitibi area at the north end of Fox Lake, part of the Spanish River system draining into Lake Huron. The Fox Lake date of 7,670 +/- 120 B.P. refers to a biface complex. The date of 5720 B.C. is the earliest yet obtained on archaeological materials in northeastern Ontario (Chris Hanks: personal communication, January 1981). Evidently, the people who made the large bifaces occupied new land exposed by the draining of glacial Lake Barlow circa 5900 B.C. (Vincent & Hardy 1979:17).

It would be extremely unusual if the Lake Abitibi area, rich in faunal and flora resources, remained unoccupied following deglaciation and drainage of the post glacial lake for some two thousand years or more until the arrival of Shield Archaic and possibly some Laurentian Archaic Vergennes Phase peoples in the area (Noble 1980:27, Knight 1977, Pollock 1976:167) circa 3000 B.C.

In conclusion, the total available evidence suggests that the Jordan site represents the earliest post glacial occupation in the Lake Abitibi area and that this complex dates to the time period between 5250 B.C. and 4000 B.C. (7,250 - 6,000 yrs. B.P.) prior to subsequent inhabitation of the area by subsequent Archaic peoples.

Prior to the cognitive based experimental technological analysis of the Jordan collection, a standard description of each biface from the site (Plate 7) including basic metric measurements, was undertaken. The results of this preliminary analysis are presented in Table 32 (in appendices).

Plate 5: The Jordan Site (DeHa-8) covered by water. Photo by John Pollock, 1979.

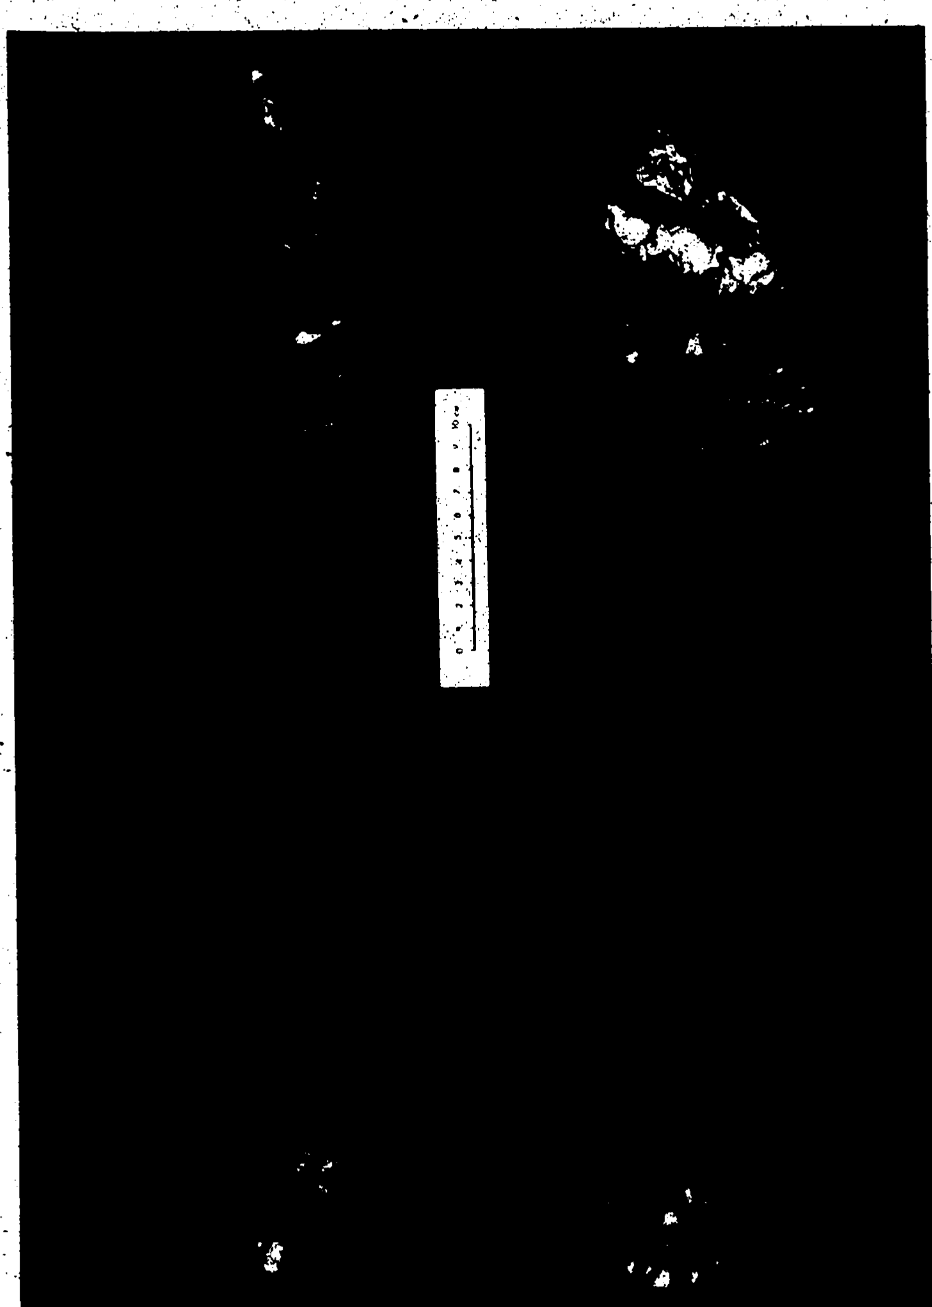

Plate 6: Total sample of large bifaces from the Jordan collection (DeHa-8). From these four, two were selected for analysis.

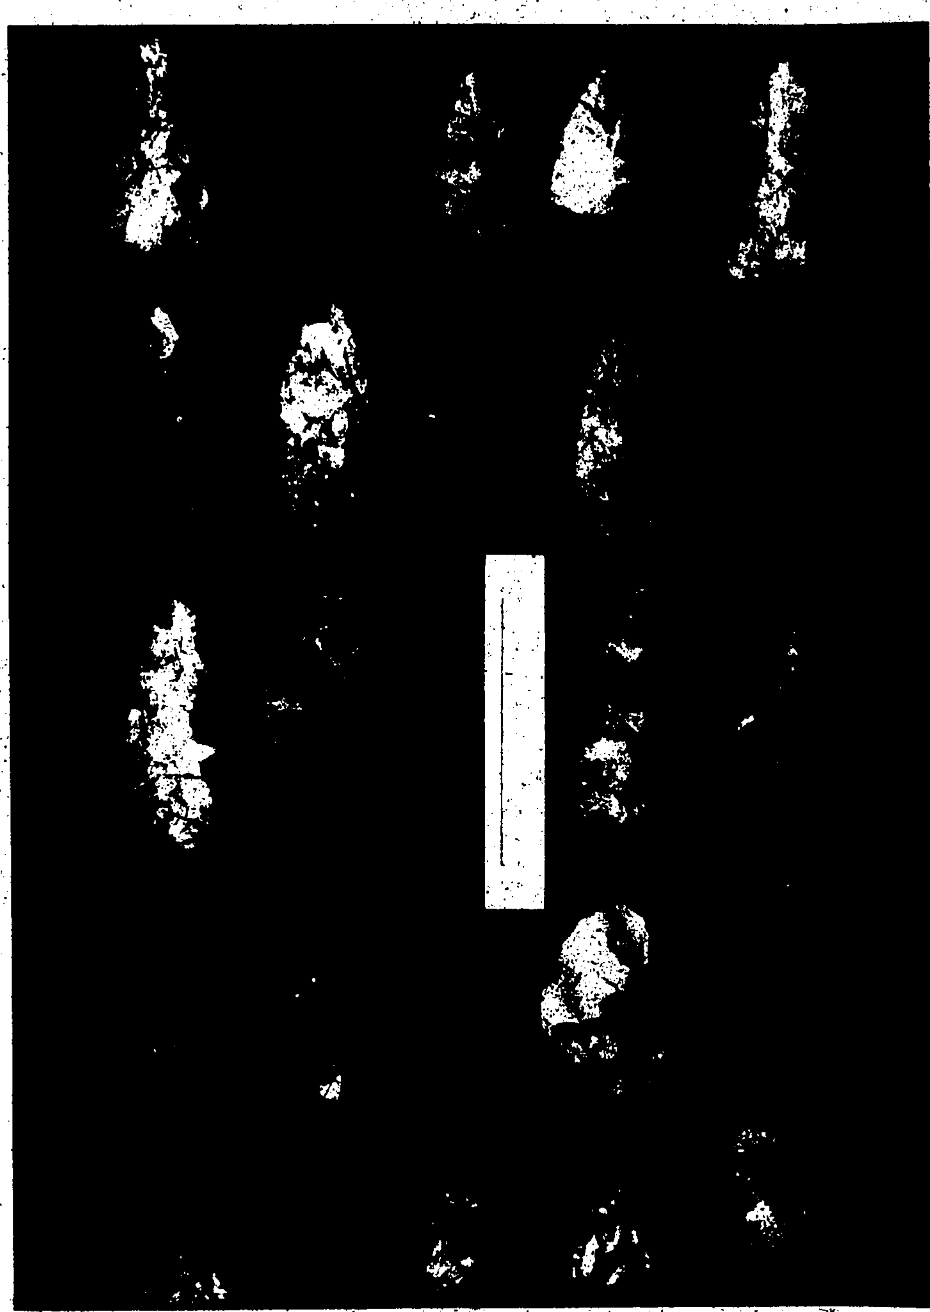

Plate 7: Total sample of medium sized bifaces from the Jordan collection (DeHa-8). From these, four were selected for detailed analysis in this thesis.

Part Two: Jessup Site (DdGw-2)

The Jessup Site (DdGw-2), a major lithic reduction and workshop site (Figure 7, Plates 8 to 12), was recorded by Marjorie and Justin Jordan (1976) who also recorded and collected materials from the site in 1977. The 1977 investigations revealed the site to be a major one for the entire Canadian Boreal Forest. The site is at least 2.5 km in length, spread out along a shoreline which varies from a low clay beach with a thin sand covering, to rocky outcrops separated by steep varved clay banks with narrow sandy beaches. A great many archaeological materials have been exposed by at least 30 metres of wave cut erosion. The beaches are covered with artifacts, mainly cores, flakes, and biface preforms or rough outs (Jordan & Jordan 1977). Only during one year of extremely low water levels (about 874.25 feet) during 1977 has the entire site been exposed. Hearths and cores were exposed along with uncountable numbers of flakes, cores and finished artifacts (Jordan & Jordan 1977). At that time the Jordans also documented evidence of extensive looting by private collectors (Jordan & Jordan 1977: no pagination). Subsequently, in the fall of 1977, Ministry of Natural Resources officers confiscated an illegal collection of artifacts from a private collector. These 20 artifacts have been analyzed and described by Thor Conway (who did not visit the site), a Regional Archaeologist with the Archaeology and Heritage Planning Branch, Ontario Ministry of Citizenship and Culture (Conway 1978).

The writer first visited the site during 1979, at which time Ingrid Kritsch-Armstrong, as part of her M.A. studies at McMaster University, conducted some excavations at the only high terrace locality

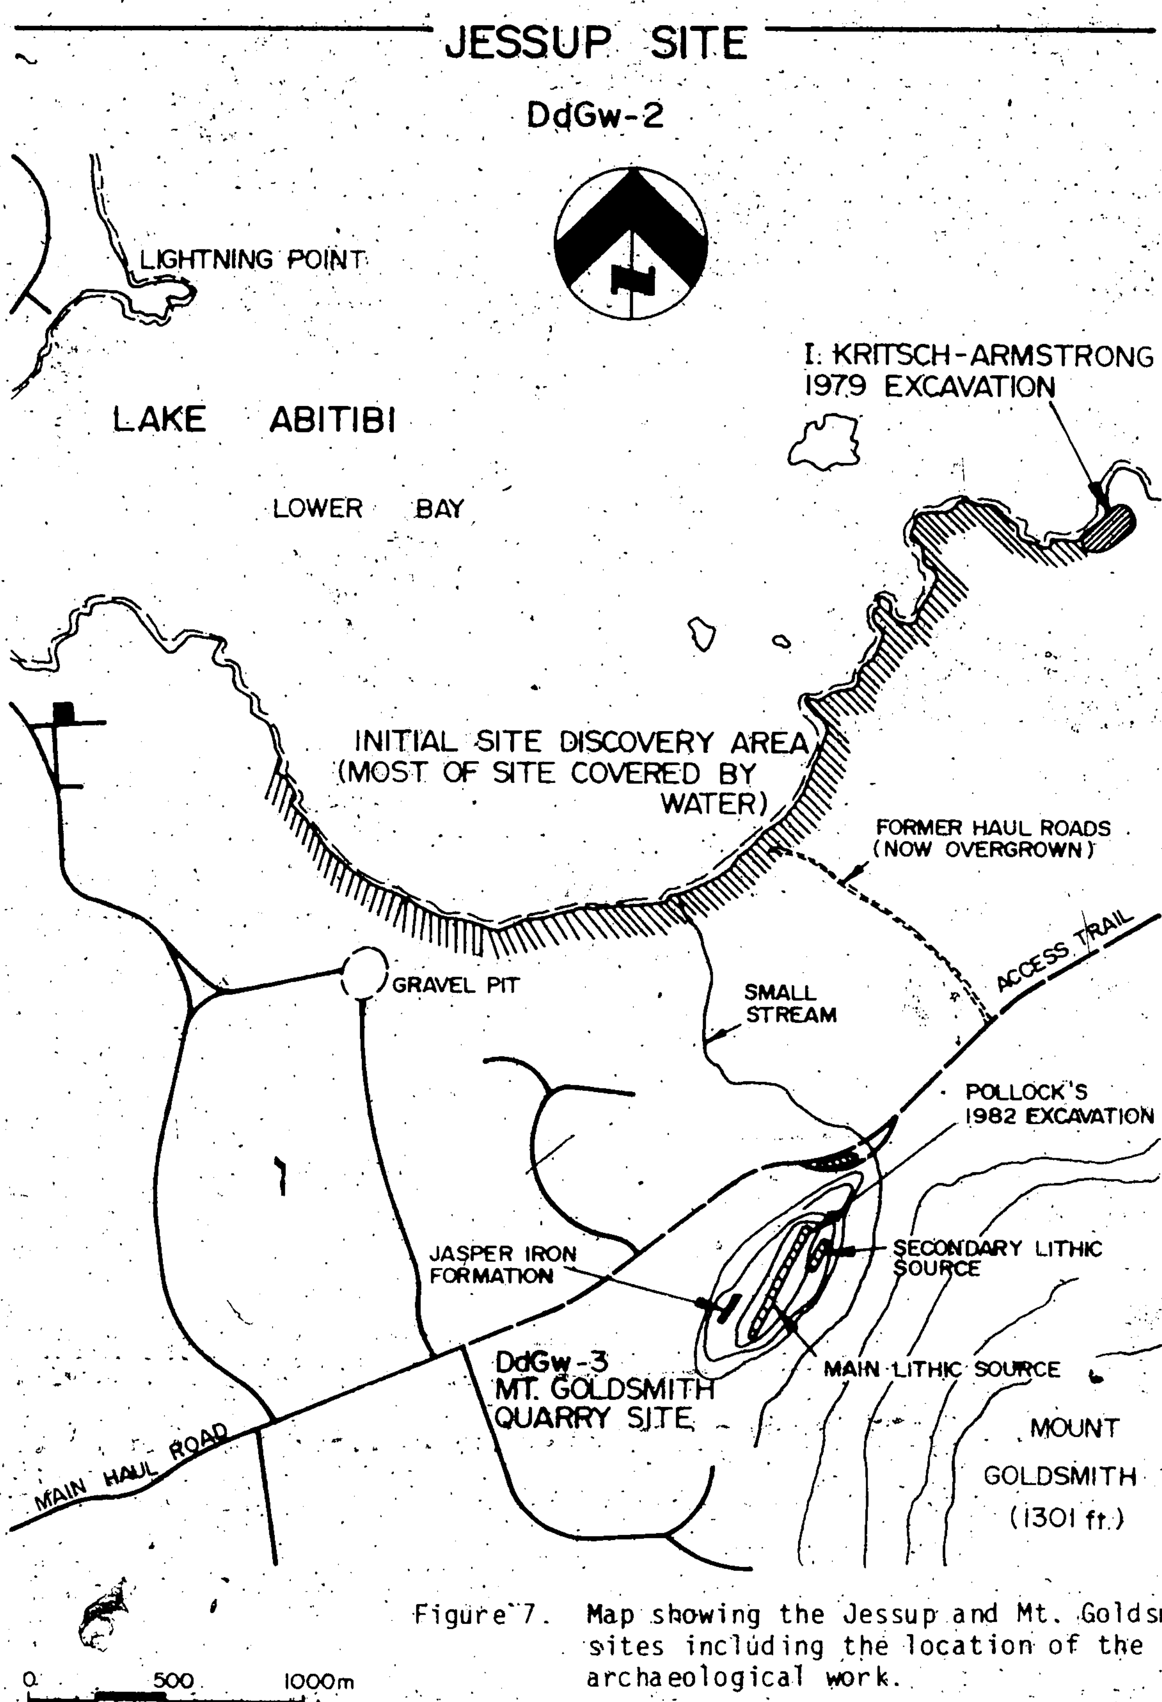

Figure 7. Map showing the Jessup and Mt. Goldsmith sites including the location of the 1982 archaeological work.

on the site (Kritsch-Armstrong 1980, 1982) (Plate 10). Her excavations of 29 square metres produced over 100,000 flakes in a 6 - 8 cm layer, amply demonstrating the quarry-workshop nature of the site. However, the actual bedrock quarry site as opposed to the Jessup workshop site(s), although suspected by Kritsch-Armstrong and myself to be nearby, was not located until the following year. During 1980, the writer, accompanied by Larry Jensen, a geologist with the Ontario Division of Mines (who has worked in the area since 1972), did locate the geological formation supplying the lithic raw material, and at least one of several possible bedrock quarry locations on nearby Mt. Goldsmith. The site was not visited again until late September of 1982, when unfortunately water levels were high and the site was entirely under water except for a narrow strip of sand (Plates 11 and 12) from which only a few flakes and cores were eroding.

Kritsch-Armstrong's excavation showed that the higher terrace contained a multi-component archaic and middle woodland occupation with no physical stratigraphic separation at depths averaging from 5 to 10 cm overlying a clay subsoil. Her excavations recorded five features comprising two pits and three hearths. Faunal identifications were sparse with only beaver (<u>Castor canadensis</u>) being positively identified along with the possibility of deer/caribou. A single attempted radiocarbon date from calcined bone did not contain enough collagen for a C-14 date (Kritsch-Armstrong 1982:50-67).

In contrast to Kritsch-Armstrong's excavated materials, the prehistoric specimens analyzed in this thesis were collected from the underwater areas of the site not accessible to Kritsch-Armstrong in 1979. The Jordans have kindly loaned the writer their extensive surface collections from the Jessup site obtained during 1976 and 1977 (Plate 13). Photographs taken by the Jordans of the site and their descriptions (1977) show that the underwater portion of the site contained hearth features and represents a true living floor occupation and not erosion deposited artifacts. Because of the lower elevation it is also possible that the underwater portion of the site contains less component mixture of later middle woodland materials. The writer agrees with Kritsch-Armstrong's conclusion that Jessup is a multi-component site inhabited by both Shield Archaic and Middle Woodland Laurel peoples; and was utilized as a lithic workshop and habitation site (due to the nearby raw material source(s) at the Mount Goldsmith Quarry) over a period of approximately 3,000 years (Kritsch-Armstrong 1982:258).

In contrast to the Jordan site materials which I estimate to date between 5250 - 4000 B.C. (7,250 - 6,000 yrs. B.P.), the Jessup site archaic materials [related to the Abitibi Narrow Phase of the Shield Archaic Tradition as defined by the writer (Pollock 1975:10, 1976:175)] are estimated to date between 3000 - 1000 B.C. (5,000 - 3,000 yrs. B.P.). These sites may or may not evolve into the succeeding Mattawan Archaic (Pollock 1976:177) and Laurel phases. Indeed, Kritsch-Armstrong's artifact analysis based on metric data and a good judgmental descriptive analysis of manufacturing techniques and technological processes found at the site, together with an analysis of the flakes recovered, showed more statistical similarities than differences between the Archaic and Laurel components, although she cautions that this may be partly a function of the same raw material being utilized. In her technological analysis Kritsch-Armstrong (1982:222) points out that the hardness of the welded volcanic tuffs at Jessup was a problem faced by the prehistoric knappers. Other features of the raw material such as bedding planes and changes from coarse to fine texture caused breakage and thinning problems. These problems were also evident in the experimental work for this thesis when two specimens broke during our experiments due to similar reasons.

As was the case with the Jordan site biface collection, bifaces from the Jessup site (Plate 13) were described and basic metric measurements undertaken prior to the cognitive analysis. The results of this preliminary analysis are given in Table 33 (in appendices).

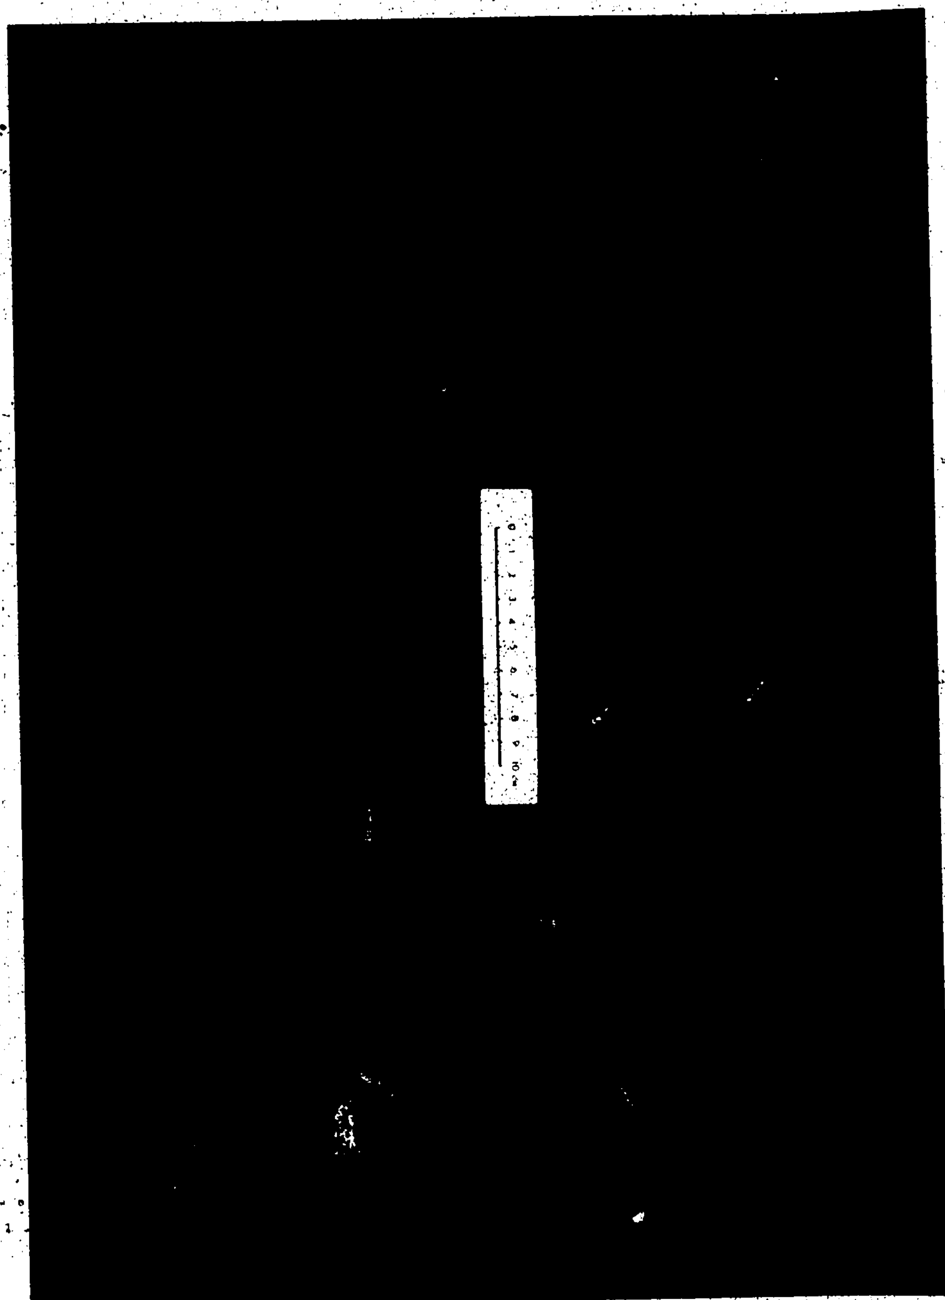

Plate 13: Total sample of medium sized bifaces from the Jessup Site (DdGw-2).

Part Three: The Mount Goldsmith Quarry Site (DdGw-3)

As previously mentioned, the location of the suspected quarry for Lake Abitibi had long been speculated upon by early researchers (Ridley, Lee, Jordans, Kritsch-Armstrong) and virtually all other researchers who have worked on the lake. However, it was not until August 1980, that I was fortunate to meet Dr. Larry Jensen, who recognized an archaeological core I showed to him from the Jessup site as being of the same laminated chert material as a nearby cherty tuff formation. The results of the 1980 preliminary geological and raw material sample collecting investigations have been outlined in Chapter III of this thesis along with a detailed geological description of the site; and the reader is referred to that chapter for the relevant geological background data to the 1981 and 1982 archaeological work at the quarry site.

Any incipient doubts regarding the connection of the Mount Goldsmith Quarry to the Jessup site workshop (Figure 7) have been answered by Ingrid Kritsch-Armstrong's chemical and trace element analysis of eight archaeological specimens from the Jessup site. The results of the analyses which indicated a 60 to 72.2% silica content (along with ten chemical and eight trace elements), indicated the archaeological specimens were of "calc-alkalic dacite tuff, which extends into calc-alkalic andesite tuff on the mafic side and calc-alkalic rhyolite tuff on the felsic side" (Kritsch-Armstrong 1982:72). From the results of the chemical and trace element analysis, Larry Jensen considers the Jessup Site prehistoric archaeological specimens to be "identical" in rock type to the nearby Mount Goldsmith quarry cherty tuffs.

The 1981 Investigations

Access to the site (Figure 7) is very difficult, as the former Abitibi haul road is now overgrown and several huge washouts of the roadway caused by beaver dams make road access impossible. By air, access is equally difficult, as the shallow waters of Lower Bay and numerous rocks make landing by float plane difficult. It is also one kilometre by trail to the quarry area from the lake (see Figure 7). During 1981, utilizing an Argo and a small ATV trike to gain access, we were able to cut a trail to the site and mark the major outcrop areas of the quarry with flagging tape. The work confirmed that the site was prehistoric, and the presence of large piles of detritus showed that it was indeed a prehistoric quarry. Bad weather limited the 1981 work, and unfortunately we were not able to test any of the large "pit" depressions. Larry Jensen and his crew as well as the Jordans, Ingrid Kritsch-Armstrong, and Dennis Armstrong assisted with the 1981 work.

The 1982 Investigations

A. Excavations at the Depressions or Pits

During September of 1982, the writer with a crew of three persons returned again to the site. This time due to drier weather the access trail was in better shape and we were able to use two ATV trikes to gain access, although each return trip into the site took about three hours of travel from our base at Perry Lake.

Upon arriving at the site, we eventually selected one of the possible quarry pits (see Figures 8 and 9) for excavation which was located at the north end of the quarry site. The quarry site itself is located on a smaller topographic high just west of the main Mount Goldsmith peak (see Figure 10, Plate 14), the first topographic high from the lake, with an excellent view (Plate 15).

After selecting a depression for excavation the difficult task of removing trees, shrubs and rock from the depression began (Plates 16 and 17). Figure 9 outlines a portion of the excavation area, which was circa eight metres long by four metres wide. The excavation was situated on the side of the hill, and contained a buried exposure of chert vein material about 30 cm wide situated in the centre of the depression (see Plate 17).

As the excavation proceeded, a problem was encountered in the form of ground water which flooded the excavation to a depth of 20 cm (Plate 17) making further progress impossible. As we did not have a water pump, work was severely hampered by these conditons. Two cores (Plate 25) and some flakes were recovered from the excavation of the pit, but there was not a great deal of detritus or debitage present.

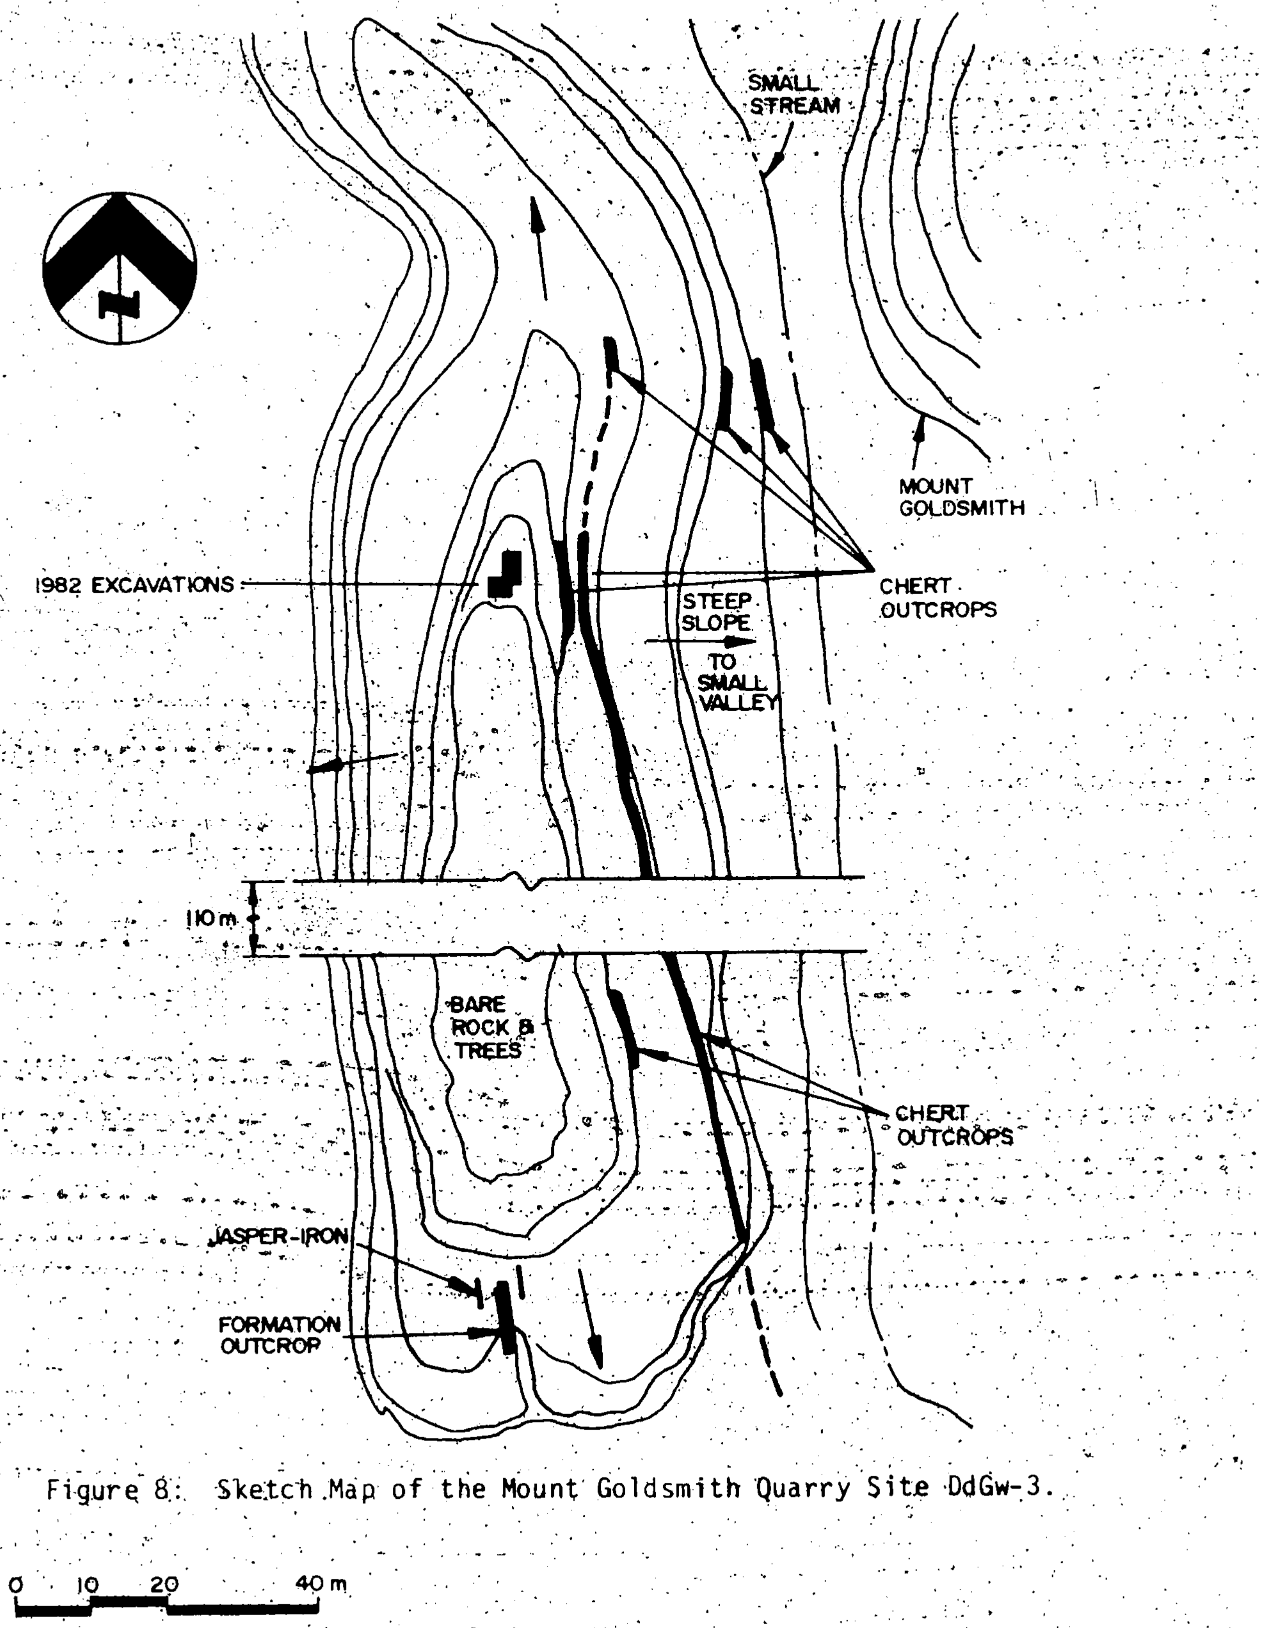

Figure 8: Sketch Map of the Mount Goldsmith Quarry Site DdGw-3.

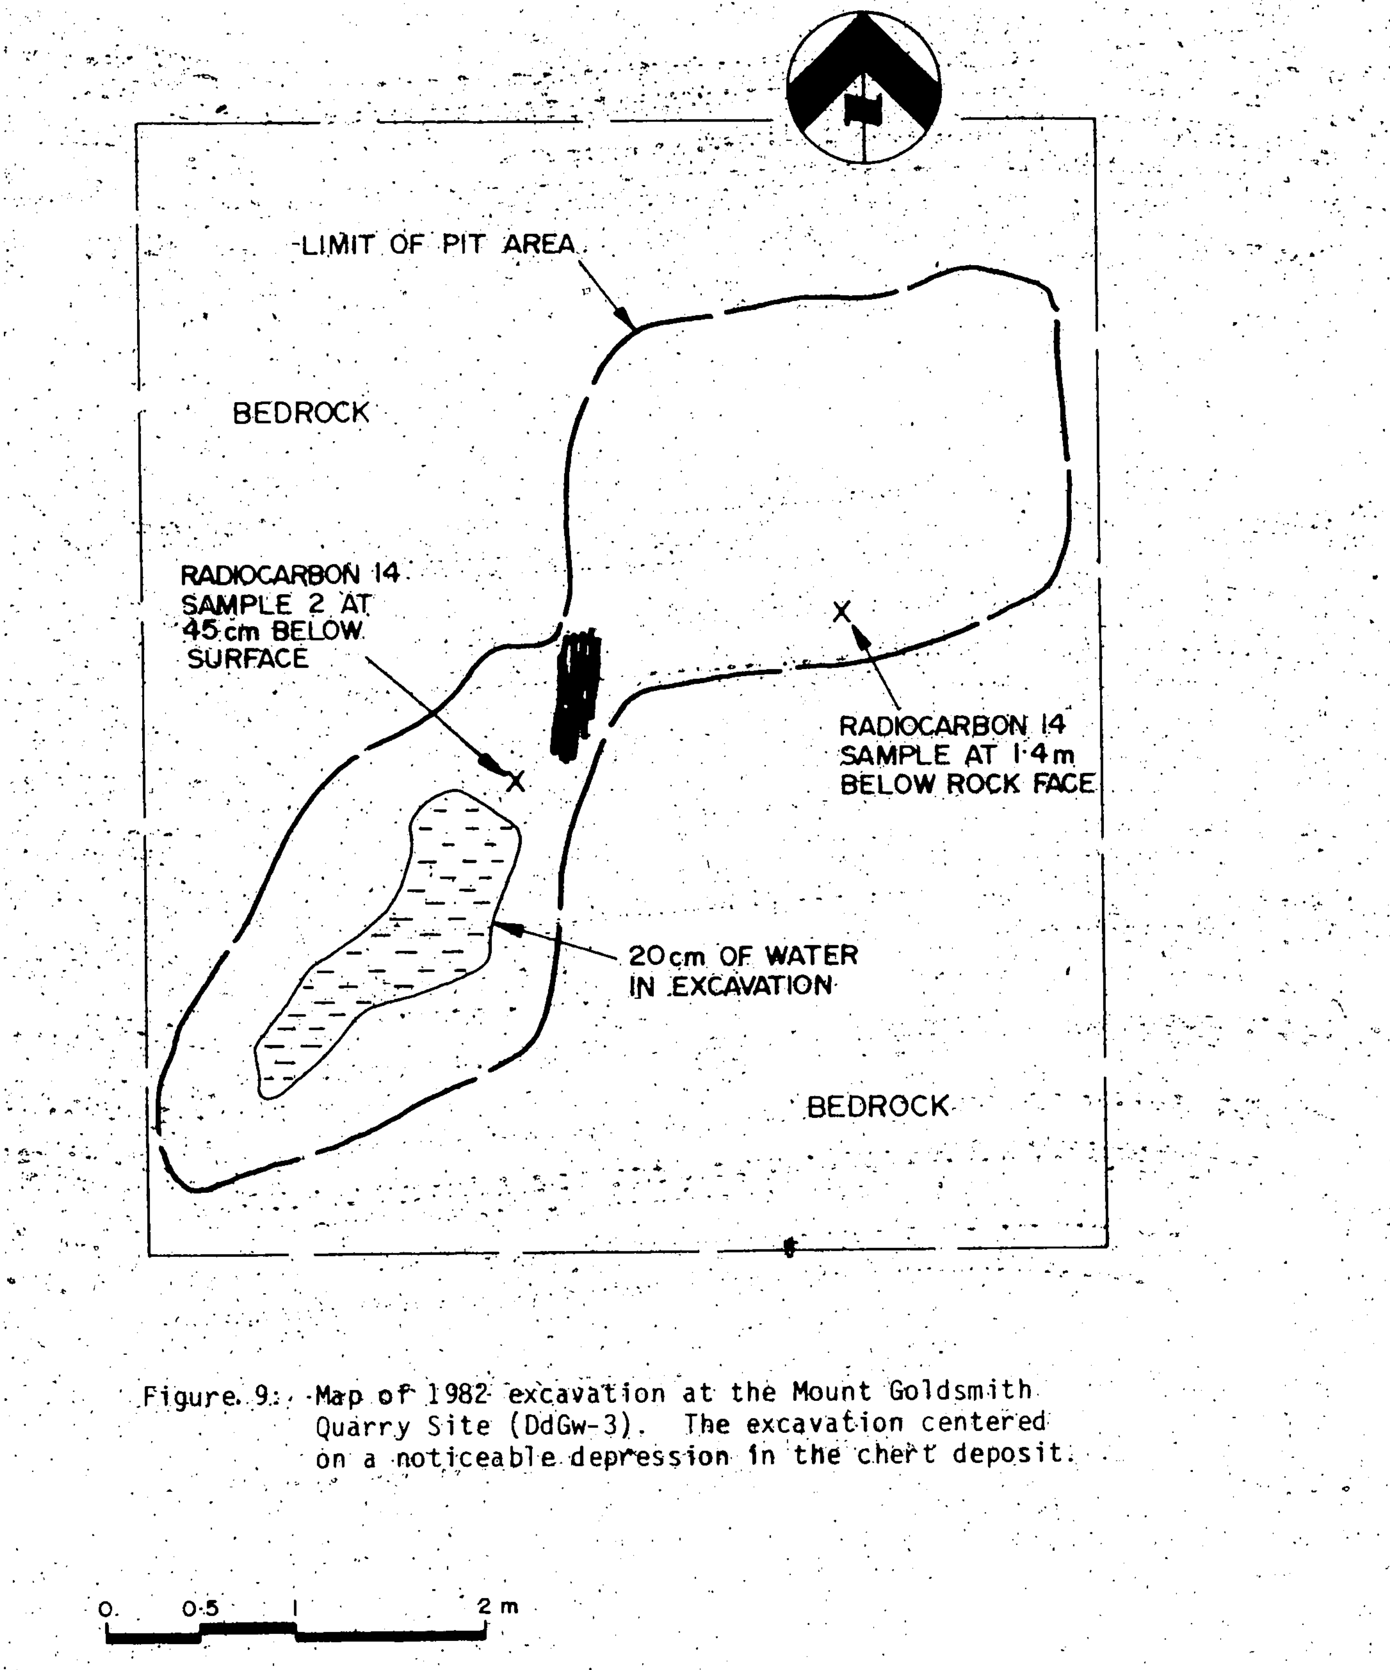

Figure 9: Map of 1982 excavation at the Mount Goldsmith Quarry Site (DdGw-3). The excavation centered on a noticeable depression in the chert deposit.

Discussion

The writer's initial thoughts following the 1982 investigation of the numerous depressions in the chert deposit area was that they were natural and may have been simply used by prehistoric peoples as disposal areas and/or for access to portions of the chert deposit (Settlement Surveys Ltd. 1983:211). No positive evidence of quarrying of rock was evident although such is very difficult to determine archaeologically. The fact that the pits are relatively free of chert flakes, etc., may be due to removal of cores and chert material, or may simply reflect the fact that they are natural features. A very positive factor for an aboriginal origin is that the pit excavated was located on the chert vein. More pits need to be excavated. If all pits are found to be centered in chert veins a pattern would be established that would argue strongly for a man made origin. In the case of the excavated pit this factor is quite significant, as the chert is only exposed in the pit depression, and no chert is visible on the bedrock surface on either side of the pit up or down strike along the deposit. If this pattern extended to all other pits a definite argument for a man made origin could be supported.

Also there is some indication from the 1982 investigation that the lithic material exposed in the pits may be a little coarse grained but at the same time more massive than the finer grained exposed chert, which has a lot of internal flaws and fracture planes. Thus, there would have been an incentive for prehistoric peoples (especially early peoples) to obtain the more massive material in order to produce large bifaces.

B. Prehistoric Chert Collecting Areas Along Strike of the Chert Deposit

In contrast to the inconclusive evidence regarding the nature of the depression features, there was ample evidence of surface mining and surface collecting of raw material along the strike of the chert outcrop which closely resembles a vein of material (i.e., like a quartz vein) (see Plate 18). The chert strikes north, 50° west; and appears to dip vertically or near 90° to the surface. As the chert has its origin as a band of ash deposited between succeeding lava flows (i.e., the banding is visible in the deposit) this feature indicates folding and deformation of the material since deposition. This has compressed and silicified the original volcanic ash into chert.

Figure 8 shows the entire exposed length of the chert outcrop at DdGw-3 and indicates the major prehistoric raw material collecting areas recognized during the 1982 fieldwork. The total length of exposed chert material is some 200 metres long and varies in width, as mentioned, from 20 cm to 170 cm at the widest point (Figure 10).

Nearby the southwest end of the deposit, there is an exposure of Jasper-iron formation (see Figure 8) which may also have been collected by aboriginal peoples. As well, there are numerous side or parallel veins of chert material some of which are more massive with less internal flaws or fractures and therefore more suitable for tool manufacture than some of the exposed materials. These are located both upslope of the main exposed vein and also downslope and in the valley to the northeast containing a small stream. A heavy overburden of humus, shrubs, trees and rock falls make the task of locating and assessing these other areas very difficult. The possibility is very good that

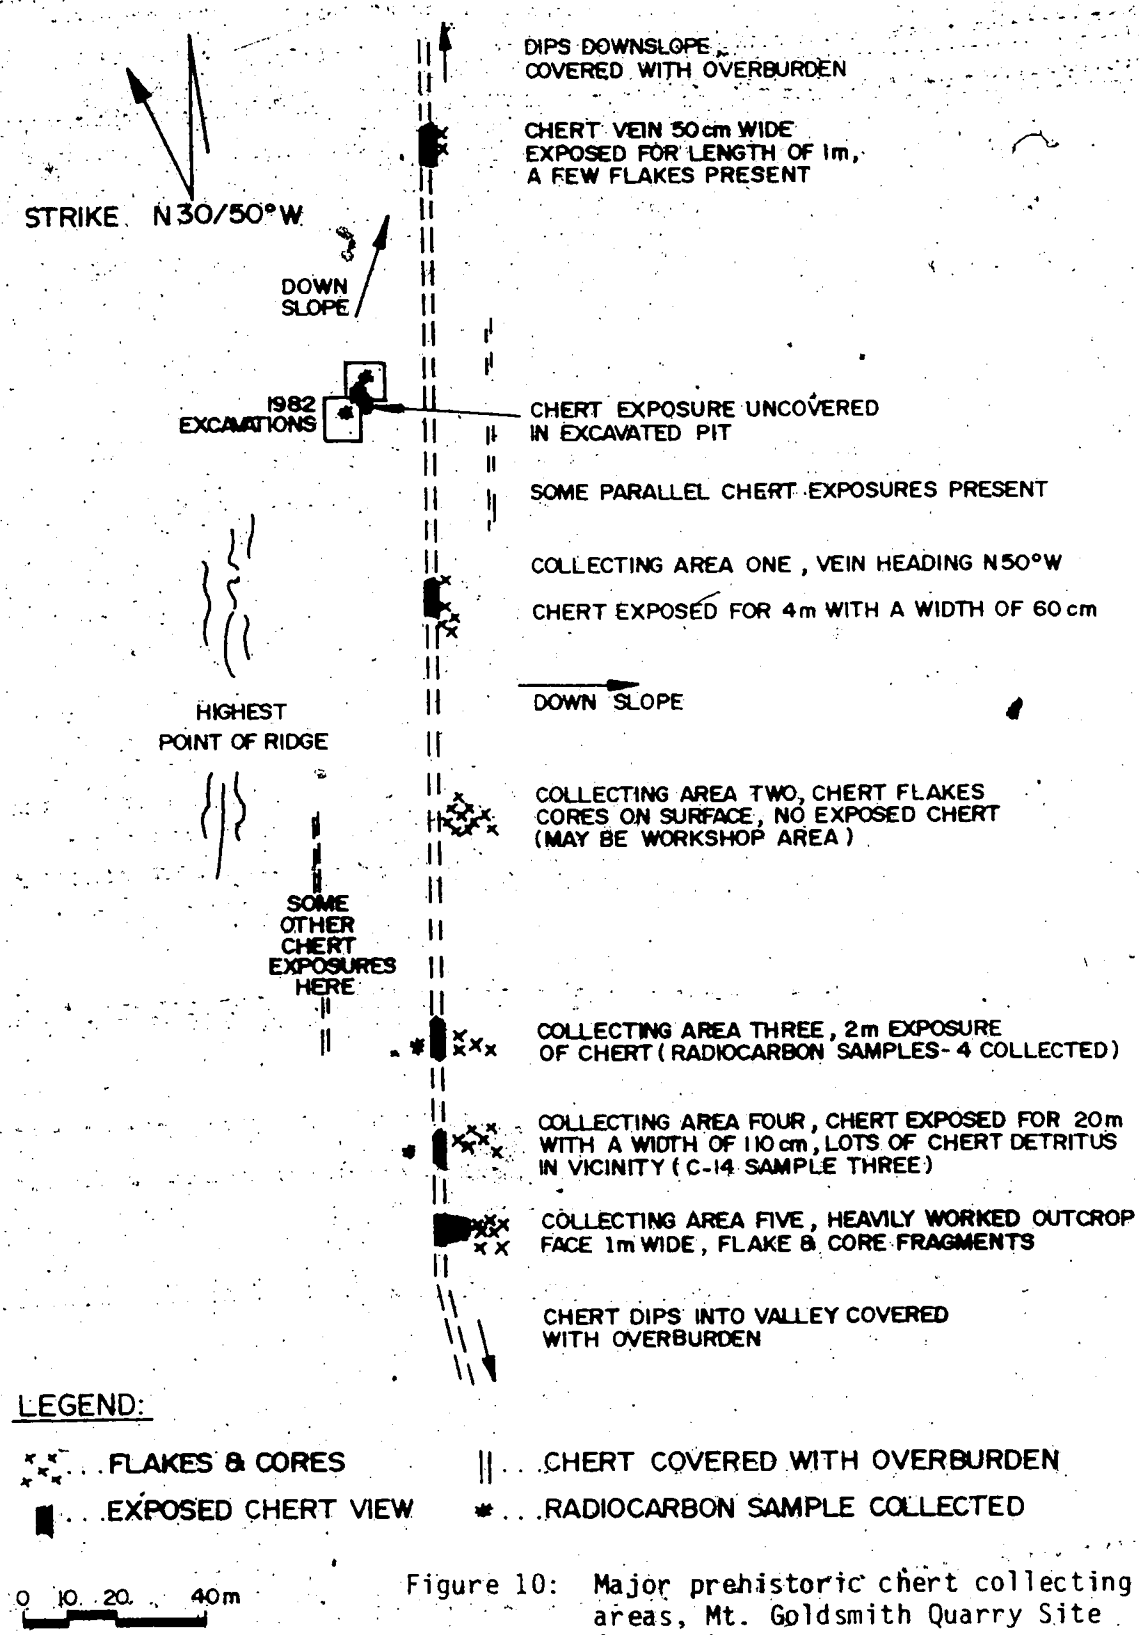

Figure 10: Major prehistoric chert collecting areas, Mt. Goldsmith Quarry Site (DdGw-3).

there are other perhaps more important collecting areas along the strike of the formation that have not yet been located.

Returning to the main exposed chert band shown in Figure 13, the first collecting area (proceeding from north to south) is located just past the 1982 pit excavations (Plate 19, also Figure 10). This exposed area, some 60 cm wide by four metres long, exhibits battering of the chert deposit and numerous piles of detritus from reduction activities including many platform flakes, etc., which could not be the result of natural weathering.

The second collecting area (Figure 10, Plate 20) has no surface exposure of chert and consists of flakes and cores on surface. This may be a workshop area for primary reduction.

Collecting area three (Figure 10, Plate 21) is an exposure of chert 170 cm wide, and contains a great deal of detritus. Here a humus layer 10 cm thick of roots, etc., covered the chert vein. Interbedded in the humus were numerous flakes and other debitage from prehistoric collecting activities. After stripping back the humus a sample for radio carbon 14 dating was obtained from the deepest area of soil cover and one with a mass of flakes. The sample was obtained from the humus/bedrock interface area and should give a minimum date for use of the quarry site.

Area four (Figure 10, Plate 22) is an extensive flat sloping area of outcrop (Figure A17) some 20 metres long by 110 cm wide. Surrounding the exposure are large quantities of detritus.

Area five (Figure 10, Plate 24) is one of the major places along the 200 metre chert outcrop where there is solid evidence of prehistoric peoples not only surface collecting but actually mining or removing "in situ" raw material from the rock face. At the base of the exposure there are piles of flakes (Plate 23). The vertical worked face (Plate 24) shows the scarring effect of prehistoric mining and removal of large quantities of chert.

Artifact-Collections

No finished artifacts have been collected from the quarry site area and there does not appear to be a prehistoric campsite at the quarry itself. There are quantities of large and small flakes, core fragments and core shatter material as well as naturally broken material. Two cores were recovered from the excavation of one of the depression areas on the chert deposit. The two cores (Plate 25) and a representative sample of larger flakes and core fragments are illustrated (Plates 26 and 27). Many of the flakes show distinct striking platforms and percussion bulbs indicating they are the product of aboriginal mining as opposed to frost cracking and other natural causes, although, no doubt, a percentage of the talus on the site may be a result of natural causes.

Comparison of the Mt. Goldsmith Quarry with other prehistoric quarries in North America demonstrates that it conforms to the general pattern of quarry sites. Details follow in the next section of the thesis.

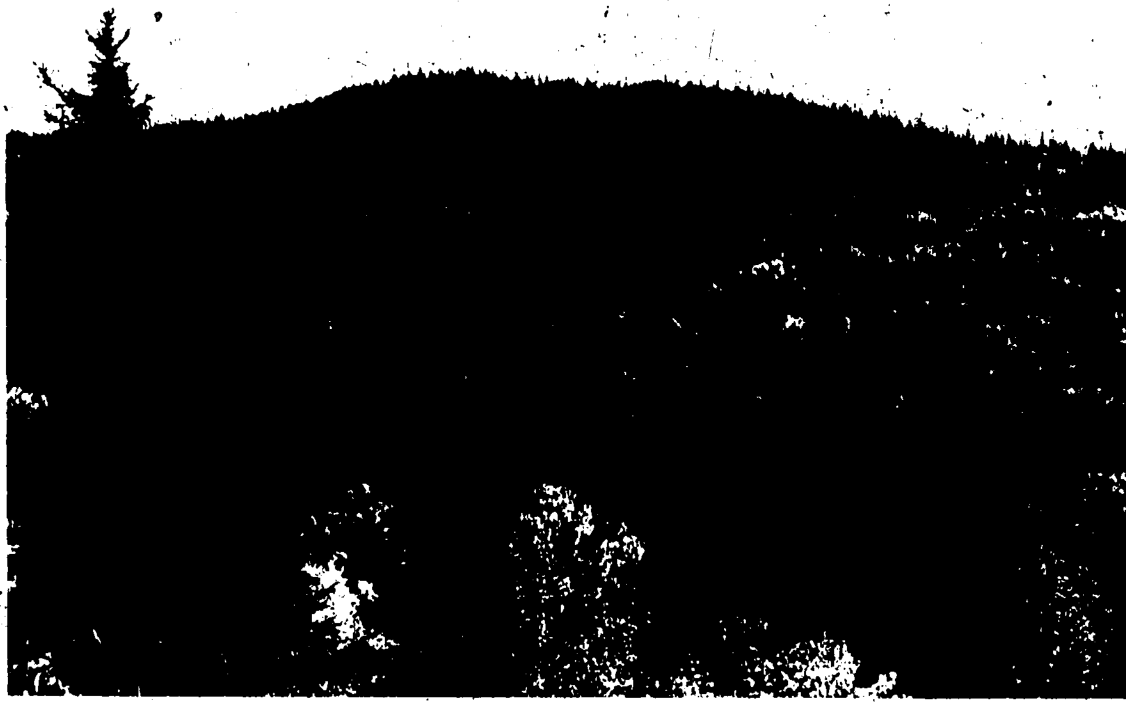

Plate 14: The main Mt. Goldsmith peak is located just east of the quarry site (1982 photo, looking east from quarry).

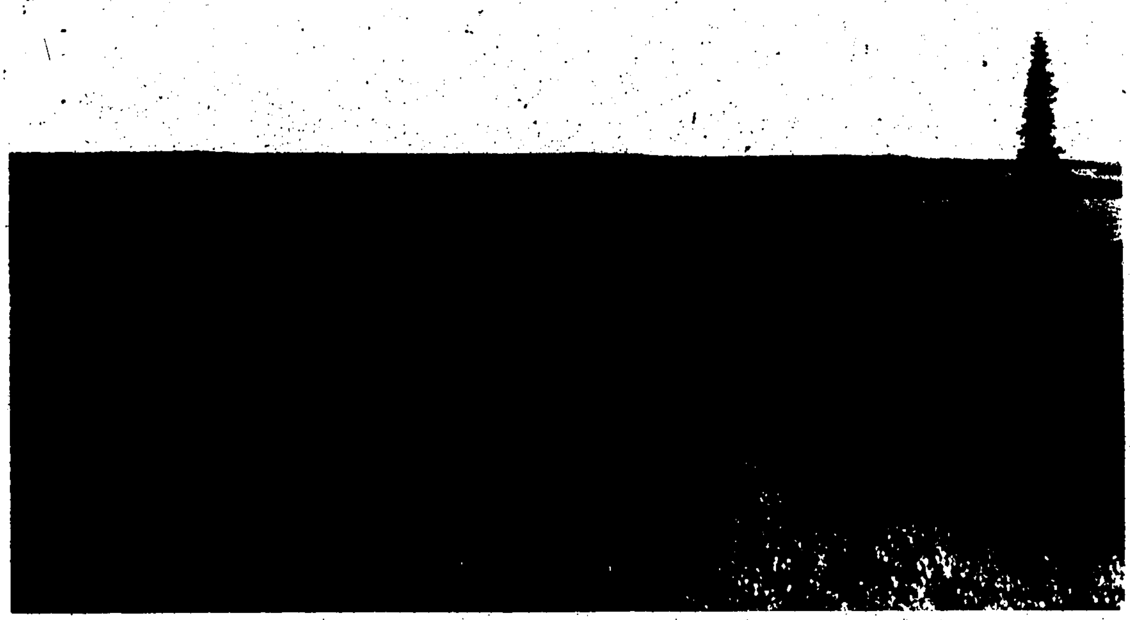

Plate 15: View of the Jessup Site (DdGw-2) and Lake Abitibi (Lower Bay and Lightning Point). 1982 photo, looking north from Mt. Goldsmith Quarry Site (DdGw-3).

Plate 16: Clearing roots, trees and rock from depression in an area where a large core was recovered (Plate 25:top item).

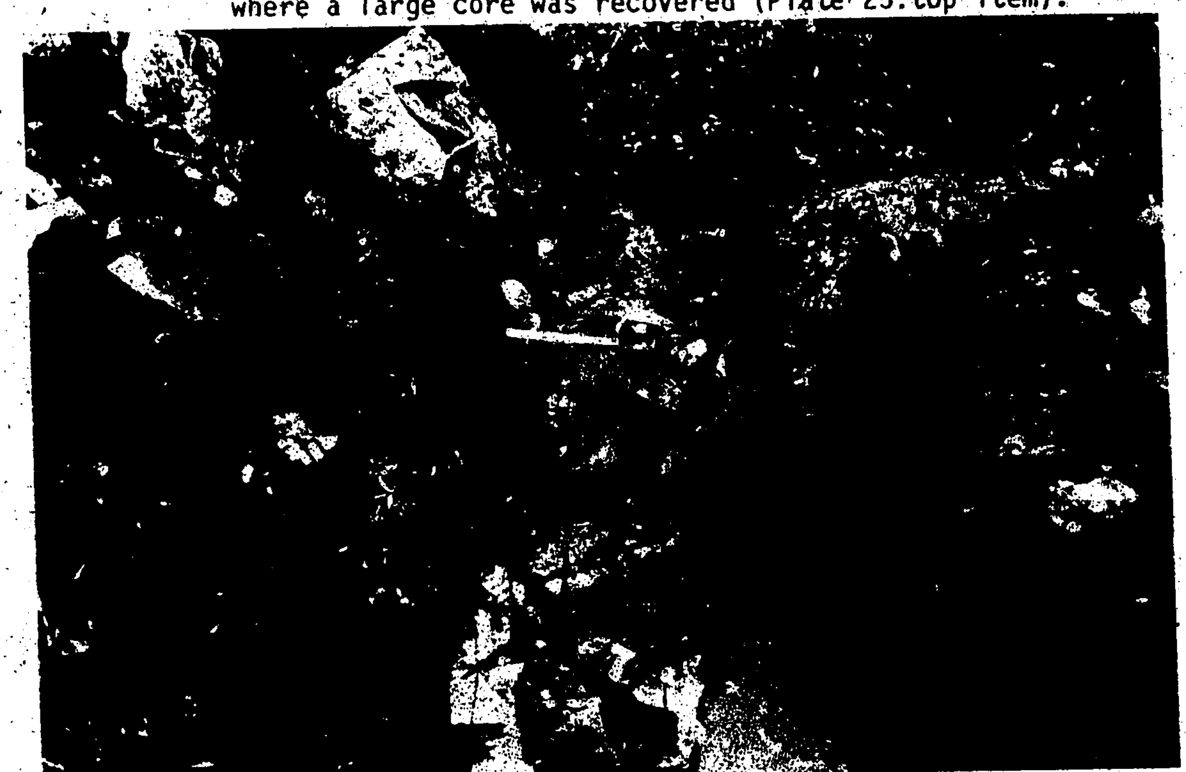

Plate 17: Main 1982 excavation area; note chert vein exposed in center of photograph (under tape measure) and groundwater in excavation.

Plate 18: The welded tuff or chert vein varies from 20 cm to 170 cm in width and consists of banded beds of green chert with considerable variation in grain size and colour.

Plate 19: Collecting Area One, Figure 10 (60 cm wide by 4 m long).

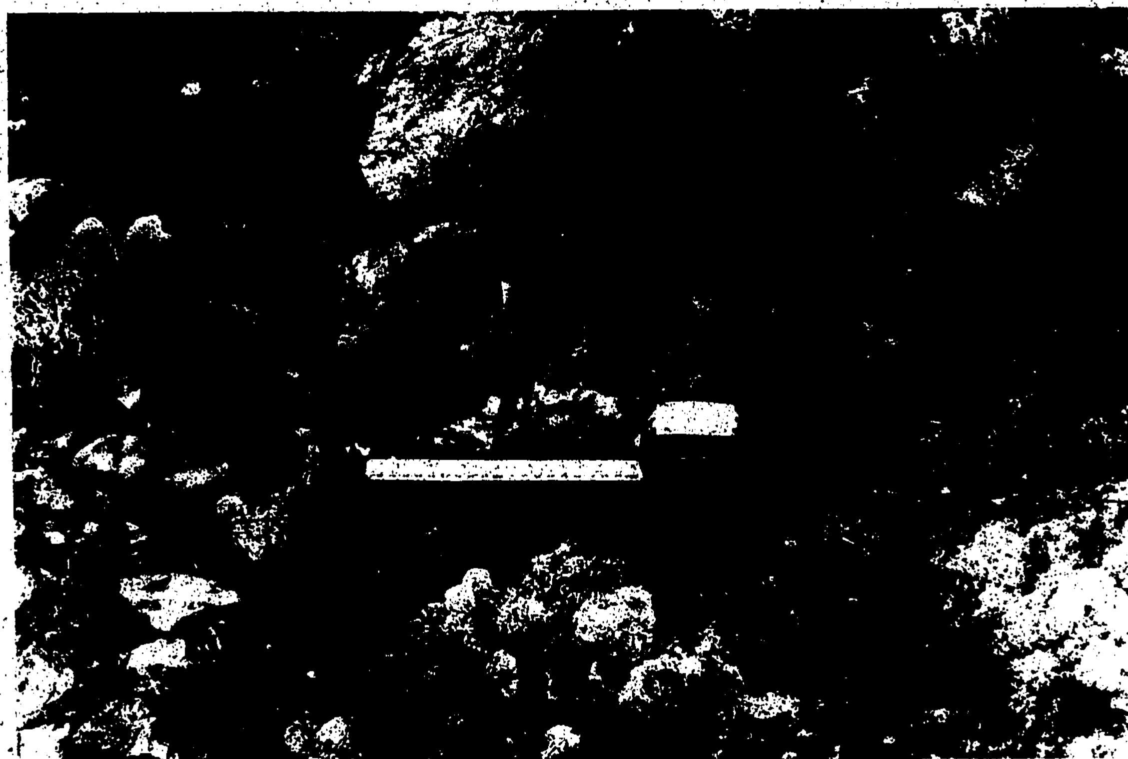

Plate 20: Collecting Area Two (Figure 10), flakes and cores on surface with no nearby exposure of chert.

Plate 21: Collecting Area Three (Figure 10). The chert here is 170 cm wide, with many flakes & cores nearby.

Plate 22: Collecting Area Four (Figure 10), numerous flakes and cores left on surface.

Plate 23: Piles of flakes are present at the base of collecting Area Five (Figure 10).

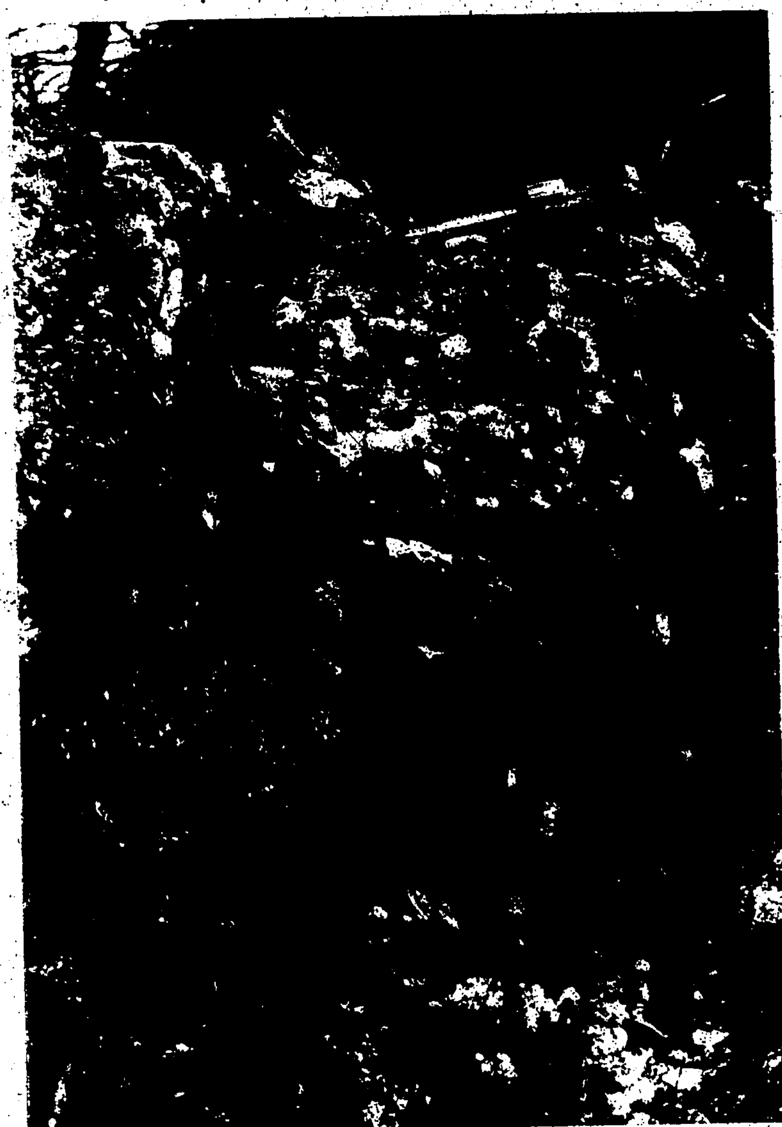

Plate 24: Collecting Area Five (Figure 10). This vertical face shows the scarring effect resulting from removal of a large quantity of material by prehistoric flintknappers.

Plate 25: Aboriginal cores recovered from excavated area (Figures 8 & 9) at the Mt. Goldsmith Quarry Site (DdGw-3).

Plate 26: Flakes and core fragments, Mt. Goldsmith Quarry Site (DdGw-3). Collected from all areas of the site during 1981 preliminary investigations.

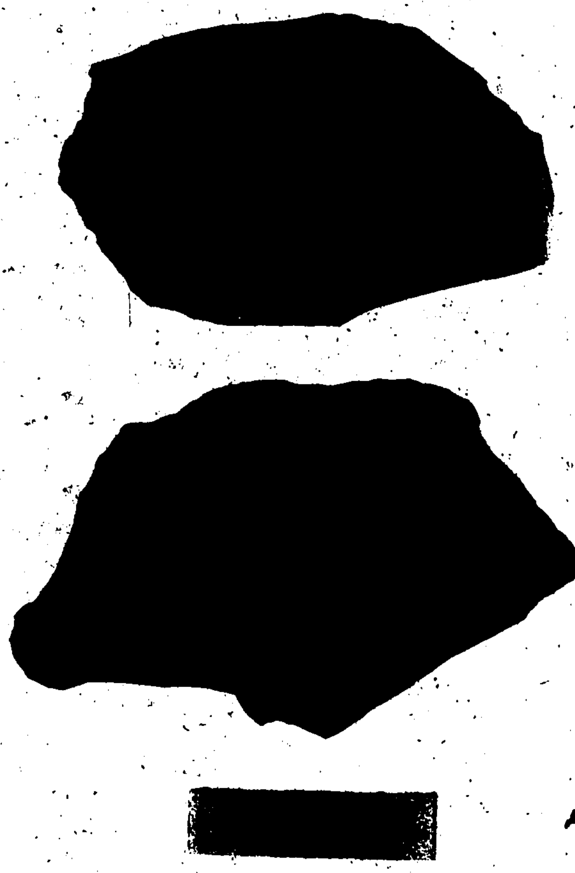

Plate 27: Core fragments and flakes, Mt. Goldsmith Quarry Site (DdGw-3). All were collected from area three of site (Figure 10, Plate 21). These pieces exhibit flake scars, platforms, percussion rings and platform crushing, etc., not found on naturally broken rock.

Part Four: Comparison of Thesis Site to Other Archaeological Sites

Introduction

This comparative data section is included in the thesis for two reasons. First, as this thesis is the first application of the cognitive approach, there are simply no comparative cognitive technological data with which to place the thesis sites in a regional context. Secondly, it is hoped that this summary of data, based on more traditional chronicling or normative approaches, can be contrasted to the results obtained in this thesis. The knowledge obtained from the cognitive approach in this initial study indicates the tremendous potential of the method. Once further sites are analyzed, it will be possible to outline regional phases and perhaps shed new light on existing chronological sequences and cultures discussed in the following part.

Jordan Site

During our preliminary analysis of the Jordan Site a number of extremely large and well formed bifaces were noted, as well as some bifaces or projectile point preforms with notable basal thinning. Upon examining these materials, Robson Bonnichsen suggested these may be similar in manufacturing technique to the Anzick materials, a Clovis site in Montana (Figure 11) (R. Bonnichsen: personal communication). Unfortunately, only the bone tools from among the over 100 artifacts recovered from the Anzick site, a small collapsed rock shelter near Wilsal, Montana, have been described (Lahren & Bonnichsen 1974:148).

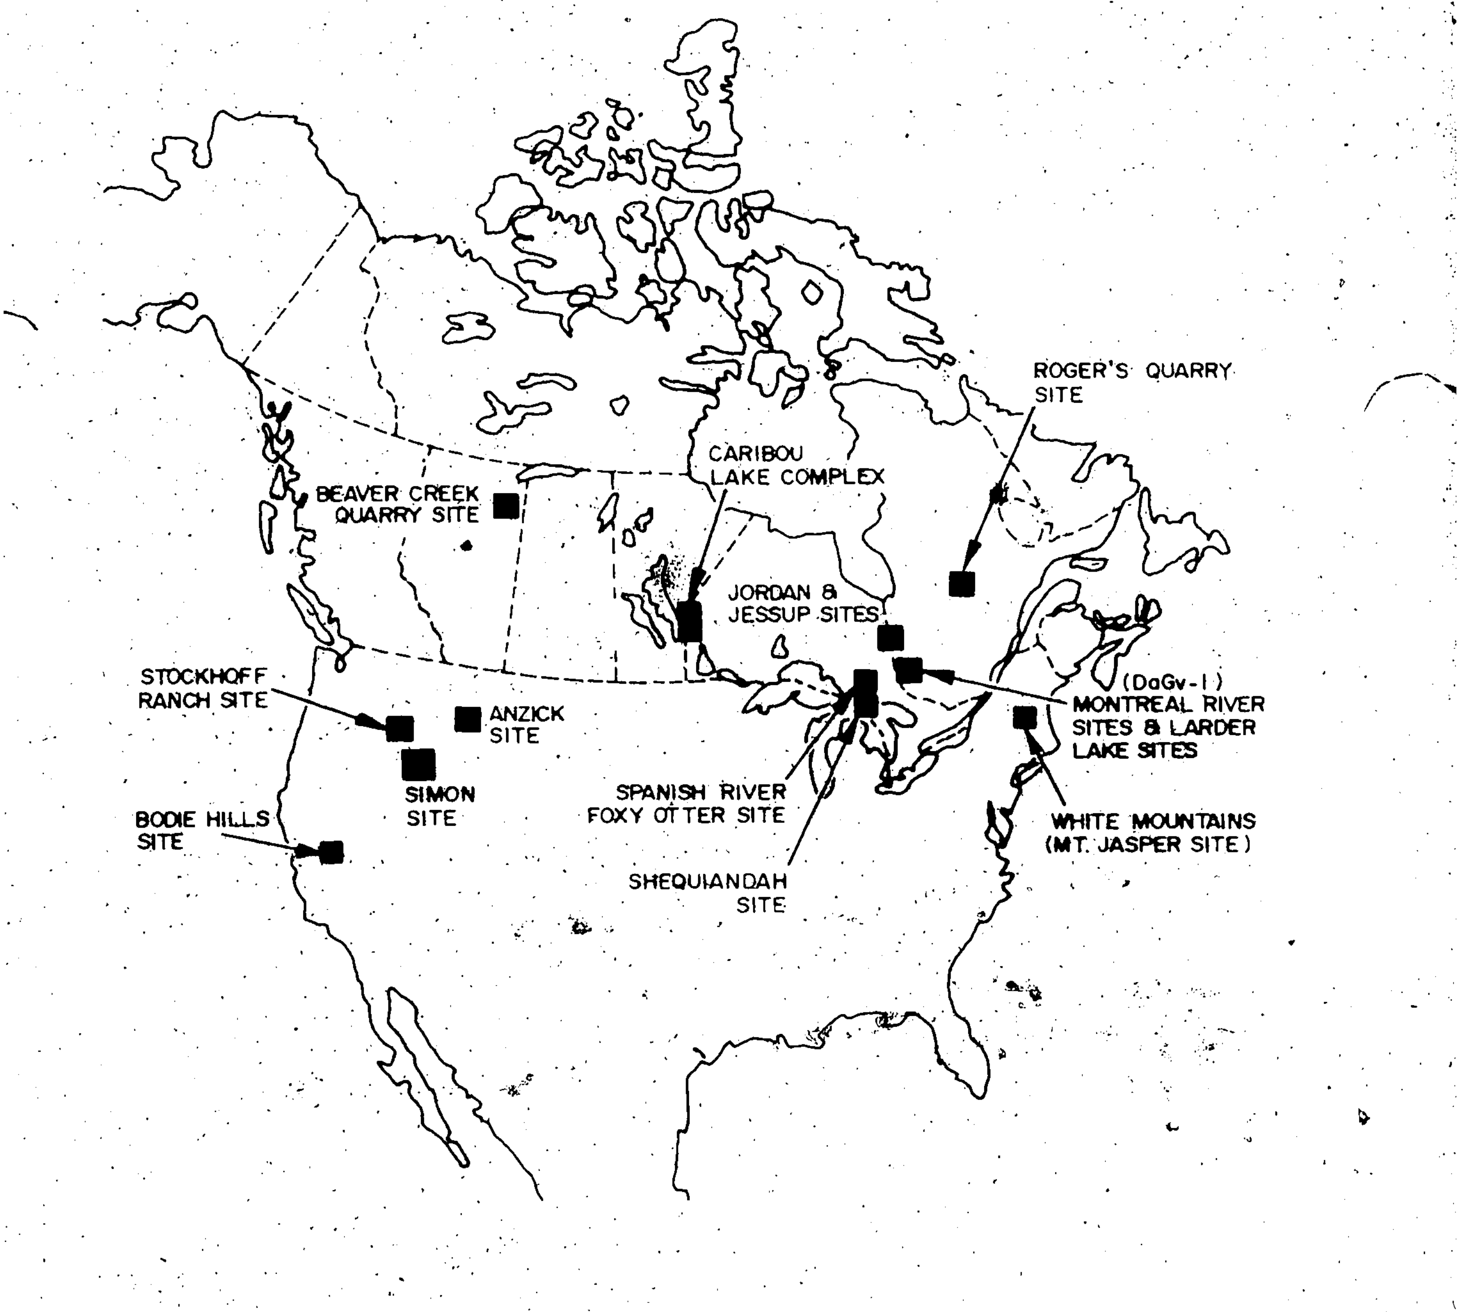

Figure 11: Map of comparative archaeological sites discussed in text.

Bonnichsen also suggested, along with Alan Bryan, that a similar technology also occurred (in the form of very large bifaces) at the Simons Site, a Clovis occurrence at Big Camas Prairie near Fairfield, Idaho (Butler 1969:62).

During a visit to Maine in the fall of 1980, I was able to examine casts of bifaces from the Anzick and Simons sites. While they are in some visual respects similar to the Jordan site specimens, they are larger with large flake scars. In order to produce large bifaces, a method of removing large, spatulate, well controlled flakes across the body of the biface is required. As the technological options for producing such flakes appear to be limited, this may have produced a resemblance between the Lake Abitibi and Anzick-Simons bifaces. Other than the mentioned similarities, there is no other archaeological, environmental or other evidence that the Lake Abitibi Jordan site materials are related to the Clovis culture, and indeed, the location of the Jordan site on post glacial clay deposits suggests that the maximum date for these materials (i.e., 5900 B.C., see Table 7) is far younger than known Clovis sites.

Other sites, such as the Giant site on Manitoulin Island, (Figure 11) Ontario, have produced large bifaces up to 20 cm long and 12 cm wide (Lee 1954:66). These are comparable in size to the two largest Jordan site specimens which are 25 and 29 cm long and 11.5 and 9.5 cm wide respectively. Lee describes the blades as broad, leaf shaped objects. The major difference here is that Lee describes them as being thick and crude while the Jordan specimens are thin and very well made.

Other reported sites that may be comparable to the Jordan and/or Jessup site is the Paleo-Indian Lakehead complex estimated by Fox to date circa 10,000 years B.P. (Fox 1976:29). Although no large bifaces are present in the Lakehead complex collections, the presence of a "diagnostic" trihedral adze (Fox 1977 and McLeod 1978, 1981) in the Jordan collection may link this site to the Lakehead complex.

During 1981, as part of the thesis research, collections at the Ontario Government's Regional Archaeologists offices at Sault Ste. Marie (Mr. Thor Conway) and at Kenora, Ontario (Mr. Paddy Reid) were visited in an attempt to ascertain if any large bifaces or collections similar to the Jordan site materials had been reported. At Sault Ste. Marie only late archaic components are present and collections bear no resemblance to the Jordan or Jessup site materials. There are two exceptions. First is the John Sago site (CcHl-2) dated at 5,910 +/- 120 yrs. B.P. (3960 B.C.) (Chris Hanks: personal communication). It is Hank's interpretation that large bifaces similar in size to the Jordan and George Lake specimens (i.e., 20 cm x 12 cm) were being thinned at the site (although none were recovered) based on the fact that some lipped bifacial thinning flakes had dorsal surfaces 6 cm long. Hank's edge angle extrapolation places the tools in a thickness range of 2 - 4 cm (letter from Chris Hanks to John Pollock, April 7, 1981).

The other important site also recorded by Chris Hanks is the Foxy Otter Site (Figure 11) located on the north end of Fox Lake, part of the Spanish Rivers system draining into Lake Huron. This site is 250 km (155 miles) south of Lake Abitibi. I have examined the bifaces from this site and in terms of general size and shape they resemble some aspects of the biface collection from the Jordan-Jessup sites although there appear to be some technological differences. The site has been dated at 7,670 +/- 120 years B.P. or 5720 B.C. and is the earliest date yet recorded for Late Plano/Early Archaic sites in northeastern Ontario.

At Kenora, only one Shield Archaic site has been reported for northwestern Ontario, despite years of continuous field survey in the area. This site is DiKm-20, located on an island in Whitefish Bay on Lake of the Woods. In the collection are a number of large flat spatulate biface thinning flakes up to 5 cm wide and 6.5 cm long as well as the tip of several bifaces in the size and shape range of the Jessup and/or Jordan collections (Paddy Reid: personal communication). Further west in Manitoba, research by the University of Manitoba (Wheeler 1978, Buchner 1979) has reported fifty-two sites designated as the Caribou Lake Complex (Figure 11) located on the eastern side of Lake Winnipeg (Steinbring and Buchner 1980). Projectile points from the complex are mainly "crude representations of Plano forms . . . essentially percussion-worked, but are well defined as to outline" (Steinbring & Buchner 1980:25). The complex contains a large range of biface variation as well as extremely large bifaces. Trihedral adzes, large percussion flaked end scrapers, and long curved prismatic flakes, all point to a relationship between the Caribou Island complex and the Jordan site materials. Settlement patterns, as well, are similar with the Caribou Lake complex sites being found mainly on large bodies of water all within the Boreal Forest, and at areas of low elevation on lakes. In the Winnipeg area, artifacts are found in lacustrine clay, suggesting a maximum date of 7000 B.C. for the component (Steinbring & Buchner 1980:25-33). It is interesting to note that the main area of most Caribou Island sites is below modern water levels. Steinbring and Buchner, therefore, suggest that occupation of Caribou Island sites occurred when water levels were depressed from modern levels. In the

Lake Winnipeg area the warmest and driest period was between 5500 and 4500 B.C. (Steinbring & Buchner 1980:33). In the Lake Abitibi area, the Jordan site was also located entirely on lacustrine clay, perhaps under even natural modern water levels (after allowing for the dams on the Abitibi River). The warmest, driest period in the Abitibi area is the 5900 to 4000 B.C. period prior to establishment of modern water levels (see Table 7 of this thesis). These time frames are compatible for the suggested age of the complex. The lanceolate projectile points, the large percussion shaped end scrapers, the trihedral adzes, the large bifaces, the Boreal Forest location, the settlement pattern on low areas now partially flooded, and paleo-environmental climatic data all strongly suggest that the Jordan site may be related to the Caribou Lake complex.

The Jessup Site (DdGw-2) and the Mount Goldsmith Quarry Site (DdGw-3)

The Jessup site, because of its demonstrated multi-component nature (Kritsch-Armstrong 1982) and large size, plus the fact it is primarily a quarry workshop site, is difficult to compare to other sites. Based on J. V. Wright's research (Wright 1972d), the Jessup site, and by extension at least some of the Mount Goldsmith Quarry operations, can be placed within the Shield Archaic Tradition (Wright 1972). At Jessup, lacking are the extremely large bifaces, large percussion chipped end scrapers, and crescentic flake blades such as those found at the (presumed) earlier Jordan site. There is a rich variety of cores and preforms at Jessup, but not a great number of finished bifaces or lanceolate projectile points or preforms. Thus, it was thought best to look for comparisons to the Jessup lithic workshop and its sister site, the Mount Goldsmith Quarry, in the form of other documented quarry/workshop situations.

The Jessup Shield Archaic site is closely related to the Abitibi Narrows Shield Archaic site (DeGx-1) (see Table 6) excavated by Frank Ridley (1966). The Abitibi Narrows materials plus material from DaGv-1, (Pearl Beach) (Pollock 1976:83), a multi-component site near Kirkland Lake, Ontario, contain a significant Shield Archaic component. The tool kit represented was thought to be so significantly different from other Shield Archaic sites, that in his M.A. thesis, John Pollock defined it as a separate Archaic phase, namely the Abitibi Narrows Phase. The existing definition of the Abitibi Narrows Phase is as follows:

> The tool kit of this phase consists of large percussion-flaked plano-convex predominantly quartzite implements, large biface blades, ovate blades, leaf-shaped bifaces, predominantly large crescentic end scrapers (over 10 gm), some small end scrapers, bifacial core chopping tools (turtle cores), core-derived lanceolate and stemmed projectile points. These implements are predominantly percussion flaked, and a low incidence of flake-derived tools is indicated (Ridley 1958, 1966; Pollock 1972, 1973).
>
> (from Pollock 1976:175)

This statement was further refined as follows:

> . . . large percussion flaked predominantly greywacke implements, large bifaces, ovate blades, leaf shaped bifaces, predominantly large crescentic end scrapers (over 10 grams), some small end scrapers, bifacial core chopping tools, core derived lanceolate and stemmed projectile points.
>
> (Pollock 1975c)

Since the earlier work, and as a result of this thesis research, it appears that there may be an earlier archaic phase in the region (i.e., an assemblage similar to the Caribou Lake complex represented by the Jordan Site).

In earlier years, Frank Ridley postulated some relationships between the Abitibi Narrows phase and the Sheguiandah site (1966:47). To the east in Quebec, Charles A. Martijn relates the A and B phases of the Wenopsk complex to the lower levels of the Abitibi Narrows site, but the connection is more a chronological than artifactual connection (Martijn and Roger 1969:335). Dean Knight (1971, 1979) did not see any direct connection between the Archaic components at the Montreal River sites and the Lake Abitibi materials, although some similarities exist in regard to scrapers and projectile points.

Other than at the Jessup and Mt. Goldsmith sites, the writer has conducted excavations in two other related sites; namely, area "C" of the Larder Lake (Pearl Beach) site (DaGv-1), and the Fretz site (DdHe-1), previously described by Wright (1972), on Moose Lake near Timmins. At DaGv-1, I conducted three separate excavations (comprising some 625 square feet) in 1973 (Pollock 1975a). It should be noted that at the Larder Lake site horizontal stratigraphy is present. Thus, the three separate areas excavated contained three separate components although some minor component mixture is present. Area "A" relates predominantly to the Duncan phase (Terminal Woodland), and area "B" to Laurel peoples, while area "C" represents a Shield Archaic Abitibi Narrows phase component.

In his 1978 paper, Thor Conway explored the relationship of the Jessup site to others in the region. He agrees with the writer that the closest relationship is to the Abitibi Narrows site, but he feels that because of raw material differences the site is only generally comparable to the Larder Lake (DaGv-1) and Fretz sites. More importantly he feels that there are few other sites on Lake Abitibi directly comparable to the Jessup site and none at all comparable to the Jordan site. In his summary, Thor Conway viewed the Jessup site materials as "a distinctive regional expression of the Lake Archaic/Initial Woodland Period in the Lake Abitibi area" (Conway 1978:6).

Turning to the Quebec side of the Lake, many years of research has been conducted here by R. Marois of the Archaeological Survey of Canada (1975) and prior to that by Thomas E. Lee (1965). Thomas E. Lee excavated during 1964 at the Louis, Iroquoian Point and Slate sites. Only a few pieces of Archaic material were recovered and these are too few for comparisons to the Abitibi Narrows Phase (Lee 1965:42), although some of the items may be related. Most of Marois' excavated sites on the Quebec portion of the lake have been late ceramic bearing sites or early historic sites with no archaic sites and only a few archaic artifacts represented (Marois 1975).

To the south around and near Lake Timiskaming there are large cores with a bifacial chopper industry (Knight 1969, 1971). Some of these cores were too large to be moved even by two people, and showed the effect of extremely large flake removals (Dean Knight: personal communication to John Pollock).

In his 1977 Ph.D. thesis entitled "The Montreal River and The Shield Archaic," Dean Knight illustrated two large bifaces, neither of which appear to be visually similar to the Jessup or Jordan specimens (Knight 1977:Plate 4, page 303). The thesis spans the time frame 300 B.C. to 180 B.C. Within this period he confirms two traditions in the study area. The first is the Shield Archaic with two phases, namely the Abitibi Narrows Phase (3000 - 2000 B.C.) and the Mattawan Phase (2000 -

800 B.C.) followed by the Eastern Laurel Tradition (500 B.C. to A.D. 500). It should be noted that John Pollock's original definitions of these phases (Pollock 1975, 1976) were confirmed and utilized in Dean Knight's thesis. Other area researchers, Conway (1978: personal communication), Hanna (1980:85), Noble (1980:26), and Kritsch-Armstrong (1982), have also used the Abitibi Narrows Phase as a recognized regional variant of the Shield Archaic Tradition. Knight also suggested in his study of the archaic peoples (about 100 km south of Lake Abitibi at the headwaters of the Ottawa River) that the archaic artifacts of the area reflect a local adjustment to the environment within a band hunting range encompassing most if not all of the seasonal sites and subsistence round activities (Knight 1977:291). A similar circumstance is probable for the Lake Abitibi sites.

Finally, Ingrid Kritsch-Armstrong's conclusion to her 1982 M.A. thesis confirms the designation of the Jessup site as a Shield Archaic lithic and habitation site (1982:258).

The Mount Goldsmith Quarry Site

Turning to the Mount Goldsmith Quarry site, one must go much further afield for comparative data. The nearest known quarry sites are the Sheguiandah Site (Lee 1953) on Lake Huron, and the Rogers Quarry Site on the east bank of the Temiscamie River in Quebec (Martijn and Rogers 1969:200). Both are quartzite outcrops that were quarried and/or surface collected for raw lithic materials by prehistoric peoples. The Rogers Quarry is typical of many quarries, including Mt. Goldsmith, in that many of the stone artifacts are problematical, and it is difficult to distinguish natural breakage of the stone from that caused by human agents. The next closest site is the Sheguiandah site on Manitoulin Island. It is a huge quarry containing many tonnes of material, several metres deep in places. No extensive excavations or research have yet been conducted at either site. It is interesting to note that some of the Lorraine quartzite from the Sheguiandah site locality has made its way to sites both at the Montreal River site on Lake Timiskaming (Frank Ridley: personal communication) and to the Jessup site itself on Lake Abitibi (Kritsch-Armstrong 1982:84). Also present at the Jessup site are tools made from greywacke, a lithic material which predominates in lithic tools from the Kirkland Lake area just south of Lake Abitibi (Pollock 1975c, 1976).

Much further afield, at the Bodie Hills Quarry site in Mino County, California, the majority of biface specimens found were broken or partially finished (as is the case at the Jessup site). As well, no hammerstones were located, and the authors (Singer and Ericson) tell us that "initial percussion for decortation or core preparation was accomplished by using a direct block on block or cobble to cobble technique (Singer and Ericson 1977:179). This feature is of interest, as no hammerstones have been located to date at the Lake Abitibi quarry; and it may be possible that blocks of the raw material itself were used as hammerstones for initial reduction and/or quarrying activities. Eight smaller hammerstones were recovered, however, from the Jessup lithic workshop site indicating use of these as percussors (Kritsch-Armstrong 1982:195).

In addition to the Singer and Ericson paper described above, work on other quarry sites has been conducted by Bryan and Tuohy 1960;

Losey 1974; Stiles, Hay and O'Neil 1974; and Gramly 1980. As well, Richard Gramly mentions several researchers who tried "to probe technological processes as well as the magnitude and duration of extraction industries . . ." (e.g., Bisson and Horne 1974; Mills 1922; Ritchie and Funk 1973; Gramly 1980:823).

Some recent ethnographic based studies on procurement of stone and aboriginal attitudes towards lithic material were examined by Gould, Koster, and Santz (1971) in regards to the western desert aboriginies of Australia. These data are interesting, as they state that the quarrying process used on scattered outcrops of chert and quartzite are varied. If there are pieces on surface a boulder is used to smash a few nodules or pieces. The desired flakes are then selected from the pile of debris. Of interest is the fact that "sometimes he preforms a little preliminary trimming by percussion-flaking on the spot; but more commonly, he carries the selected flakes away with him to trim at some later time" (Gould, Koster, and Santz 1971:161). This procedure by far seems to be the pattern at most quarry sites where desirable raw material is collected and then transported to another area for reduction into preforms or finished artifacts. It is certainly the pattern apparent at the Mt. Goldsmith Quarry outcrop site as no finished artifacts or preforms have been recovered at the bedrock source site in comparison to the multitude found at the nearby workshop and campsite. This pattern of collecting raw pieces of material and then reducing it at a nearby campsite into biface blanks or 'rough outs' was also reported at a basalt quarry in northeastern Oregon by Bryan and Tuohy (1960). Here, scattered basalt nodules were utilized as a raw lithic source. The percussion 'blade blanks' found are similar to such blanks found at the Jessup site and many other quarry workshops such as the Strathcona Science Park site (FjPi-29) near Edmonton, Alberta (Newton and Pollock 1979). Also comparable is the fact that only one habitation site was found in the quarry area (Bryan and Tuohy 1960:489).

Turning to Northern New Hampshire excavations at the Mt. Jasper rhyolite lithic source area, shallow audits were used by aboriginal peoples to mine the lithic material. Again, the main processing area is away from the immediate lithic outcrop or deposit, and is located below the mountain (Gramly 1980:3). As Gramly states, "the workshops on and below the mountain possess no special advantages apart from the direction of access. All are within a short distance of water" (Gramly 1980:3). This situation is directly comparable to conditions at the Mt. Goldsmith Quarry. As with the Mt. Goldsmith Quarry, at Mt. Jasper it was not possible, due to the lack of evidence, to reconstruct the mining process. However, the writer certainly agrees with Gramly's suggestion that the nature of mining operations may be quite variable within cultures and between cultural periods depending on transportation available and the season (and perhaps the type of finished tool desired) (Gramly 1980:8).

In northeastern Alberta, the Beaver Creek Quarry and related sites are based on lithic material derived from formerly unconsolidated sediments within bituminous sands (possibly part of the McMurray Formation) that were silicified. The unit is narrow (10 - 20 cm) and the degree of silicification varies greatly (Ives & Fenton 1983:78-88). In contrast to the Mt. Goldsmith and Jasper Mtn. quarry sites, at Beaver Creek the lithic workshop is located beside the quarry. This situation may be due to the fact that the quarry is itself located on a substantial creek used for travel and that it is also near a preferred environmental setting for sites in the area (i.e., the valley rim of a creek or river). It is interesting to note that similar to other discussed quarry sites, very few finished artifacts were recovered from the quarry or workshop areas (Losey 1974:V).

The practice of gathering raw lithic material at a nearby quarry and processing site to produce finished preforms or artifacts for transportation to other localities or use sites has a 1.6 million year history in human evolution, as documented at the M.N.K. chert factory site, Olduvai Gorge, Tanzania (Stiles, Hay, and O'Neil 1974). The quarrying and reduction procedure at this site is similar to the Beaver Creek Quarry, where the workshop is located near the source material and the flake debitage from the workshop site is larger than sites away from the quarry workshop area (Stiles, Hay, O'Neil 1974:304).

In summary, if one considers that the quarry site is the starting point or source for all lithic tool processes, then no study or lithic typology or technological traditions can be truly complete without an examination of the source and methods used to obtain the raw materials for tool manufacture. This conclusion is especially so as it is apparent that initial steps to produce stone tools are almost always undertaken at the quarry or a nearby quarry workshop. The unfinished tool blanks produced here are then transported to the other resource procurement localities during the seasonal subsistence round. Depending on need they are then processed into particular tools depending on the economic activity underway at that locale. Thus, quarry workshop blanks at one site may be used to make spears or projectile points for killing large mammals; at another site for blades and scrapers to process meat, fish, etc.; while at a third they may be used as woodworking tools for canoe manufacture, etc. By analyzing tools from these function-specific sites, important insights into the initial lithic production and distribution processes may be missed or misinterpreted. Clearly, the quarry sites, despite the inherent difficulties of excavation and analysis, are a very important part of archaeological lithic studies.

CHAPTER V

APPLICATION OF THE COGNITIVE APPROACH

Part One: The Historical Development of Experimental Archaeology

It is important to note that the purpose of the experimental thesis research was not to replicate stone tools in shape or form from the Lake Abitibi archaeological sites but rather the purpose was to replicate the technological repertoires and production 'grammars' used by particular prehistoric groups in the manufacture of stone tools. As the experimental research is central to the purpose of this dissertation a brief background history of the development of experimental archaeology is presented in order to provide a context for the thesis experiments.

Despite its lengthy history, experimental archaeology is still considered by many to be "no more than simple auxiliary data collection methods which are resorted to only on rare occasions to test the reasonableness of a belief concerning an artifact's usage or method of fabrication" (Saraydar and Shimada 1973:344).

In order to refute this notion, a number of works in the field are examined beginning with Ascher's 1961 definition of the experimental archaeology field as a "category of experiments which entails operations in which matter is shaped, or matter is shaped and used, in a manner simulative of the past" (Ascher 1961:793). Although somewhat narrowly stated, Ascher's definition marks the beginning of a major expansion of experimental archaeology. In 1973, Thomas R. Hestor and Robert F. Heizer published a major reference work in their Bibliography of Archaeology 1: Experiments, Lithic Technology and Petrography. This work marked an era of major expansion in the experimental field, with works on experimental lithic archeaology regarding controlled pressure flaking (Ackerby 1978), the role of abrasives in the formation of lithic use-wear (Brink 1978), experiments and definitions in flintworking (Crabtree 1971, 1972), prehistoric hide scraping (Levitt 1976), and experimentation in the formation of edge damage (Tringham et al. 1974) to name only a representative sample.

Despite its recent popularity, the role of experimentation in prehistoric studies, however, is neither new nor recent, extending well back in time to the late nineteenth century. Johnson L. Lewis, in a recent (1978) paper, has provided us with a lucid summary of the history of flintknapping experimentation as summarized in the following paragraphs.

Two of the earliest experimenters were Sven Nilsson, who commented on making gunflints, and Sir John Evans who described percussion and pressure flaking in 1868. It is interesting to note that the 1890-1899 decade is "the most prolific in reports of the entire period prior to the 1960s." Most important among the thirty-four papers published were those by William H. Homes (Lewis 1978:340).

The context of experimental work during the period 1890-1899 was the prevalent assertion that North American bifaces were not ancient—despite the fact that they resembled European handaxes. Following the establishment of the above "fact," the majority of work over the next few decades is attributable to European researchers. Many papers during these times were concerned over the eolith controversy (an eolith is a crude problematical stone tool). The argument was over whether or not specific groups of items were of cultural origin or natural formations. S. Hasseldine Warren was one of the notable authors during the period. His 1913 paper describes his experiments in replicating natural fracture, percussion flaking, and pressure flaking (Warren 1913).

The 1920-1929 period saw little in the way of major papers and the eolith debate continued. One of the more notable publications was Pond's study of the knapping techniques of Halvor Skavlem (Pond 1930). It contains a discussion of the fracture mechanics and mentions the importance of raw material. During the 1930-1939 period one of the most important papers is by Wen Cung Pei (1936). This paper is concerned with distinguishing natural from human flaking and indeed should be useful to modern researchers (see Pei, 1936). Pei notes that while stones chipped on beaches, due to natural causes, bear little resemblance to those made by man, those chipped underwater are much more similar because of the absorption of vibrations by the water (Lewis 1978:390).

The remainder of Johnson's paper and a summary discussion detailing current trends in lithic experimentation deal with more recent papers. The main areas covered are heat treatments, mechanical nature of fractures, problematic artifacts, bipolar techniques, replication of artifacts, sequence of the lithic reduction process, and the study of individual variation and fracture processes. This article is of great use in providing time depth, and as a source of

Details of Steps Outlined in Table 10:

A. Experimental Specimens

1. Before undertaking a technological analysis of artifacts from the Jordan and Jessup Sites, it was necessary to engage in some preliminary investigations designed to tentatively identify the type and range of flintknapping behavior used in the manufacture of the Lake Abitibi prehistoric bifaces.

In order to conduct these experiments with Robson Bonnichsen, the writer and David Young travelled to the University of Maine during December, 1980. A first step was to examine the prehistoric artifacts themselves to infer behavior units responsible for the morphological units (i.e., flake scars, platforms, etc.) observable on the specimen. In the case of the Lake Abitibi biface artifacts (both sites), the following behavior units were identified by Drs. Young and Bonnichsen and the writer. Previous experimental research on the flake scar morphology produced by these units was used as a reference base. For the Lake Abitibi artifacts the following behavior units, composed from variables in Table 11, were tentatively identified:

1. Moderate percussion thin with billet 3-41-51
2. Substantial percussion thin with billet 4-51-51
3. Minimal pressure shape with pressure flaker 2-32-31
4. Edge buffet with hammerstone or substitute 2-12-41
5. Edge abrade with grinder 1-11-41 (edge grinding)
6. Moderate percussion shape with hammerstone 3-42-41
7. Substantial percussion shape with hammerstone 4-42-41

Column 1: Function

Series A: Core

01 Face-creating
02 Edge-dulling
03 Edge-thickening
04 Margin-contouring
05 Platform-isolating
06 Face-paring

Series B: Preform Edge

20 Edge-dulling
21 Edge-thickening
22 Edge angle-reducing
23 Edge-centering
24 Edge-straightening
25 Edge-regularizing

Series C: Preform Margin

30 Margin-regularizing
31 Margin-contouring
32 Margin-bevelling
33 Margin-moving
34 Platform-isolating

Series D: Preform Face or Side

40 Face-paring

Series E: Artifact Finishing

50 Notch/stem/barb-creating
51 Flute-creating
52 Contour-correcting
53 Edge-dulling
54 Base/stem-paring

Column 2: Extent of Effect

1 Very minimal
2 Minimal
3 Moderate
4 Substantial
5 Very substantial

Column 3: Type of Behavior

10 Rub:
- 11 Rub abrade
- 12 Rub buffet
- 13 Pressure rub

20 Shear:
- 21 Shear thin
- 22 Shear shape

30 Pressure:
- 31 Pressure thin
- 32 Pressure shape

40 Direct percussion:
- 41 Percussion thin
- 42 Percussion shape

50 Indirect percussion:
- 51 Percussion thin
- 52 Percussion shape

Table 11 Continued:

<u>Column 4:</u> <u>Tool</u>

10 Edge-dulling tool (used to abrade or buffet):
- 11 Stone
  - 111 Cobble (natural surface)
  - 112 Grinder (flat surface of small split cobblestone)
- 12 Antler
  - 121 Small (such as side of pressure flaker)
  - 122 Broad (such as side of billet)

20 Shearer:
- 21 Stone (flat surface of small cobblestone or grinder)
- 22 Antler (side of tool such as pressure flaker)

30 Pressure flaker:
- 31 Antler
- 32 Wood
- 33 Metal

40. Hard percussor:
- 41 Hammerstone
  - 411 Small
  - 412 Medium
  - 413 Large

50 Soft percussor:
- 51 Antler billet
  - 511 Small
  - 512 Medium
  - 513 Large
- 52 Wood billet
  - 521 Small
  - 522 Medium
  - 523 Large

60 Punch (intermediate tool used in indirect percussion):
- 61 Antler
  - 611 Pointed tip (such as tip of pressure flaker)
  - 612 Broad tip (such as tip of billet)
- 62 Wood
  - 621 Pointed tip
  - 622 Broad tip

<u>N.B.</u> If variables are taken from all four columns the 4-digit number code is a production unit; if only the last three columns are used the 3-digit number code represents a behavior unit. This table is reproduced from a similar one in Young & Bonnichsen (1984:43). Definitions and explanation of terms used in the table are given in the glossary at the end of Part Two.

Table 10 continued.

to what extent sequencing of production units are shared by the prehistoric artifacts. On the basis of this information, conclusions are made regarding the amount of technological overlap within and between sites.

5. The final step is to produce a branch diagram of production strategies (Table 31) and repertoire(s). This is the final, most general level of analysis and constitutes the production grammar.

Table 10: Outline Diagram of Analytical Methods

A. Experimental Specimens

1. Visual examination and tentative identification of some behavior units on prehistoric specimens are made.
2. Raw lithic materials for experiments are obtained.
3. A modern craftsman undertakes preparation of preforms and behavior unit experiments. All experiments are video taped for future reference.
4. Experimental specimens are coded on individual flake scar attribute coding forms and are photographed.
5. A final step involves the preparation of summary tables and componential analysis.

B. Prehistoric Artifacts

1. Coating of the prehistoric specimens with ammonium chloride (NH_3Cl) and stereo photography plus line drawings and numbering of individual flake scars.
2. Relevant flake scars are coded on individual flake scar attribute coding forms.
3. Prehistoric flake scar morphologies are related to experimental behavior unit flake scar morphology and an identification made in respect to the prehistoric scar.

C. Analysis

1. Preliminary metric and shape analysis (optional).
2. Summary tables of basic behavior units for each prehistoric artifact and site are compiled.
3. Next, summary tables of production units (behavior unit with function added) are prepared and results further summarized by means of a matrix chart and figure showing unique and shared production units for each artifact.
4. The final level of analysis concerns the sequencing of the preceding production units. First, flow diagrams showing how each artifact was made are produced and a matrix chart and a figure used to show

Part Two: Outline of Analytical Methods and Glossary of Technical Terms

An outline of analytical steps and methods used in the cognitive approach is presented here (Table 10) in order to allow the reader to follow the analysis and comparison of the experimental specimens and prehistoric artifacts. Much of the experimental analysis here is also discussed in Young and Bonnichsen (1984). It should be emphasized that this thesis is not intended to be a "cook book" for the application of the cognitive approach but is only one building block in a series of publications which will culminate in a definitive laboratory manual. The purpose of this thesis is to show that the method can be applied to a set of prehistoric data.

Following the initial outline of methodological steps in Table 10, a more detailed sequential breakdown of the methodology is given, ending with a glossary of technical terms.

bibliographical references for modern researchers. One possible criticism is the fact that, if anything, the author understates the potential contribution of experimental archaeology to lithic technology.

Another useful reference monograph on early experimentation in archaeology is Thomas R. Hester and Robert F. Heizer's bibliography on lithic experiments (1973). During recent years Robson Bonnichsen, who made the experimental artifacts for the research presented in this thesis, has been one of several researchers who have carried on the work of early experimental archaeologists. Through his 1977 monograph on stone tools and a 1979 monograph on bone tools, he has made a major contribution to experimental archaeology and an understanding of technological processes at the aboriginal level.

In summary, it appears that in order to extend beyond the boundaries of traditional morphological analyses of shape and metrical attributes of prehistoric archaeological assemblages, an archaeologist should have a basic understanding of percussion and pressure flaking and other essentials of flintknapping. Without further research based on experimental work archaeological lithic analysis will find it ever more difficult to reach a higher level of understanding regarding aboriginal stone tools.

8. Substantial indirect percussion thin with billet (billet on billet) 4-51-51.

Number eight was a new unit. Examination of flake scars on the large bifaces suggested neither billet, hammerstone, nor pressure flake morphology. Attributes suggested a previous unknown combination of pressure and percussion; therefore, it was decided to try an experiment with indirect percussion, a technique only infrequently employed by modern knappers. The results of the initial experimental testing were quite successful, and in fact this technique may be one of great importance when very large bifaces are produced.

The next major step was the experimental isolation of significant technological attributes utilizing a living craftsman. First:

2. Raw lithic material, as close as possible to that used by the aboriginal peoples for the excavated artifacts, was obtained. In the case of the Lake Abitibi materials, the rock, a volcanic tuff, was obtained and shipped to Maine by the writer. A range of flint-knapping materials from the bedrock formation was obtained similar to that found in artifacts at the archaeological sites (see Table 9).
3. Sixteen biface preforms were made. No attempt was made to replicate shape of existing bifaces and a variety of forms resulted. Of the sixteen biface preforms that were made, two broke leaving fourteen which were used for the subsequent experiments.

Before the experiments began, all experimental specimens were coated with white dye in order that the resulting flake scar morphology from each behavior unit would be clearly visible.

A number of basic experiments were devised to test assumptions about the behavior units identified on the prehistoric artifcts. These involved having the craftsman undertake one behavior unit on each side of the experimental specimens, such as unit 2-41-41, minimal percussion thin with hammerstone. Morpho-contrast sets contained on opposite sides of experimental specimens proved productive in comparing morphologies resulting from different behavior units. Altogether, some twenty-three basic behavior units were replicated on the fourteen experimental specimens by Dr. Bonnichsen as outlined in Table 12. These basic experiments on the Lake Abitibi materials covered a wide range of technological behavior choices; they include the technological repertoires of Bonnichsen and another modern knapper, Errett Callahan. All experiments were videotaped. Table 34 (in appendices) provides an abstracted script of the approximately two hours of black and white videotape which records the experiments. This videotape (#V-22-04-001) is on file at the University of Alberta, along with the experimental specimens and stereo photographs. All are available for reference purposes to other researchers.

As mentioned previously, experimental specimens one and four broke during the experiments and were not used, leaving a total of fourteen usable experimental bifaces. During the experiments, Bonnichsen commented that in general the Lake Abitibi lithic material "is similar to felsite although there are a lot of flaws in some pieces. The material has a fair bit of variation in texture or grain even within the same core. There are complex joint plain surfaces and cracks which have been 'healed' or filled in with silica. Surface raw material has been patinated due to acid forest

Table 12: Basic Experiments Undertaken With the Lake Abitibi Material Based on the Most Common Technological Behavior Units Used by Lithic Craftsmen.

Edge Preparation Units:

Specimen	Code *	Behavior Unit
AB10-1(a)	(2-12-41)	Minimal rub buffet with stone
AB10-1(b)	(2-12-51)	Minimal rub buffet with billet
AB2-2(a)	(1-11-41)	Minimal edge abrade with hammerstone
AB2-2(b)	(2-32-31)	Minimal pressure rub with pressure flaker
AB2-2(c)	(2-13-31)	Minimal platform isolation with pressure rub

Thinning Units:

Specimen	Code	Behavior Unit
AB9-5(b)	(2-31-31)	Minimal pressure thin with pressure flaker
AB9-5(a)	(3-31-31)	Moderate pressure thin with pressure flaker
AB8-6	(4-31-31)	Substantial pressure thin with pressure flaker
AB16-7(b)	(2-41-41)	Minimal percussion thin with hammerstone
AB16-7(a)	(3-41-41)	Moderate to substantial percussion thin with hammerstone
AB5-9(a)	(2-41-51)	Minimal percussion thin with billet
AB5-9(b)	(3-41-51)	Moderate percussion thin with billet
AB7-10	(4-51-51)	Substantial percussion thin with billet
AB11-11	(4-51-51)	Substantial indirect percussion thin with billet on billet

Shaping Units:

Specimen	Code	Behavior Unit
AB6-13(a)	(2-22-30)	Minimal to moderate shear shape with pressure flaker
AB6-13(b)	(3-22-30)	Moderate to substantial shear shape with pressure flaker
AB13-15	(2-32-31)	Minimal pressure shape with pressure flaker
AB14-16(b)	(1-42-41)	Minimal percussion shape with hammerstone
AB14-16(a)	(3-42-41)	Substantial percussion shape with hammerstone
AB3-17	(4-42-41)	Moderate percussion shape with hammerstone
AB15-18(b)	(2-42-51)	Minimal percussion shape with billet
AB15-18(a)	(3-42-51)	Moderate percussion shape with billet
AB12-19	(4-42-51)	Substantial percussion shape with billet

* Production codes and behavior units derived from Table 11.

soils and weathering. Generally, the lithic material from locations 2 and 3 (see Table 9) is of a better quality, 'finer grained, denser and has a sharp translucent edge with good flaking qualities'" (R. Bonnichsen: videotape V-22-04-001:451-621).

4. Following the video taping of the experiments, (all or a representative sample of flakes were saved from each specimen) the experimental specimens were photographed in stereo (Plate 28) preparing the way for an individual flake scar analysis of the experimental bifaces as outlined in the following part.

5. Using the stereo photo as a base, line drawings were made of all flake scars (Figure 12). Scars on the line drawings were numbered providing a reference for each individual flake scar. Individual flake scar attribute coding forms were filled out for each of the twenty-three experimental behavior units (Tables 35 to 57, in appendices).

Componential analysis (Table 15) was used to illustrate and test the morphology in order to demonstrate that the morphological patterns relative to the experimental bifaces can be partitioned by attributes into a patterned clustering (Wallace 1972:115-16).

Finally, a written description of major behavior unit groups (i.e., pressure flaking), based on the experimental data and previous experiments, was given (see pages 186 to 193).

B. Prehistoric Artifacts

Please note that once sufficient reference collections for a wide range of raw lithic materials are established, it will not always be necessary for a researcher to undertake new experimental work.

1. Following the experimental work, the next step is to analyze the prehistoric archaeological artifacts. Each specimen is coated with ammonium chloride (NH_3Cl) and photographed in stereo photo pairs. Line drawings are made of both artifact faces.
2. Each scar is coded in terms of the same fourteen attributes and attribute states used for the experimental specimens (Table 13).
3. Once the prehistoric artifacts are coded, the attribute configurations on each prehistoric flake scar is identified on the basis of the closest matching experimental flake scar configuration (Table 17). Because it was the first attempt at such matching which I have called "scoring," I necessarily proceeded on a trial and error basis. Having undertaken such a laborious task by hand and having worked out the basic methodology, it is anticipated that on future research studies, attribute matching between experimental and prehistoric flake scars can be accomplished by computer programming.

C. Analysis

After the basic data has been gathered in the preceding steps, the next series of procedures is to process this basic data into higher levels of generalization.

1. If desired, a preliminary metric and shape analysis can be undertaken using more traditional methods of analysis (Figure 15).
2. Following this, behavior units for the prehistoric artifacts are listed on a summary table (Table 23) and then transformed into production units (Table 26) by assigning a function on an informed judgment basis, applied in a systematic fashion.
3. A matrix chart (Table 28) can be used to discover patterned

production unit results not obvious from the summary tables. Specimens with over 50% of shared production units are then isolated from the matrix chart and illustrated in a figure which shows the strength of artifact relationships (Figure 16).

4. The next level of the analysis is the sequencing of production units used to make the prehistoric artifact. It should be noted that, although beyond the behavior unit stage, the analysis is based on a selection of logical possibilities, the reasoning and basis for each are clearly documented throughout the analysis and therefore testable and replicatable by other researchers. The first step of the production unit sequencing analysis is to produce coded production unit flow diagrams for each artifact (Figures 17 and 18). Then a matrix chart (Table 30) is used to indicate the percent of shared production unit sequences between and within the two sites. Final production unit sequencing data can then be taken from the matrix chart and illustrated on a figure (Figure 19).

5. The final step is the defining of the repertoires and rules constituting the production grammars found at each site (Table 31).

Please note that one of the reasons the methodology used in this thesis is not suitable as a laboratory manual is that in order to use the just described procedures, a certain amount of expertise is needed in identifying and recognizing the attributes and attribute states, as well as in transforming behavior units into production units and sequences of production units.

the artifact.

- Indirect percussion: Indirect percussion involves seating a tool such as an antler on the edge of the artifact and hitting it with another tool.
- Pressure: Pressure is the type of force that occurs when the tip of a pointed tool is set on the edge of the artifact and then pushed either inward and/or downward with increasing force.
- Thin: Thinning involves the removal of relatively long thin flakes from the underside of the artifact by the application of force at an acute angle to the edge of the specimen. Although the top face is slightly affected by the total or partial removal of the platform, the underside is much more drastically affected. The result is to thin the specimen much more rapidly than the margins are moved in.
- Shape: Shaping involves the more or less perpendicular application of force behind the edge on the top face of the specimen. This rapidly and efficiently removes large chunks of material we call shaping flakes. The result is to move the margins in at a much faster rate than the specimen is thinned..

2. <u>Production Unit</u>: A production unit consists of the behavior unit plus the function it serves. A behavior unit can have more than one function. Only the functions (taken from column 1, Table 11) discussed in this thesis are presented here. For a complete list with illustrations see Young and Bonnichsen (1984:39-42).

- Face paring: Face paring removes thinning flakes from the artifact face. A thinning flake is at least twice as long as the depth of the platform area.

Glossary of Technical Terms

1. Behavior Unit - A specific type of action performed by a craftsman; encompasses variables such as degree and angle of force, and a specific tool. It can be described in terms of attributes and attribute states. Types of behavior comprising behavior units (taken from column 3 of Table 11) and based on Young & Bonnichsen (1984:30-32) are as follows:

- Rub: Edge rub units involve rubbing the edge of the artifact to blunt it slightly. This strengthens the platform in preparation for subsequent flaking activity. Edge rubs are also used to isolate a platform or to smooth the edge after flaking activity has occurred. The amount of material removed is very minimal.
- Abrade: Rubbing the edge of the artifact with a back and forth movement, parallel to the edge, with an abrasive tool such as a rock (grinder).
- Buffet: Dragging a tool such as the flat side of an antler across the edge of an artifact.
- Pressure rub: Rubbing across the edge with the tip of a pointed tool such as a pressure flaker; usually the artifact is held flat so the pressure rub can be applied downward; if the tip of the pressure flaker is applied in an upward motion it can be referred to as a "pressure flick."
- Shear: Shearing involves pressing the flat side of a tool against the artifact edge and slowly twisting it (either perpendicularly or diagonally) across the artifact edge.
- Direct percussion: Percussion occurs when a tool such as a hammerstone or billet is used to deliver a blow to the topside or edge of

- Margin moving: Margin moving involves removing a portion of the margin on both faces simultaneously in order to move the margins inward, thereby shaping the artifact.
- Edge-dulling: Blunting an overly-thin edge so it will not crush when used as a platform for the removal of flakes; can also be used to smooth an edge after the removal of flake.
- Edge-thickening: Removing the overly-thin edge with a pressure, percussion, or shear technique so the edge will not crush when used as a platform for the removal of flakes.
- Margin contouring: Removing material on the margin(s) of an artifact in order to achieve the desired thinness and curvature near the edge; margin contouring may involve reducing the edge angle (if the margin near the edge is overly-thick); if, however, the margin is too flat, contouring may require increasing the edge angle.
- Edge-centering: Removing material on the margins of both faces so that when viewed in cross-section, the edge where the two faces meet wavers as little as possible.
- Edge-straightening: Removing projecting material so that when viewed from the top (rather than in cross-section), the edge wavers as little as possible.
- Edge-regularizing: Edge strengthening, reducing, straightening, and centering - all in one operation; this is most efficiently accomplished with a shearing movement around the edge from one face to the other.
- Margin-regularizing: Removing irregularities on the margin of an artifact; a primary source of such irregularities are the inter-flake scar ridges left by the previous removal of flake; may also be used to

eliminate step fractures.

- Platform-isolating: Removing small notches on either side of area to be used as a platform for removal of a thinning flake; notching helps direct the force so it moves toward the center of the artifact rather than spreading out; sometimes a notch is used to provide a place to set the tip of a pressure flaker.

3. Morphological Attributes and Attribute States - These are used to define the behavior units on experimental specimens and prehistoric artifacts and are used in this thesis in Tables 2, 14, 15, 17 and 18. Table 13 defines the fourteen attributes and fifty-seven attribute states used in this thesis.

4. Morpho-Unit - These are individual flake scars resulting from a behavior unit.

5. Componential Analysis - Use of a matrix table to reveal how behavior units cluster in terms of attribute states. Shows pattern variation and can help to indicate attribute differences between raw material types.

6. Repertoire - The technical options available to a craftsman.

7. Grammar - The total repertoire of behavior units plus the rules governing their application.

N.B. The above glossary is based largely on Young & Bonnichsen (1984). Rather than duplicate their extensive definitions here, I have abstracted only ones relevant to this thesis.

Part Three: Attribute Coding of Individual Flake Scars on the Experimental Specimens

The analysis of each of the experimental specimens (as listed in Table 12) involves use of a master list (Table 13) comprising fourteen attributes and fifty seven attribute states. The attributes are arranged in a logical sequence beginning with the overall size of the flake scar, followed by four edge attributes, three flake scar profile attributes, four flake scar interior morphology attributes and two flake scar distal edge attributes. Within attribute variation is accounted for by the fifty seven different attribute states distributed among the fourteen attributes (see Table 14).

The above procedure is illustrated for the pressure thinning experiment (see Table 14). Plate 28 is one-half of a stereo pair of photographs of substantial pressure thinning, and Figure 12 is a line drawing based on this photograph. The same procedure was carried out for all of the behavior units employed in the experiments. The remaining experiments are coded and described in Appendix 4 (Table 36 to 57). After all the experimental artifacts are coded, the results are summarized in a componential paradigm (see following section).

Table 13

Morphological Attributes and Attribute States Used to Describe Flake Scars on Experimental Artifacts

1.0 Flake Scar Size Attributes:

1.1 Flake Scar Size (based on a ratio between the length of the flake scar and the maximum width of the artifact; measured from the point of force application):
  1.1.1 Very minimal (less than 1/8 maximum width)
  1.1.2 Minimal (1/8 - 1/4 maximum width)
  1.1.3 Moderate (1/4 - 3/8 maximum width)
  1.1.4 Substantial (3/8 - 1/2 maximum width)
  1.1.5 Very substantial (greater than 1/2 maximum width)

2.0 Flake Scar Proximal Edge Attributes:

2.1 Sharpness of Proximal Edge (based on tactile test):
  2.1.1 Sharp
  2.1.2 Intermediate
  2.1.3 Dull

2.2 Proximal margin damage (stepping, hinging, imbedded flakes or shattering along margin of proximal edge due to initial application of force):
  2.2.1 Absent or rare (0-10% of experimental flake scars exhibit this attribute state)
  2.2.2 Limited (10-25%)
  2.2.3 Moderate (25-50%)
  2.2.4 Extensive (50-75%)
  2.2.5 Very extensive (75-100%)

2.3 Microflake scars on Proximal Edge (a series of tiny edge indentations produced by the same action that removed the primary flake):
  2.3.1 Absent or rare (0-10%)
  2.3.2 Limited (10-25%)
  2.3.3 Moderate (25-50%)
  2.3.4 Extensive (50-75%)
  2.3.5 Very extensive (75-100%)

2.4 Morphology of Proximal Edge of Flake Scar (resulting from the type and extent of force applied when the flake is removed)
  2.4.1 Edge relatively straight (can be smooth or rough). No noticeable platform collapse
  2.4.2 Distinct U-shaped notch
  2.4.3 Notch is a flat curve
  2.4.4 Edge not notched but contains distinct convex projections
  2.4.5 Other

(Table 13 continued)

3.0 Flake Scar Profile Attributes:

3.1 Distinctiveness of Bulb (based on tactile test)
- 3.1.1 Not Applicable
- 3.1.2 Indistinct
- 3.1.3 Distinct

3.2 Transition Angle From Bulb to Flake Scar Interior
- 3.2.1 Not Applicable
- 3.2.2 Gradual rise
- 3.2.3 Steep rise

3.3 Flake Scar Thickness (depth of scar as measured from adjacent inter-flake ridges)
- 3.3.1 Thin - 2 mm
- 3.3.2 Thick - greater than 2 mm

4.0 Flake Scar Interior Morphology Attributes:

4.1 Ribs (waves extending toward distal edge from platform)
- 4.1.1 Absent or rare (ribs occur in 0-10% of all flake scars produced by a given behavior unit)
- 4.1.2 Limited (10-25%)
- 4.1.3 Moderate (25-50%)
- 4.1.4 Extensive (50-75%)
- 4.1.5 Very extensive (75-100%)

4.2 Distinctiveness of Ribs
- 4.2.1 Not applicable
- 4.2.2 Indistinct
- 4.2.3 Moderately distinct
- ~~4.2.4~~ Pronounced
- 4.2.5 Variable on same flake scar

4.3 Rib Spacing
- 4.3.1 Not applicable
- 4.3.2 Relatively far apart and fairly evenly distributed across flake scar
- 4.3.3 Relatively far apart and found primarily on distal half of flake scar
- 4.3.4 Relatively close together and evenly distributed across flake
- 4.3.5 Relatively close together and found primarily on distal half of flake scar
- 4.3.6 Variable on same flake scar

4.4 Tearing (a mass of short but parallel lines concentrated along or near the margins of the flake scar)
- 4.4.1 Absent or rare (occur in 0-10% of all flake scars)
- 4.4.2 Limited (10-25%)
- 4.4.3 Moderate (25-50%)
- 4.4.4 Extensive (50-75%)
- 4.4.5 Very Extensive (75-100%)

(Table 13 continued)

5.0 Flake Scar Distal Edge Attributes:

5.1 Flake Scar Shape at Distal Edge
- 5.1.1 Scar terminates in relatively straight distal edge
- 5.1.2 Scar terminates in relatively rounded distal edge
- 5.1.3 Scar terminates in irregular distal edge

5.2 Flake Scar Termination (relation between fracture surface and original surface at distal end of flake scar)
- 5.2.1 Feather termination
- 5.2.2 Step termination

Above attributes partially based on Young & Bonnichsen (1984:91).

Table 14: Individual Flake Scar Attribute Form - Experimental Specimen AB8-6 - Substantial Pressure Thin with Pressure Flaker

1.0 Experimental Specimen Catalogue Number: AB8-6

1.1 Experimental Specimen Storage Location: University of Alberta

1.2 Lithic Raw Material Type Used: Welded Tuff from Lake Abitibi, Ont.

1.3 Modern Lithic Craftsman: Dr. R. Bonnichsen

1.4 Flake Scar Attributes

Coded From: Photograph(s) X Drawing(s) X Artifact(s) X

1.5 Photographic Plate Identification Number: Roll 4, A4, #16

1.6 Video Tape Reel Identification Number: V-22-04-001

2.0 Description of Experiment:

Substantial pressure thin with pressure flaker. Two attempts were made during the experiment (videotape 5098-5202). The material is hard to pressure flake (R. Bonnichsen: personal communication).

2.1 Extent of Effect: substantial 4 (code numbers refer to Table 11)

2.2 Type of Behavior: pressure thin - 31

2.3 Tool Used: pressure flaker - 31

2.4 Total Flake Scars on Specimen: 4 (#5 is a failed scar not used in analysis)

2.5 Attributes on the following coding form are taken from Table 13:

Attributes and Attribute States	Attribute States Present on Experimental Flake Scars	#'s of Flake Scars Exhibiting Attribute State Checked in First Column	% of Relevant Scars Exhibiting Attribute State Checked in First Column
1.0 FLAKE SCAR PROXIMAL EDGE ATTRIBUTES			
1.0 FLAKE SCAR SIZE			
1.1.1 very minimal			
1.1.2 minimal			
1.1.3 moderate	X	all	substantial force was used - material is very hard to pressure flake

Componential Analysis

Componential analysis is important as it can be used to demonstrate that the different morph-units representing experimental behavior units are not random in nature but represent a systematic patterning (Wallace 1962:352-53). The componential analysis (Table 15) shows that there is a patterning of morphology related to specific groups of behavior units. Five different clusters are observable in Table 15. These clusters are as follows:- hard hammer percussion (hammerstone), soft hammer percussion (billet), pressure flaking and shearing, edge units (minimum percussion, rub buffet, rub abrades and pressure rubs), and finally, minimum platform isolating with a pressure flaker.

By demonstrating that morphological patterns specific to individual experimental artifacts cluster into patterns, the componential analysis helps to define the taxonomic system and present it diagramatically. Table 15 also demonstrates that no behavior unit overlaps or includes another and that every behavior unit is discriminated by at least one attribute. However, I do not argue that this is the only or even the best representation according to the arrangement of attributes, only that it appears adequate to show that the morphological separation of behavior units and their patterning is not random but follows a logical pattern. It is also important to point out that many of the blank spaces on the componential analysis chart are also "logical possibilities" (Sturtevant 1964:143) for behavior units, even though they have not yet been identified from experimental work or prehistoric specimens.

Table 15: Componential Analysis Chart

The componential analysis, I believe, indicates even with the relatively small numbers of experimental specimens, that behavior units can be isolated on the basis of morphological attributes. This analysis also allows one, at a glance, to compare other componential analysis charts for other raw lithic materials to the Lake Abitibi welded tuff. This, in the future, should allow for some general conclusions regarding the role raw material plays in formation of force attributes relative to each behavior unit.

Summary Analysis

The following descriptive summary is based upon the results of analysis of all the experimental behavior units, one example of which was discussed in the preceding section. The results of the total analysis can be found in Appendix 4. It should be noted that an edge unit, as used in this thesis, refers to behavior units that primarily affect the edge of the artifact in that they remove a minimal amount of material and do not extend far into the artifact.

Soft Hammer (Billet) Percussion

It should be noted that in the following discussions, "flake" refers to the negative flake scars left on bifaces, not the actual flakes themselves.

Substantial and moderate soft hammer (billet) flake scars share several attributes such as sharp edges, flat curved notches, and limited to extensive tearing in common with hard hammer.

Distinguishing and diagnostic features of soft hammer percussion are a tendency to have a distinct and deep percussion bulb extending well into the flake scar. Flake profiles tend to taper with a mixture of rounded and straight distal edges and a combination of feather and step terminations. Ribs, when present, begin past the percussion bulb and are relatively far apart on the distal end of the scar. Often, two distinct ridges are located near scar termination. Proximal edge damage varies but is generally present especially in areas of platform failure. Microflakes are rare to moderate and are generally less than that found on hard hammer specimens although the range overlaps. Tearing is moderate to extensive and tends to be more pronounced than hard hammer percussion. The other behavior which produces a similar morphology is indirect percussion. Some problems can be anticipated in separating direct percussion with a billet and indirect percussion with a billet under some conditions such as when direct percussion flakes are removed from a ground platform allowing the removal of very large and relatively thin flakes. Minimal soft hammer (like minimal hard hammer percussion) has quite a different attribute regime than the substantial to moderate flakes. In minimal soft hammer percussion, the edge is sharp with extensive to very extensive margin damage with moderate to very extensive microflakes, straight proximal edge or straight with convex projections, and no distinguishable percussion bulbs. Straight and irregular plus rounded distal flake edges are found along with both feather and step terminations (with a tendency towards feather terminations). Generally, minimal billet percussion is similar to other minimal units such as minimum pressure rub with an antler pressure flaker and therefore may be difficult to separate on prehistoric specimens.

Indirect Percussion

Indirect percussion flake scars are usually large spatulate flakes with a flat curved notch for a platform area. There are ribs in some cases (33.3%) but no microflaking on the experimental specimens. Ribs are generally found on the distal half. Tearing is light on the lateral margins. The negative bulb of percussion can be distinctive (33.3%) or indistinct (66.6%). The flake scar rises at a gradual angle and is very flat in cross section. Flakes have an irregular distal edge with feather terminations.

Indirect percussion appears to have characteristics that fall between billet percussion and pressure flaking. Further research needs to be done on this behavior unit to define the range of attribute states and to separate it more definitively from substantial billet percussion thinning, especially when billet percussion follows platform preparation such as abrading.

Hard Hammer Percussion

Substantial and moderate hard hammer (hammerstone) flakes have sharp edges, flat curved notches in the platform area and limited to extensive tearing. These attributes are shared with soft hammer or billet percussion.

Distinguishing features of hard hammer percussion are a strong tendency to have an indistinct negative percussion bulb and flat, thin flakes (not tapering like billet flakes) with predominantly straight and stepped terminations. Ribs, when visible, are indistinct, relatively far apart, and evenly distributed across the scar. Proximal edge damage overlaps with billet percussion. In contrast to the above thinning flakes, some hammerstone shaping flakes can have distinct percussion bulbs but these are associated with short flakes used for moving in the margins of the artifact (D. Young: personal communication). On both thinning and shaping scars, microflaking is common and found at moderate to extensive levels. Tearing is limited to moderate at the moderate and substantial force levels but disappears at limited force levels.

Minimal hard hammer percussion is quite different, having no percussion bulbs, small scars and an intermediately sharp edge only. The proximal edge is straight and margin damage is very extensive. Flake scar terminations are generally straight and either stepped or feathered. The minimal percussion closely resembles rub buffets and other minimal percussion and pressure units.

It should also be noted that in some experiments other than the ones in this thesis, if the craftsman properly prepares the edge and does not take too much material in striking the platform, hard hammer flakes will terminate predominantly in a feathered fashion (D. Young: personal communication).

The preceding discussion of billet and hammerstone flaking is in reference to biface thinning flakes, not initial stages of core reduction. Numerous researchers (Crabtree 1972, Solberger 1976) have stated that hammerstone usually produces a distinct bulb of percussion and this is the case in primary core reduction and some substantial hammerstone shaping flakes. However, our definition of hammerstone flakes refers to biface thinning flakes. It is instructive to note that Patterson and Solberger state (1978:107), "contrary to some popular concepts, flakes made with a hard hammerstone do not necessarily have a high percentage of concentrated force bulbs. . . ." Patten (1980:17) states that a soft to medium hammerstone produces flat, thin flakes useful in the final stages of tool finishing. In commenting on Patten's article, Errett Callahan (1980:18) states, "now that we know soft (to medium) hammers are capable of doing work confused with billet, let's get down to brass tacks and define the real but subtle differences that exist between the two." Finally, Solberger (1981:15) asserts that hammerstones can also produce the "lipped" flakes often stated as being diagnostic of soft hammer. It is apparent from this that more experiments need to be done to define the effect of percussion tool type on percussion bulbs.

Pressure Flaking

Pressure flake scars have sharp edges in common with percussion flakes but otherwise are quite different. Common to all forms of pressure flaking are U-shaped notches on the proximal edge, limited to moderate margin damage and a lack of microflakes. Some pressure thinning flakes have indistinct ribs, relatively close together and evenly distributed across the scar. Tearing is not common. Scar shape at the distal edge can be rounded with some straight or irregular edges. Terminations are predominantly feather but there are also some step terminations.

It should be noted that in some special cases a thick, strong, well prepared edge can be used to remove substantial pressure flakes without the platform collapse that causes a U-shaped notch. In this case, the remnant platform edge will be straight (e.g., microblade cores). The edges of the bifaces under study here, however, are seldom strong enough to support such pressure flaking. A distinctive attribute of pressure flaking is the "pinching" of the pressure bulb. This means that the bulb does not extend across the entire width of the platform as, for example, in billet percussion. Sometimes small imbedded flakes are also present in the pressure bulb at the point of the pressure flaker contact.

Pressure shape flakes have more edge damage and more platform collapse (i.e., more U-shaped notches) leaving a rough and irregular edge. This distinguishes them from pressure thinning flakes.

Rub Buffet, Pressure Rub, Rub Abrade, Shear Shaping and Platform Isolating (All Edge Units)

Some of these ~~units~~ are similar to minimum percussion shape (with billet and hammerstone).

Pressure rub and minimal percussion shape with billet both have sharp edges. Minimum percussion shape with hammerstone and minimal rub buffet with hammerstone both have intermediate sharp edges. Minimal rub buffet with antler billet, minimal shear shape with pressure flaker, and minimum rub abrade with hammerstone, all have dull edges. Most proximal edge morphology is either straight or the attribute follows the existing preform edge. Minimal pressure rub with pressure flaker, however, leaves convex projections on the edge.

All have in common a lack of ribs, very minimal to minimal flake scar size, and a lack of tearing.

Flake shape at distal edge varies among straight, rounded, and irregular terminations with the following two exceptions. Minimal rub abrade with hammerstone produced 100% rounded scars with 100% feather terminations, while minimal rub buffet with antler billet produced 100% irregular scars with 92% feather terminations. Minimal rub abrade with hammerstone produced 100% rounded scars with 100% feather terminations, while minimal rub buffet with antler billet produced 100% irregular scars with 92% feather terminations.

Minimal platform isolating with a pressure flaker (AB2-2c) is distinct from all other units. It has a sharp edge, no ribs, a U-shaped notch and extensive margin damage. Scars have indistinct bulbs rising steeply with curved bottoms with a 'scalloped effect' or troughing effect that produces distinctive flake scars. There are often tiny little pressure platforms produced by the tip of the pressure flaker.

Although some units, such as minimum percussion thin with a billet and minimum percussion thin with a hammerstone, are quite similar in morphology (heavy edge damage, heavy microflakes, straight proximal edges), other edge units have some generalized distinctions which can be used to identify them. Minimum pressure rub with pressure flaker produces minimum sized flakes with sharp edges and heavy margin damage and microflakes, see experimental specimen AB2-2b). Proximal edge morphology is straight with convex projections and occasional U-shaped notches.

Shear shaping, with a pressure flaker (experiment AB5-13), produces an irregular surface or 'face' with a rough topography due to overlapping scars and pressure bulbs — flake scar outlines are usually not clear. If a projection is present, shearing will remove this and sometimes take off a large flake in the process (D. Young: personal communication).

Rub buffets produce flat little scars (experiment AB10-1) sometimes with straight terminations. Scars do not overlap as in shear shaping and are generally distinct. Scar removal is not continuous along the edge.

Part Four: Analysis of the Prehistoric Artifacts

In a similar fashion to the experimental specimens, each prehistoric artifact selected for analysis is photographed in stereoscopic photo pairs and then line drawings are made of each of the artifact faces. Each flake scar on the line drawing is numbered starting at the top right hand margin. Again, each scar is coded in terms of the attributes found in Table 14. In contrast to the experimental artifacts where all scars could be coded together as the extent of effect, type of technological behavior and tool used is known, for the prehistoric artifacts each scar must be coded separately (some attributes are only recorded as present or absent) for each of the fourteen attributes. This is because in most cases there are overlapping technological behaviors and tools represented in the prehistoric artifacts. Therefore, the writer has designed a separate form (Table 18) to be used when coding flake scar attributes on prehistoric archaeological artifacts. As each prehistoric artifact analysis requires extensive stereo paired photographic work of both artifact faces and detailed coding, a sample of six prehistoric specimens judged to be representative from each site were used for the individual flake scar attribute analysis.

From the available sample total of large and medium sized bifaces from the Jordan site, six were selected on a judgmental basis for detailed analysis in this thesis; two of the four large bifaces shown in Plate 6 and six of the twenty-four medium sized bifaces shown in Plate 7. For sites with larger total samples to draw from a random or stratified random sampling method might be considered.

As with the Jordan site, six artifacts were selected from the Jessup site from those shown in Plate 13.

The details of how these prehistoric artifacts were coded is presented in the following sample analysis (Table 18) for one artifact. These standardized analysis forms contain the photographs, flake scar drawings and coding procedure necessary to analyze prehistoric artifacts. Data on the remaining prehistoric artifacts is contained in the appendices.

The prehistoric analysis differs substantially from the experimental artifact analysis in that a system of scoring is used to match the prehistoric morphological attributes to the experimental behavior units (Table 17).

Table 17 is a complex table based on the attribute data abstracted from the experimental analysis tables. In this table the percentage or average of the various attributes states for each behavior unit has been taken from the appropriate experimental specimen coding form (e.g., Table 14 - substantial pressure thin with a pressure flaker specimen AB8-6). The "%" signs on the table indicate the values to be used in the scoring system when prehistoric attributes are matched to the experimental specimens. For future studies it is anticipated that computer programming will be used to match up attributes between the experimental specimens and prehistoric artifacts, thereby producing a behavior unit identification. The computer can also be used to conduct a probability analysis and an estimation of the correctness of the identification. This will eliminate a lot of manual work and speed up considerably the time needed for analysis.

Following Table 17, another table (Table 18) is used as an example to show how a prehistoric artifact (C01073 Jordan Site) is coded and interpreted utilizing the scoring system and data contained in Table 17. To facilitate this, Table 18 was designed to list the fourteen prehistoric flake scar attributes (Section 2.2 of Table 18). Sometimes not all fourteen attributes are present or codable on the prehistoric flake scar and in this case the procedure proceeds with the available attributes. Ten seems to represent an average number of available attributes. If, however, the number of codable attributes drops below six, the chances of making a positive identification decreases substantially. Once the prehistoric attributes are recorded, a comparison is made between each prehistoric attribute and its experimental counterparts (which are listed in Table 17). Comparisons are not made to all experimental behavior units as some are clearly inappropriate, as for example, comparing attributes from a substantial prehistoric flake scar with the attributes from minimum sized experimental flake scars. Generally, three to five comparisons are sufficient to cover the range of possibilities.

As many of the experimental attributes contain within them a number of attribute states, some method of comparison had to be found to evaluate which experimental behavior unit most closely matched the prehistoric morpho-unit. To this end, a method of scoring was used in which each attribute was assigned a value of + 1 in the case of an attribute match or a - 1 in the case of a mismatch. If attribute states were involved, a partial match received a partial score. For example, the experimental behavior unit "substantial percussion thin with hammerstone" has flake scars that terminate 60% of the time in step fractures and 40% of the time in feather fractures. Thus, if the prehistoric flake scar being compared had a feather fracture, its score in the hammerstone comparison would be + 40 - 60 for that particular attribute. If the experimental behavior unit was negative for an attribute and the prehistoric specimen is also negative a + 1 is given. If the attribute is not present on the prehistoric specimen (i.e., has been removed by subsequent edge retouch as in the case of many edge attributes), the attributes are scored n/a and are not included in the analysis. For attribute 4.1 (ribs), if ribs are not present a score is given for this attribute only and the following two rib attributes are scored n/a.

Edge treatment units (in contrast to individual platform preparation) generally extend along a major portion of an edge. In order to increase the accurate identification of these edge treatment units, they are first identified on the artifact margins and that portion of the edge scored as a whole. A separate page is used to score edge units. Both sides of the edge are usually coded together, but if the edge treatment is unifacial, a note is made of that fact. In summary, each complete flake scar on a prehistoric attribute is seen as a natural unit of analysis and that portion of the edge which has received the same treatment is also seen as a natural unit of analysis. Prehistoric flake scars that have been severely overlapped — have had the proximal portions largely removed (remnant scars) — or failed scars (for example, a thinning flake that severely crushed the platform and terminated in a steep hinge fracture) are not suitable candidates for identification and are disregarded.

Once the scars are coded and scored, the positive and negative scores are added at the bottom of the form and then expressed as a per cent (%) of total available attributes. The resulting score (for example a + 68) is then compared to a scoring scale (see Table 16) for an evaluation of the probability of positive identification. A score of + 68 then, would indicate a highly probable identification as compared to a score of + 18 which would indicate a much lower matching of attributes and would rate only an indeterminate identification. In some cases, scores are close together, meaning that the prehistoric scar could be assigned to more than one behavior unit. Then an argument can be made for not giving a specific identification. Or, on the basis of judgmentally weighing some particular attribute thought to be more diagnostic (i.e., rib distribution), an identification can be made and the reasoning noted.

Table 16

+/-, % SCORING SCALE FOR FLAKE SCAR IDENTIFICATION

highly improbable	unlikely	indeterminate	possible	highly probable		
- 100%	- 66.6%	- 33.33%	0% (50+) (50-)	+ 33.33%	+ 66.66%	+ 100%

To Get % Score

1. A 50% overlap is scored as a zero on this scale.
2. Compute score by computing the difference between positive and negative scores.
3. Divide score by total # of attributes to get %.
4. Find appropriate category on above scale.

Table 17 continued.

Summary Remarks

Table 17, as mentioned, is a lengthy table which contains the summary of experimental attribute data for each experimental specimen. The next table (Table 18), also a lengthy one which contains the basic technological data for prehistoric artifact C01073 from the Jordan site, is used as an example. The remaining specimens are analyzed in the appendices. Part one of Table 18 contains basic artifact descriptive data on page 214. This is followed by many pages of data relating to individual flake scars. Each flake scar coding sheet designated as 2.0 - 2.1 (see page 215) is followed by an interpretation or identification sheet (see page 216). On this page the attributes or coding on the prehistoric scar is matched up against the most logical possibilities from the experimental collection as summarized in Table 17 and a behavior unit identified (Section 2.3). These steps (2.1 to 2.3) (i.e., identification or coding of prehistoric attributes and their identification through comparison to the experimental specimens) are repeated for each flake scar and form the bulk pages in Table 18. The results from each flake scar identification are then summarized in part 2.4 of the table on page 257. On page 259 a discussion of how behavior units are transformed into production units is given for each flake scar. The resulting production units are placed into a sequenced flow diagram of production units on page 260. The table is concluded with a written description (page 261) of the technological grammar illustrated in the flow diagram along with photographs and line drawings of the artifact.

Similar analysis of the other prehistoric specimens included in the study are found in Appendix 5.

Table 18: Form for Coding and Interpreting Prehistoric Artifacts
C01073 - Jordan Site

1.0 Prehistoric Artifact Identification

1.1 Artifact Face: Obverse and Reverse

1.2 Prehistoric Specimen Provenience: DeHa-8 - Jordan Site

1.3 Specimen Catalogue #: C01073

1.4 Photographic Plate Identification: special negatives

1.5 Standard Artifact Description:

1.6 Raw Material: welded tuff

1.7 Shape/Artifact Class: ovoid biface

1.8 Flaking (Bifacial/Unifacial): bifacial

1.9 Metric Size: length - 27.5 cm
width - 10.4 cm
thickness - 1.5 cm

1.10 Form/Morphology Description:

This is a very large biface (i.e., 27.5 cm long) while at the same time being quite thin (1.5 cm) for its length and width. It has large spatulate thinning flakes on the main body with extensive secondary thinning flakes along the lateral margins. The specimen was broken bilaterally when collected and has subsequently been glued back together for analysis. The base of the specimen tapers to a straight and clean bedding plane fracture which was present at the time of manufacture as it has been used as a platform for retouch flakes.

Please Note

1. On many of the analysis forms (i.e., page 215 following) some edge attributes for the main flake scar are missing. These are not coded, as the original scar edge has been altered by subsequent edge treatment and is coded in the next column under 'Edge Treatment on Same Scar.' Edge treatments, although coded on one form, cover more than one scar as explained in the note column.
2. Diagrams illustrating the individual flake scars and edge units analyzed are placed at the end of the table (Figure 13 on page 265 and Figure 14 on page 266).
3. After examining the first few examples, the reader may wish to turn to the summary section (2.4) on page 257 of the table.

Table 18 continued.

2.0 Coding and Identification of Technological Attribute States Found on Individual Flake Scar(s)

2.1 Scar Coding Form for Individual Flake Scars

	Artifact # C01073	Main Flake Scar # 01	Edge Treatment on Same Scar	Notes
1.1	Scar Size	moderate	minimal see note 1	1. Edge Unit 1 (a) is composed on minimum to moderate sized thinning flakes 2. Edge Unit 1 (b) consists of a very minimal effect applied over the 1 (a) unit along the edge of the flake scars. Unit 1 (a) is coded on this flake scar sheet. Unit 1 (a) covers the larger minimal sized flake scars 1 to 24 and 36-46 on the obverse face and scars 1 to 14 and 33-40 on the reverse face.

Score		+ 60	+ 52	+ 10	+ 18	+ 46

2.3 Behavior or Morpho-Unit Alternative Chosen from Above:

* Although the scar size is moderate relative to this specimen, compared to other artifacts, it is substantial; therefore, some substantial comparisons are made (i.e., AB11-11 Sub. Indirect Percussion). All are coded +/1 for size.

* Possible + 60 Sub. Indirect Percussion (based on the size of the scar).

Please Note

The above scoring system is derived from comparing the attribute coding in section 2.0 of Table 18 with the coding of the appropriate experimental artifact in Table 17. A perfect match is scored + 1, a perfect mismatch - 1, partial scores are also possible as explained on page 196.

2.3 Behavior or Morpho-Unit Alternative Chosen from Above:

Cannot identify - the indirect percussion score was lowered by attribute 3.3 (scar thickness), therefore, this scar may be a failed indirect percussion scar in that too much material was removed resulting in the hinge fracture.

Table 18 continued.

3.0 Interpretation of Behavior (Technological) Units: C01073

3.1 Function of Percussion Thinning/Shaping Units (moderate to very substantial size scars on specimen)

(a) Substantial Indirect Percussion Thinning: This behavior unit dominates the prehistoric artifact with six flakes (01, 07, 022, 04, R11, R18) identified. Indirect percussion involves placing one end of a billet on a platform, then hitting it with a second billet. In morphology it lies between billet and pressure flaking and produces generally, extremely large, thin spatulate flakes with irregular feather terminations. Production Unit Code is 40:5, 51, 51. This unit was used for primary face paring.

(b) Moderate/Substantial Percussion Thin with Billet: Identified on four scars (030, 037, R19, R20, R32), this unit was used for secondary face paring and margin contouring by increasing the edge angle. Production Unit Code is 31/40:4, 41, 41.

3.2 Function of Pressure Thinning/Shaping Units (minimal to substantial size scars on specimen)

There are minimal, moderate and substantial pressure thinning units present on the specimen [identified from scar R3 and many scars in edge unit 1(a) (scored together)]. Pressure is a type of force produced when the tip of a tool (i.e., antler) is placed on the edge of the artifact and pushed inwards and/or downwards. It is used here for secondary thinning and margin regularizing (removal of inter-scar ridges). Production Unit Code 30/40:3/4, 31, 31.

3.3 Function of Edge Units (minimal to very minimal size scars on specimen)

(a) Edge Unit 1(a): Because of the extreme size of the specimen, one of the edge units 1(a) actually consists of the pressure flaking outlined above. The pressure flaking is not universal and is confined primarily to the edge unit 1(a) area. This was used to thin the tip of the specimen.

(b) Edge Unit 1(b) and Edge Unit 2: These two edge units both have the same behavior unit, namely minimal pressure rub with a pressure flaker. This unit consists of using the tip of a pressure flaker to rub across the edge of an artifact which strengthens an overly thin edge by removing material to blunt the edge. Some minimal flakes are removed and the resulting edge is characteristically rough with numerous small convex projections and some U-shaped notches. Production Unit Code is 21:2, 13, 31.

Table 18 continued.

(b) Reconstructing Sequencing of Production Units: C01073

3.4 Flow Diagram of Production Units (below)

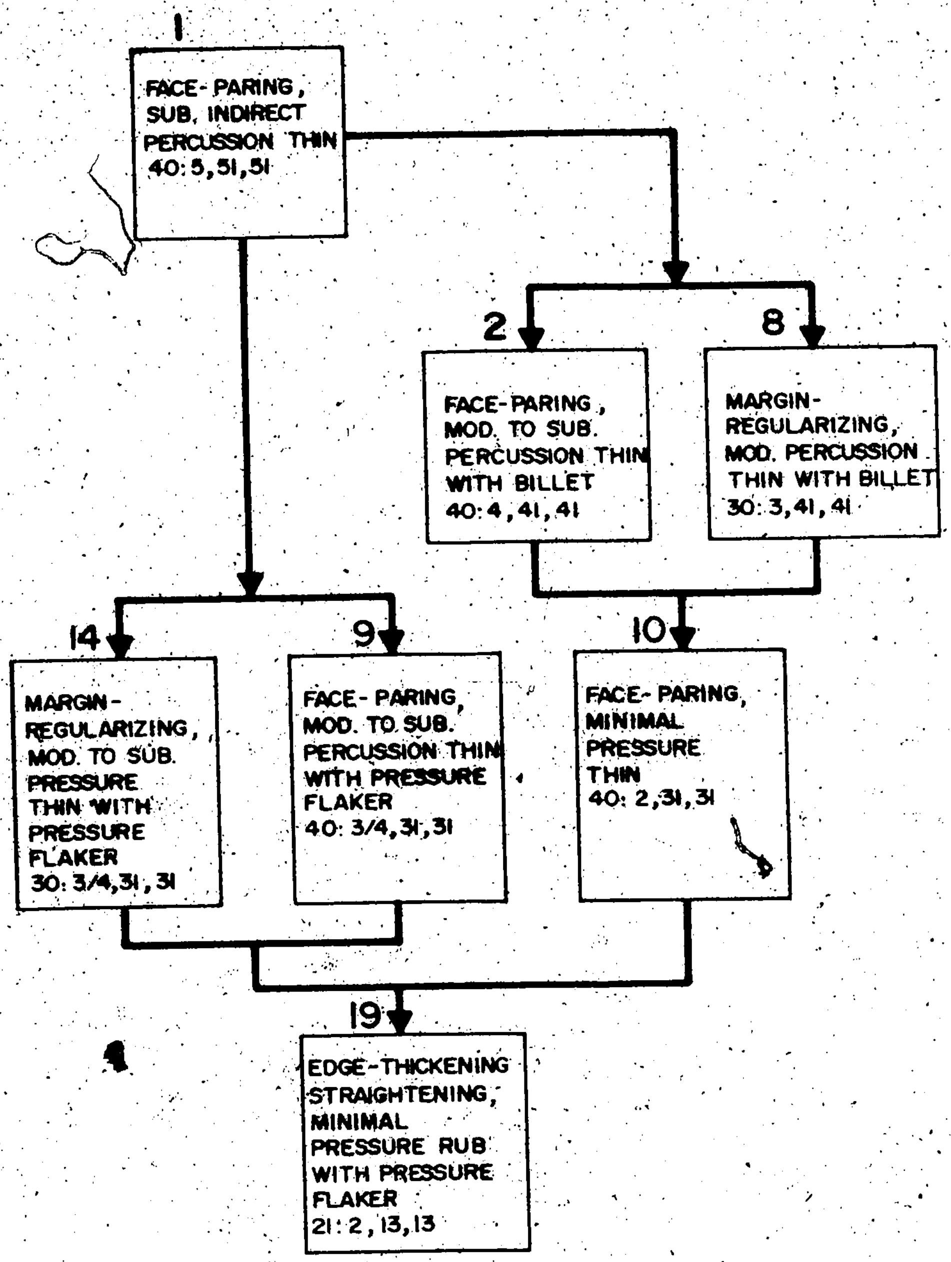

Table 18 continued.

3.5 Description and Discussion of Technological Grammar Found on Artifact

Consisting of an extremely large biface, this prehistoric artifact has long been a source of speculation and interest to the researcher after having first examined it in 1975. The "secret" of its manufacture, especially considering the width and thinness of the item, has long eluded any concrete analysis up to this point in time. However, as observable from the flow diagram of production units the technological basis for the specimen consists of only seven behavior units verifiable on the artifact. No doubt there may have been other units, especially shaping ones, earlier in the production process but these are no longer visible on the artifact faces and have been removed by subsequent thinning flakes. The major thinning unit identified from six scars is the very substantial indirect percussion thinning (face paring) which was used to thin the greater part of the item, especially the interior portions. This initial thinning was followed up by secondary thinning, namely substantial percussion thinning with a billet identified by four individual flake scar coding and scoring results. As well, since significant areas of the surface are not thinned by substantial indirect percussion, the billet units also served as a margin regularizing agent by removing the inter-soar ridges in some cases (i.e., scars 19-21).

Secondary units consist of Edge Units 1(a) and 1(b) and 2. Edge Unit 1(a) is considered as an edge unit due to the small size of the flakes in relation to the large size of the artifact. In fact, however, this unit contains a whole range of pressure thinning from substantial to minimal. The pressure flaking has been positively identified from an analysis of scar number 3 and many composite scars scored together under Edge Unit 1(a). The purpose of the pressure thinning is to thin areas not suitable for further hammerstone thinning due to the already thin nature of the specimen or in areas where one does not want to be forced to remove further margin material such as at the tip of the specimen (percussion flaking leaves shallow curved notches which require edge straightening). Depending on the amount of thinning desired, substantial, moderate or minimal force was used. The pressure flaking is restricted generally to the area identified as Edge Unit 1(a). As well as thinning, some removal of inter-scar ridges was accomplished by pressure flaking (see scars R9-12). The final step in preparing the specimen involves a minimal pressure rub with a pressure flaker. Virtually all edges of the artifact were treated (Edge Units 1(a) and 2). This behavior unit strengthens overly thin edges left by percussion flaking it, and to some extent helps to straighten out the edge by levelling somewhat, the flat curved notches and negative percussion bulb left from indirect and direct percussion flaking and also the U-shaped notches left by pressure flaking. Although the artifact is broken bilaterally this seems to be the result of post manufacturing trauma and not a flaw in the manufacturing strategy or flintknapper's skills.

As mentioned, the specimen is a large and unusual one not only for the boreal forest but for North America as a whole. It is not unwarranted to speculate that manufacture of such specimens is not possibe without the use of the indirect percussion technique. In fact, after examining this specimen, the late Francois Bordes told the writer that

Table 18 continued.

the skill exhibited in this specimen was in the top 30 percentile on a world wide basis (personal communication: Francois Bordes to John Pollock).

APPENDIX 3. EXPERIMENTAL VIDEOTAPE SCRIPT

Table 34: Abstracted Script of Lithic Experiments, Videotape V-22-04-001

Introduction

30 John Pollock introducing the experiment.
285 Young talking about experiment research design. First Rob will make preforms. They will be dyed white. Then Rob will apply the units that they isolated in looking at the collection of Lake Abitibi artifacts. They will be photographed. Third stage will be taking preforms and applying one unit at a time to a preform.

Raw Material Evaluation

643 Rob on tape discussing what he is going to do, physical qualities of rock.

Making Preforms

947 Buffeting edge with granite hammerstone.
984 Hits rock, it splits. (Hard to hear talking).
1040 Striking again.
1066 Takes smaller hammerstone, striking off small edges sticking out.
1130 Using larger hammerstone to try to take off a larger flake. Angle is not right, he adjusts how he's holding rock. Gets a flake. Says rock is very grainy, hard to work.
1228 Continues to strike.
1248 Gets another nice flake.
1285 Striking again. Gets some crushing.
1300 Clearing area of crushing, results in remaining core being a "good slab."
1347 Doing shaping on slab with small granitic hammerstone. It breaks in half due to flaw of iron precipitate in centre. Continues shaping now smaller piece.
1433 It splits in half lengthwise.
1454 He continues to shape. Running into more problems due to material. Decides to stop and move to some larger pieces.
1540 Shaping a rough piece with small hammerstone.
1684 Changes to a billet. Says if he had a choice of materials he would throw this piece away. Changes to billet because it will distribute force over a wider area, maybe not shatter as much.
1777 He says he's setting up platforms.
1792 Says now billet is too light, won't deliver enough energy, changes back to hammerstone.
1850 Trimming off a lump.
1865 Abrading edge with hammerstone.
1880 Changes back to billet. Takes off a flake.
1904 Getting rid of thin sharp edge.
1927 Taking off short shaping flakes.
2060 Material breaks. He shows flaw to camera. Did get a thinning flake.
2140 Shaping another flake with a small sandstone pebble.
2160 Sound problem.

Table 33 continued.

Cat. No.	Description	No. Spec.	Metrics
C02068	biface	1	refined biface - slightly convex base - some bi-lat. second retouch. L. 8.05, W. 3.82, T. .900 cm
C02069	biface	1	bifacially flaked preform - no retouch - on a hinged flake blank - slightly convex base - some secondary retouch. L. 7.43, W. 3.20, T. 1.03 cm
C02082	biface	1	in two sections - snapped bi-lat. rounded (convex) base - bi-lat. step fractures either from thinning or edge preparation. L. 13.70, W. 3.63, T. 1.19 cm
C02929	biface	1	bifacially flaked biface - in two sections - secondary retouch uni-facially at distal end - poss. intended re-use of broken section as a scraper - very slight use-wear - rounded base. L. 9.32, W. 4.26, T. .903 cm
C02363	biface	1	rounded base assymetrical biface - no secondary retouch - tip broken L. 7.80, W. 2.90, T. .808 cm
C02364	biface	1	rounded base - no retouch. L. 9.15, W. 3.20, T. 1.17 cm
C02163	biface	1	narrow pronounced convex based biface - basal section - refined biface - broken. L. 6.36, W. 4.14, T. .90 cm
C02263	biface	1	narrow with pronounced convex base - complete bi-facial flaking - crude collateral flaking on one face - broken. L. 7.40, W. 3.54, T. 1.19 cm
C02289	biface	1	narrow with pronounced rounded convex base - complete bif. flaking.
C02080	biface	1	biface preform incomplete bif. flaking rounded base. L. 10.20, W. 4.92, T. 1.59 cm

Table 33 continued.

Cat. No.	Description	No. Spec.	Metrics
C02074	biface	1	complete bif. flaking - light second retouch bi-lat. & dist. - pronounced rounded (convex) base. L. 7.54, W. 4.23, T. 1.10 cm
C02138	biface	1	incomplete unifacial flaking on dorsal surface - light retouch distal and uni-lat. edges. L. 8.03, W. 4.53, T. 1.40 cm
C02185	biface	1	primarily unifacial flaking - dorsal surface - partially flaked on ventral face - thin - step flakes removed - broken. L. 7.26, W. 4.45, T. 1.61 cm
C02140	biface	1	complete flaking dorsal surface - incomplete flaking ventral surface - marked bi-lateral stepping - rounded base. L. 6.93, W. 3.24, T. .59 cm
C02076	biface	1	light retouch distally & uni-laterally - other lateral edge unmodified - too thick for effective reduction - naturally backed edge? L. 8.46, W. 4.06, T. 1.50 cm
C02555	biface	1	tip section of refined biface. L. 5.64, W. 3.30, T. .93 cm
C02100	biface	1	in two sections, snapped bi-lat. - prob. straight base, however, basal edge removed accidentally during thinning process. L. 9.10, W. 3.93, T. 1.20 cm
C02357	biface	1	biface on hinged flake preform - incomplete bifacial flaking - rounded base (convex) no retouch. L. 10.78, W. 3.66, T. 1.30 cm
C02096	biface	1	in two sections - snapped bi-lat. - straight base - rounded edges - slight bi-lat. secondary retouch. L. 8.75, W. 3.37, T. .908 cm

Table 33 continued.

Cat. No.	Description	No. Spec.	Metrics
C02359	biface	1	two pieces - slight bilat. retouch - probably edge preparation - straight base - rounded corners. L. 9.64, W. 4.06, T. 1.30 cm
C02075	biface	1	crude biface preform - complete rounded (convex) base - slight second retouch - prob. edge preparation. L. 851, W. 4.28, T. 1.52 cm
C02365	biface	1	straight base - refined except for mass near base. L. 8.58, W. 3.70, T. 1.50 cm
C02135	biface	1	broken - two pieces - refined except for mass in centre at break - rounded base, some retouch. L. 10.28, W. 3.50, T. 1.72 cm
C02362	biface	1	base unfinished - incomplete bifacial flaking. L. 8.21, W. 3.80, T. 1.90 cm
C02099	biface	1	rounded base - small unfinished preform. L. 7.0, W. 3.12, T. 1.24 cm
C02085	biface	1	straight base - thin preform. L. 8.83, W. 3.80, T. .97 cm
C02084	biface	1	unfinished base - platform still on base from initial removal of flake on which biface was manufactured. L. 7.60, W. 4.0, T. .94 cm
C02169	biface	1	complete bifacial flaking - light second retouch bi-lat. and distally - shallow convex base. L. 10.53, W. 4.38, T. 1.41 cm
C02070	biface	1	complete bifacial flaking - light second retouch bi-lat. and dist. - shallow but more pronounced convex base. L. 9.31, W. 4.24, T. .94 cm

Table 33 continued.

Cat. No.	Description	No. Spec.	Metrics
C02173	biface	1	broad based thin biface basal section - broken - base shallow convex-rounded - incomplete bifacial flaking - step fractured distally - unsuccessful basal thinning - broken. L. 8.90, W. 5.64, T. 1.03 cm
C02330	biface	1	broad based refined bif. - broken - base shallow convex-rounded - complete bif. flaking. L. 6.60, W. 5.50, T. 1.41 cm
C02193 Stage 3	biface	1	broad based thin biface - broken - base shallow convex-rounded - complete bif. flaking - lat. edges ground - platform prep. L. 7.69, W. 5.61, T. 1.35 cm
C02186	biface	1	broad based - shallow convex base - broken - complete bif. flaking. L. 5.32, W. 5.09, T. 1.04 cm
C02176	biface	1	refined biface basal section - broken - base broad but pronounced round (convex). L. 6.64, W. 5.0, T. 1.03 cm
C02183	biface	1	refined biface basal section - broken - base broad with a more pronounced convexity- rounding - incomplete bif. flaking. L. 7.19, W. 4.91, T. .90 cm
C02081	biface	1	short broad based biface - pronounced convex base - possibly reworked from larger broken biface - complete bifacial flaking. L. 6.78, W. 4.74, T. 1.15 cm
C02077	biface	1	broad based with rounded pronounced convex base - complete bifacial flaking - two sections. L. 9.76, W. 4.80, T. 1.36 cm
C02072	biface	1	complete preform - rounded (convex) base - no second retouch. L. 8.10, W. 3.45, T. 1.20 cm

Table 34 continued.

2183	Continues to shape.
2260	Thinning thick edge.
2290	Also trying to center the edge more.
2345	Abrading edge.
2354	Changing to caribou antler billet (it's harder than other antler).
2370	Gets a flake where he wanted.
2380	Continues to flake. Says his edge is a little too thin so he's taking off a series of short flakes to center it.
2400	Abrading edge with hammerstone. He grinds because if edge is real thin when you strike it will crush.
2419	Striking with billet.
2437	Edge grinding. He says this isn't just grinding, takes a few flakes off too (hammerstone moved vertically across edge).
2455	Striking with billet.
2494	Dulling edge with hammerstone.
2520	Gets nice flake.
2540	Edge grinding.
2550	Flaking with billet.
2555	Straightening edge with small hammerstone, says it's sort of a combination of flaking and grinding.
2584	Strikes with billet, gets a flake.
2634	Trimming flakes with billet to get a convex face.
2720	Taking off minimal thinning flakes, trying to get convex surface.
2760	Abrading edge.
2775	Thinning flakes with billet.
2850	Sound problem.
2903	Trimming with hammerstone on new flake. Wants to take off a bunch of short flakes.
3012	Continues flaking with hammerstone after discussion on why hammerstone instead of billet.
3070	It breaks in half. He says he hit it too hard, shocked it.
3106	Continues to thin and shape one of the broken halves.
3130	Changes to large billet, striking off thinning flakes to get rid of a few lumps.
3143	Abrading edge with billet to make sure edge is strong.
3150	Strikes, gets flake.
3169	Changes back to hammerstone.
3226	Striking with billet
3251	Cleaning edge up with small hammerstone.
3262	Abrading edge with hammerstone.
3270	Striking with billet.
3331	Using hammerstone to get rid of sharp little surfaces on edge.
3345	Striking with billet.
3366	Using small hammerstone to strike flakes.
3402	Got a sort of step fracture.
3431	Moving to experiment #4, early stage preforming.
3450	Striking large chunk with large hammerstone.
3480	Discussing undulations in rock.
3499	Setting up platforms.
3535	Changes to smaller hammerstone.
3547	Still trying to split off one ridge.
3580	Trimming edge with small hammerstone.

Table 34 continued.

3596 Strikes with large hammerstone, it splits because he had too big a mass. It split lengthwise, will continue with one piece.
3620 Break in tape.
3630 Starts with Rob holding large core that he's taking flakes off with large hammerstone.
3813 Using smaller hammerstone to set up platform.
3826 Using larger hammerstone to remove flakes.
3838 Using small hammerstone on edge.
3855 Using large hammerstone to take off flakes.
3869 Showing pile of flakes that they've just taken off.
3903 Rob appears to be filing a pressure flaker.

Start of Experiments

(This section from here to 4719 is out of place. Should be after point 5327)

3938 This section of tape is out of order, should be somewhere at end of recordings. It's part of Experiment #7.

3942 AB16-7. Moderate percussion thin with hammerstone.

3975 AB11. Indirect percussion Experiment - from 3975 to 4719. Young says this is the end of the basic experiments in terms of units that they've analyzed before. Now are going to experiment with a new unit that they've never recorded before, the punch technique.
4017 Rob grinding edge so he'll have a more solid place to work from.
4042 Rob says punch techniques are awkward, hard to use, stand a good chance of breaking the end of your punch.
4065 Holding small antler punch on edge of preform, striking end of it with antler billet.
4108 Showing model artifact, shows what they are trying to get.
4130 Indirect percussion with billet as punch. Gets nice flat flake, what they wanted.
4175 Decide to call this experiment #11.
4202 Abrading edge of preform.
4215 Doing indirect percussion with billet as punch on other face.
4265 Abrading edge.
4285 Doing indirect percussion ~~with~~ billet, gets little flake.
4310 Beveling edge with hammerstone.
4329 Doing indirect percussion with billet. Gets little flake.
4351 Does it again.
4380 Trimming edge with hammerstone.
4390 Does indirect percussion with billet again.
4410 Same thing again.
4432 Same thing again.
4460 Rob wants to try it on obsidian.
4467 Abrading edge of obsidian preform.
4490 Doing indirect percussion with billet. Gets flake. Says it looks like a pressure flaker flake.
4538 Doing it again using small antler punch. Works better to use as lever.

Table 34 continued.

4570 Doing same thing again.
4599 Rob says it's pure tension, no compression.
4622 Doing indirect percussion with billet held sideways as lever and preform held by his shoe.
4658 Trimming edge with billet using direct percussion.
4682 Doing indirect with billet, preform held by shoe again.

4719 AB10-1. Cut to Rob abrading edge of white painted preform.
4785 AB10-1. Abrading edge of preform with side of antler billet.

4838 AB2-2. Pressure rub with tip of pressure flaker. Rob says he doesn't really like the word rub because this is a unidirectional movement, rub implies two directions.
4900 AB2-2. Doing platform isolation with tip of pressure flaker. It is actually doing three different things. Middle one is edge rub, where he's just cleaning it up a little.
4990 AB2-2. Doing abrading of edge with hammerstone.

5019 AB9-5. Minimal pressure thinning/beveling with pressure flaker.
5049 Other side. Moderate pressure thin with pressure flaker. (They just said "This is still experiment #5).

5098 AB8-6. Experiment #6 - substantial pressure thin with pressure flaker.
5155 Holding up artifact to see flake scars. Says they look like moderate even though substantial force was applied.
5183 Doing platform preparation, edge rub with tip of pressure flaker.
5197 Shearing with edge of pressure flaker.
5202 Substantial pressure thinning with pressure flaker. Not really successful.

5242 AB5-9. Minimal percussion thinning with the billet.
5284 AB5-9. No sound at first. He's doing percussion thinning to other edge.

5327 AB7-10. No sound at first. Substantial percussion thinning with billet.

N.B. Break in continuity. Return to point 3942 for AB16-7 and AB11.

5407 No sound. He's doing something with pressure flaker to edge, taking off projections, not thinning.

5443 AB13-15. Says they're "still on experiment #15." Moderate pressure shaping with the pressure flaker. This is what he usually uses almost exclusively for notching. It's an attempt to remove a fair amount of material straight down, not to thin. He breaks tip of pressure flaker.
5466 AB13-15. Switches to copper tipped pressure flaker. Doing moderate pressure shaping on base.

Table 34 continued.

5488 Experiment AB14-16. Minimal percussion shape with hammerstone.
5511 Other edge, moderate percussion shaping with the hammerstone.

5542 Experiment AB3-17. Substantial percussion shaping with the hammerstone.

5565 Experiment AB15-18. Minimal percussion shaping with the billet.

5592 Experiment AB15-18. Other edge, moderate percussion shaping with the billet.

5613 Experiment AB12-19. Substantial percussion shaping with the billet.

5640 Experiment AB6-13. Minimal shear shaping with the pressure flaker. Decide it was really moderate. Hard to do with antler, switches to copper tool min-mod to maximum-minimal on other side.

5679 End of cassette.

APPENDIX 4. EXPERIMENTAL SPECIMENS

2.0 Description of Experiment:

Experiment AB10-1 involved the edge buffet with a hammerstone using minimal force in a working direction from the tip of the preform to the base along the left lateral margin as shown in diagram (Side A). The edge is blunted or rounded so that it will not crush when used as a platform for removal of flakes. An alternative purpose would be to smooth the edge after removal of flakes (Nicholas & Bonnichsen n.d.:10-11).

2.1 Extent of Effect: minimal - 2

2.2 Type of Behavior: rub buffet - 12 (edge - dulling)

2.3 Tool Used: hammerstone - 41

2.0 Description of Experiment:

Moderate pressure thinning/bevelling with antler pressure flaker (left lateral side) (videotape 5019-5049). Pressure is the type of force that occurs when the tip of the pointed tool is set on the edge of the artifact and then pushed either inward or downward with increasing force. Pressure thinning involves the removal of flakes from the underside of the artifact and thins the artifact more rapidly than the margins are moved in (Nicholas & Bonnichsen n.d.:28).

2.1 Extent of Effect: moderate - 3

2.2 Type of Behavior: pressure thin - 31

2.3 Tool Used: antler pressure flaker - 31

1.4 Flake Scar Attributes

Coded From: Photograph(s) X Drawing(s) X Artifact(s) X

1.5 Photographic Plate Identification Number: Roll 2, A2 #8A

1.6 Video Tape Reel Identification Number: V-22-04-001

2.0 Description of Experiment:

Moderate percussion thinning with an antler billet. Scars on the right lateral margin of the flaked face were used (videotape 5242-5327). Percussion flaking involves the use of fairly rapid blows to the edge of the artifact with an antler billet. The object is to thin material from the artifact face rather than to move in or regularize the edge. Minimum percussion flaking either hard or soft hammer does not seem productive for this purpose (see note below).

2.1 Extent of Effect: moderate - 3

2.2 Type of Behavior: percussion thin - 41

2.3 Tool Used: billet - 51

2.4 Total Flake Scars on Specimen: 5 used (8 failed or overlapped scars not used)

2.5 Attributes on the following coding form are taken from Table 14:

N.B.

As with the minimum percussion thin with hammerstone (experiment AB16-7), the minimum percussion thin with a billet was also generally unsatisfactory. Minimal effects in both cases produced platform crushing, extensive hinge fracturing, and small stepped flake terminations which are difficult to tell apart. This being the case, minimal percussion may not have been extensively used by prehistoric peoples utilizing this material.

1.5 Photographic Plate Identification Number: Roll 2, A2, #21a

1.6 Video Tape Reel Identification Number: V-22-04-001

2.0 Description of Experiment:

Minimal/moderate shear-shaping (coded as minimum) with an antler pressure flaker (side A in diagram) (videotape 5640 to 5679). Shearing involves placing the flat side of a tool against the artifact edge and slowly twisting it diagonally or vertically across the artifact edge (Nicholas & Bonnichsen n.d.:22). This unit reduces, strengthens, straightens and centers the edge all at the same time.

2.1 Extent of Effect: minimum - 2

2.2 Type of Behavior: shear shape - 22

2.3 Tool Used: pressure flaker

2.4 Total Flake Scars on Specimen: 6

1.6 Video Tape Reel Identification Number: V-22-04-001

2.0 Description of Experiment:

Substantial percussion shape with hammerstone (side A in diagram) (videotape 5488 - 5542). (Originally experiment was classed as moderate.) Edge shaping involves removing material so that the edge is regularized in a symetrical curve. The major intent is shaping rather than thinning the artifact. This is accomplished by taking off large chunks of material from the edge which results in the margins being moved in at a much greater rate than the specimen is thinned.

2.1 Extent of Effect: substantial - 4

2.2 Type of Behavior: percussion shape - 42

2.3 Tool Used: hammerstone - 41

2.4 Total Flake Scars on Specimen: 3

2.5 Attributes on the following coding form are taken from Table 14:

<u>N.B.</u> Substantial percussion shape with hammerstone is often used on cores (R. Bonnichsen: personal communication).

Main Scar #	Edge Unit Scar #	Rating on Scoring Scale	Final +/- Score	Behavior Unit	Experimental Control Specimen

3.0 Interpretation of Behavior (Technological) Units

(a) Transforming Behavior Units into Production Units:

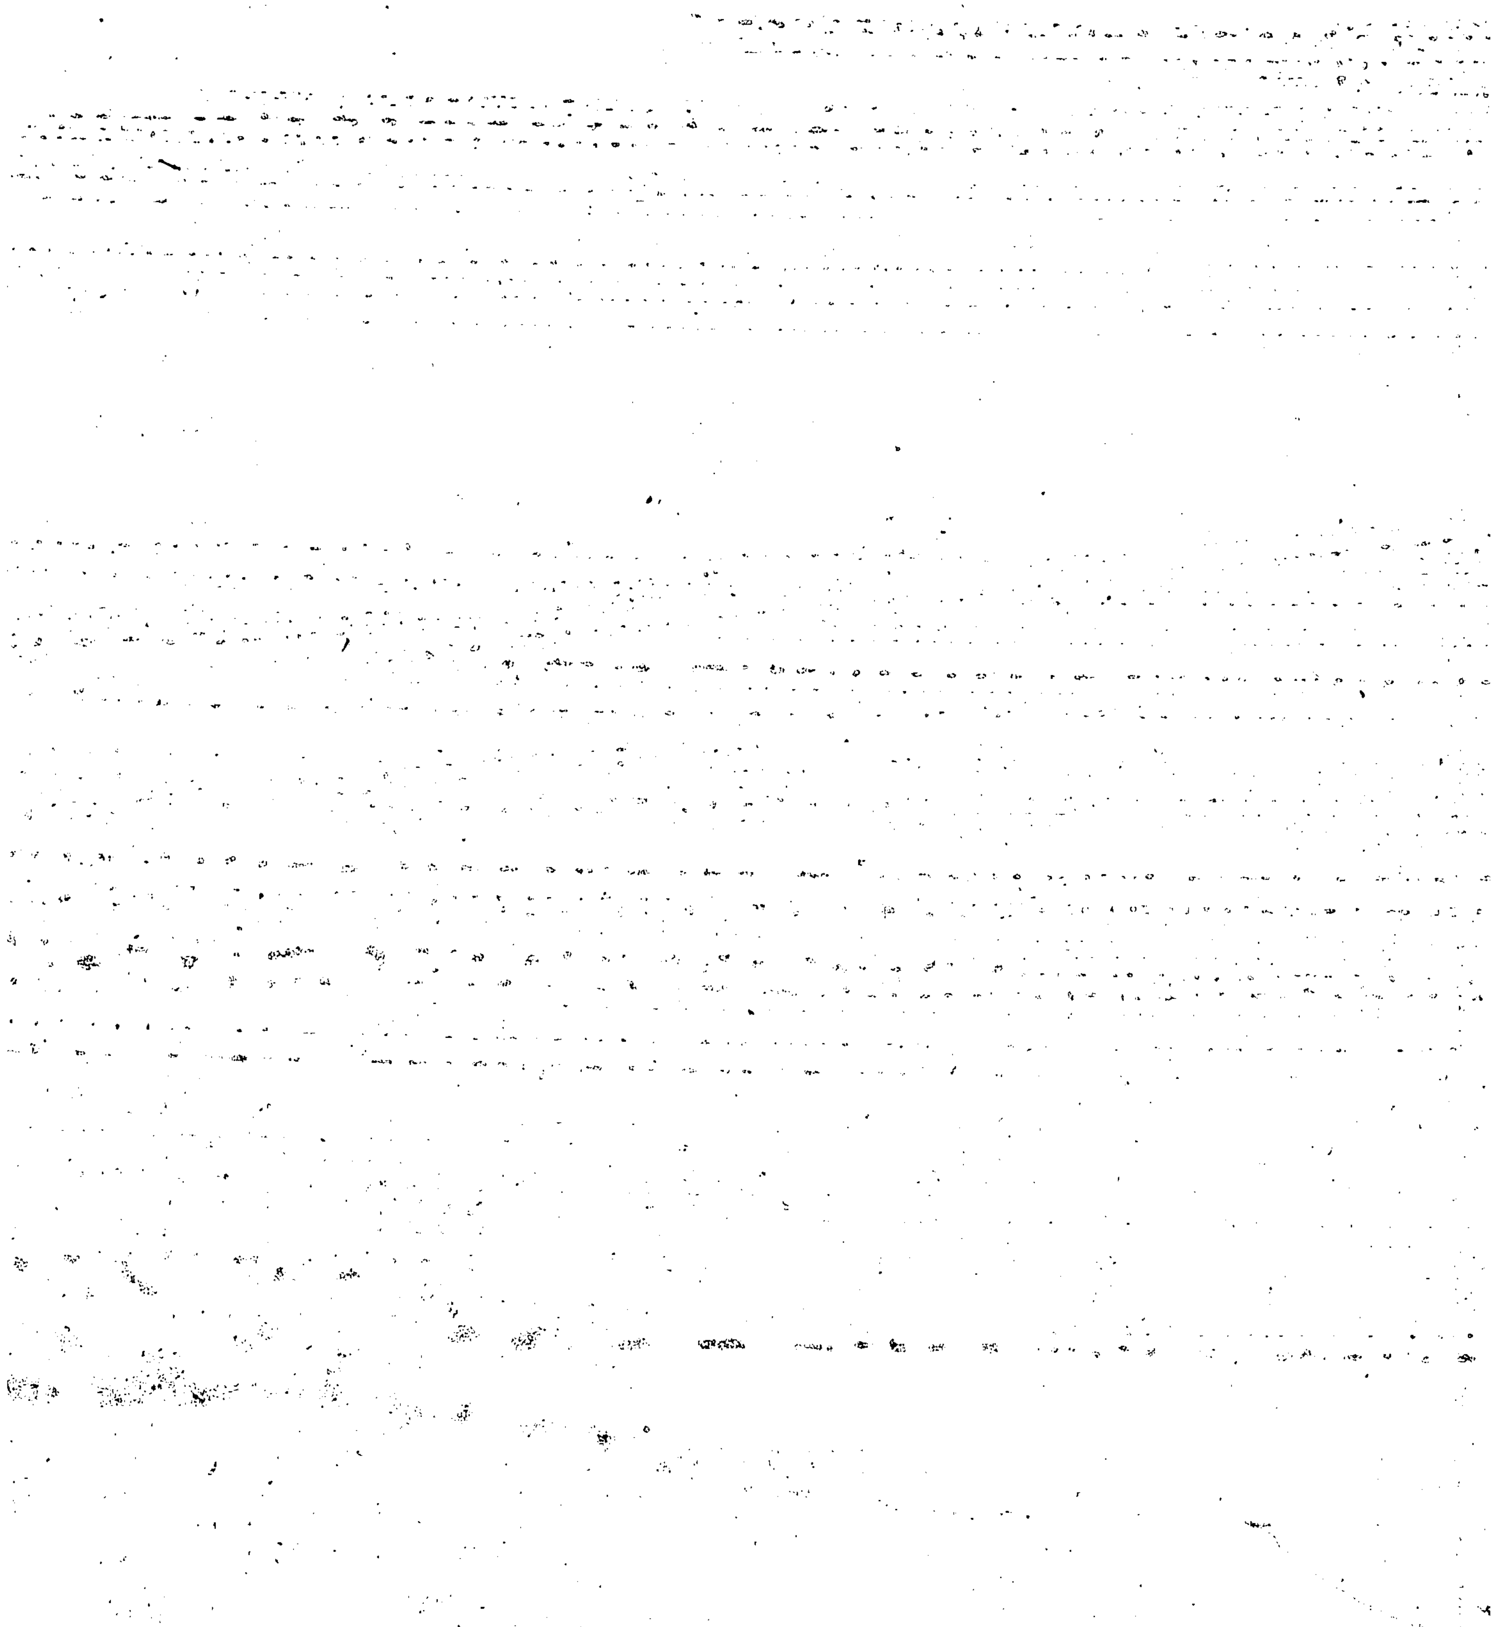
3.1 Function of Percussion Thinning/Shaping Units (moderate to very substantial size scars on specimen)

3.2 Function of Pressure Thinning/Shaping Units (minimal to substantial size scars on specimen)

3.3 Function of Edge Units (minimal to very minimal size scars on specimen)

(b) Reconstructing Sequencing of Production Units:

3.4 Flow Diagram of Production Units (below)



3.5 Description and Discussion of Technological Grammar Found on Artifact

Table 59: Form for Coding and Interpreting Prehistoric Artifacts

1.0 Prehistoric Artifact Identification

1.1 Artifact Face: Obverse and Reverse.

1.2 Prehistoric Specimen Provenience: DeHa-8 - Jordan Site

1.3 Specimen Catalogue #: C01083

1.4 Photographic Plate Identification: Roll 2, B3, #30A
Roll 3, B4, #27

1.5 Standard Artifact Description

1.6 Raw Material: Welded Tuff

1.7 Shape/Artifact Class: Lanceolate Biface

1.8 Flaking (Bifacial/Unifacial): Bifacial

1.9 Metric Size: length - 10.3 cm
width - 4.8 cm.
thickness - 1.3 cm

1.10 Form/Morphology Description:

This is a finished, broad, lanceolate biface which was originally a large flake. The obverse side of the former flake has been subjected to a series of shallow thinning flake removals while the reverse side exhibits an even larger number of flake scars. From a judgmental viewpoint, the specimen appears to be well made. Finally, some water-caused wear or polish is visible on the scar ridges of the reverse face.

2.0 Coding and Identification of Technological Attribute States Found on Individual Flake Scar(s)

2.1 Scar Coding Form for Individual Flake Scars

	Artifact # C01083	Main Flake Scar # 0-5	Edge Treatment on Same Scar	Notes
1.1	Scar Size	sub.	very (2) minimal (3)	1. bulb of force removed by edge treatment.
2.1	Edge Sharpness		intermediate to dull	
2.2	Margin Damage		0	2. Edge Unit #1 coded from scars 1 to 7 and 25-29.
2.3	Microflakes		light	
2.4	Proximal Edge Morphology		straight with minor convex. projections	
3.1	Negative Bulb of Force	(see Note 1) n/a		
3.2	Bulb to Scar Transition Angle	n/a

	Edge Unit 2	possible	+ 64	min. rub buffet hammerstone	AB10-1(a)
R19		possible	+ 60	sub. indirect percussion	AB11-11
R23		possible	+ 60	moderate perc. thin billet	AB10-1(b)

3.0 Interpretation of Behavior (Technological) Units

(a) Transforming Behavior Units into Production Units: C01083

3.1 Function of Percussion Thinning/Shaping Units (moderate to very substantial size scars on specimen)

(a) Substantial Indirect Percussion: These flakes (R6, R10, and R19) were used to remove large face paring or thinning flakes. Production Unit Code is 40:5, 51, 51.

(b) Moderate Percussion Thin Billet: Only one flake (023) was identified for this face paring unit. Production Unit Code is 40:3, 41, 51.

3.2 Function of Pressure Thinning/Shaping Units (minimal to substantial size scars on specimen)

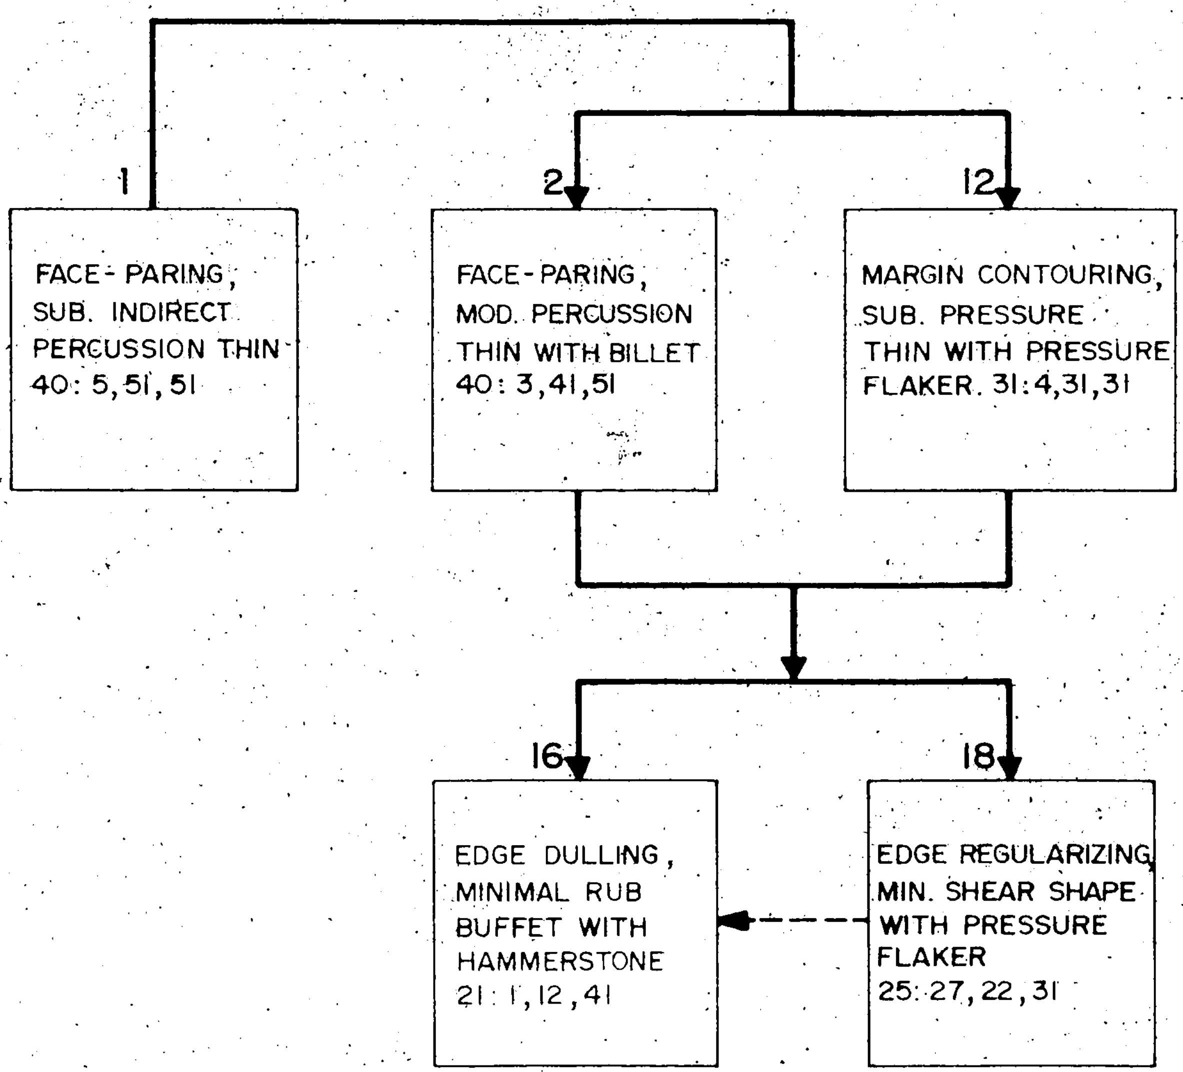
(a) Substantial Pressure Thinning with a Pressure Flaker: Scars in the vicinity of 012 and 026. In this case the function of the face paring was to contour the margin and create or increase the edge angle on the flat flake core surface to make a bifacial instead of a unifacial edge. Production Unit Code is 31:4, 42, 51.

3.3 Function of Edge Units (minimal to very minimal size scars on specimen)

Edge units, because of their limited number of morphological attributes which are often very similar, are hard to identify in some cases. On this specimen, Edge Unit #1 has been identified as min. rub/buffet with a hammerstone, production unit code 20-1-12-41. Edge Unit 2 has also been identified as min. rub/buffet hammerstone. Some shearing may also be present especially on scars 014-018. Production Unit Code is 21:1, 20, 31. Finally, edge unit 3 has been identified as min. rub buffet hammerstone - Production Unit Code is 20:1, 12, 41 (same as 1 & 2 above).

Shearing units are used to strengthen, reduce and center the edge of the artifact all in one movement around the edge from one face to another utilizing a pressure flaker (scars R14, 15, 18).

Rub buffet units consist of dragging the tool such as a hammerstone or billet across the edge of the artifact. This blunts the edge and strengthens the platforms. Flat scars with little overlapping are removed (i.e., scars R2, R7).



(b) Reconstructing Sequencing of Production Units: C01083

3.4 Flow Diagram of Production Units (above)

3.5 Description and Discussion of Technological Grammar Found on Artifact

The prehistoric biface was manufactured from a large flake with only one large remnant scar (O-23) remaining from the original flake core.

The obverse side of the artifact has at least one moderate billet percussion shaping flake which is likely a remnant left from an earlier stage of manufacture. The billet work was followed by substantial pressure thinning on the obverse face as evident from scars O8, O9, O11, O12, O13, O26, etc., which was used to contour the margin by increasing the edge angle and creating a bifacial edge on the flake core.

On the reverse face where a larger amount of face paring was needed, substantial indirect percussion was used to remove large thinning flakes (scars R6, R10, R19). Some earlier billet thinning work is also present on this face (i.e., scar R23).

The artifact margins were blunted and strengthened by means of a rub/buffet with possibly a small hammerstone. This strengthened the edge. Regularizing and centering of the edge was accomplished with a shearing movement around the edge from one face to another, primarily on the base, utilizing a pressure flaker.

Plate 45: Prehistoric Artifact C01083, Reverse Face.

Table 60: Form for Coding and Interpreting Prehistoric Artifacts

1.0 Prehistoric Artifact Identification

1.1 Artifact Face: Obverse and Reverse

1.2 Prehistoric Specimen Provenience: DeHa-8, Jordan Site

1.3 Specimen Catalogue #: C01085

1.4 Photographic Plate Identification: Roll 2 B3 #34A and Roll 3 B3 #24

1.5 Standard Artifact Description:

1.6 Raw Material: Welded Tuff

1.7 Shape/Artifact Class: Biface

1.8 Flaking (Bifacial/Unifacial): Bifacial

1.9 Metric Size: length - 11.0 cm
width - 5.0 cm
thickness - 1.2 cm

1.10 Form/Morphology Description:

This specimen is a preform or rough out of a broad lanceolate shaped biface with a distinctive convex base. It is manufactured from a bifacially retouched flake-core and several original flake-core surfaces remain intact. Notable on the specimen are two areas of distinctive platform crushing and the grinding along the lateral sides. The base, however, has a sharp edge.

R25		possible	+ 40	Mod./Sub. Perc. Thin Hammerstone	AB16-7(a)

3.0 Interpretation of Behavior (Technological) Units

(a) Transforming Behavior Units into Production Units:

3.1 Function of Percussion Thinning/Shaping Units (moderate to very substantial size scars on specimen)

(a) Substantial Indirect Percussion Thin Identification scars 025, R13: This unit is used for face paring (thinning flakes). Production Unit Code 40:5, 51, 51.

(b) Substantial Percussion Thin with Hammerstone: This behavior unit was used on the prehistoric specimen for face paring or substantial thinning of the artifact. Production Unit Code 40:4, 41, 41.

(c) Moderate Percussion Shape with Hammerstone: These behavior units were used on the base of the specimen to move in the margin of the artifact (i.e., to control the outline shape of the artifact rather than just thin it). Production Unit Code 33:3, 42, 41.

3.2 Function of Pressure Thinning/Shaping Units (minimal to substantial size scars on specimen)

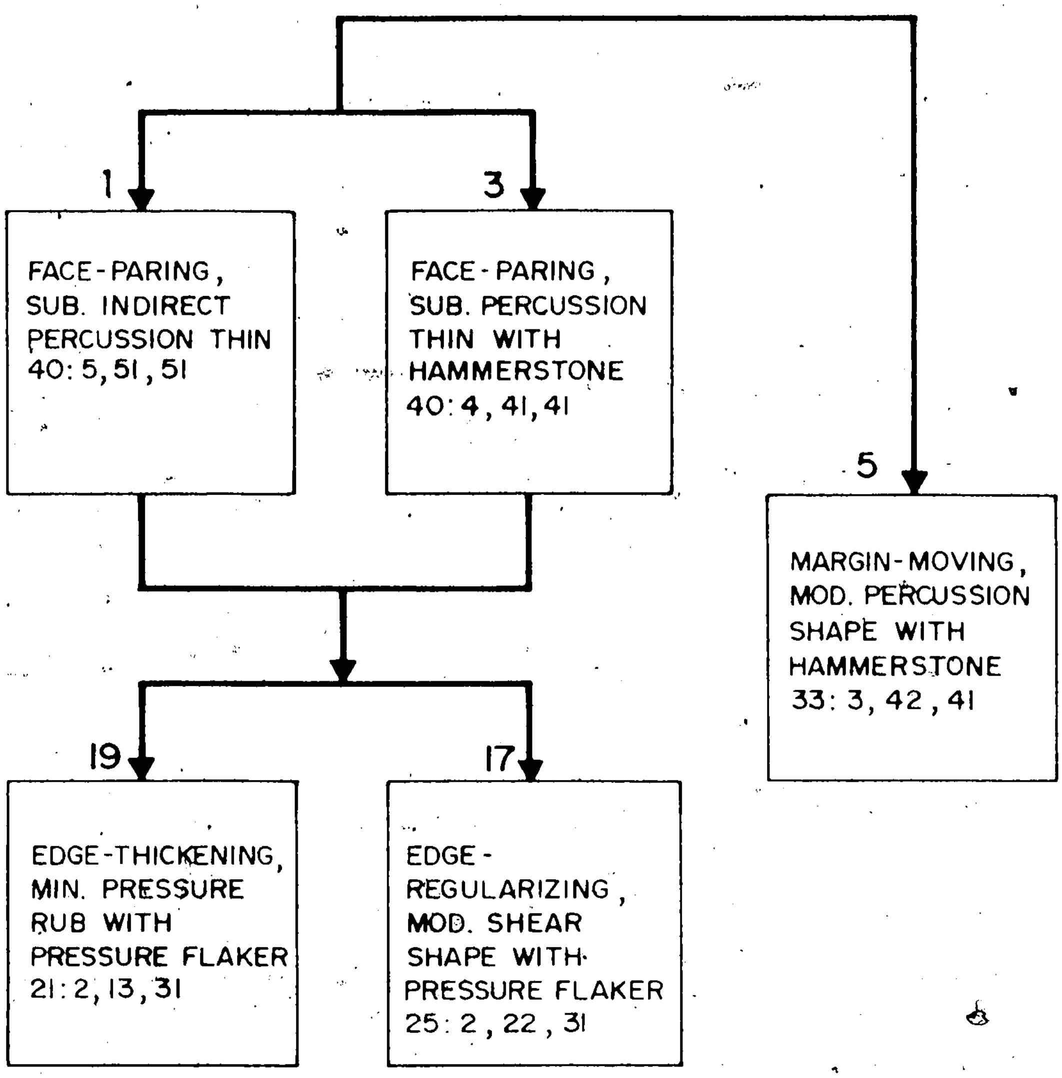
There are no pressure thin or shape units on this specimen.

3.3 Function of Edge Units (minimal to very minimal size scars on specimen)

Two edge units are identified:

(a) Minimum Pressure Rub with P.F.: This behavior unit was used to remove a thin edge and thicken/strengthen it prior to removal of further thinning/shaping flakes. A pressure rub removes a relatively small amount of material from the edge. Production Unit Code is 21:2, 13, 31. (Edge Unit # 1).

(b) Moderate/Substantial Shear Shape with Pressure Flaker: This behavior unit was used to straighten, center, reduce and strengthen the edge by means of a shearing movement around the edge from one face to another. Production Unit 23/25:2, 22, 31. Although edge unit # 2 could not be identified due to the scores being too close together it is possible that it is either a minimum shear or a minimum pressure rub as these units are represented elsewhere on the specimen.



(b) Reconstructing Sequencing of Production Units: C01085

3.4 Flow Diagram of Production Units (above)

3.5. Description and Discussion of Technological Grammar Found on Artifact

This prehistoric biface rough out or preform was manufactured from a large flake of which only a small remnant area remains (see scar 023). This flake core was thinned utilizing substantial percussion thinning with a billet. Shaping of the convex base area was accomplished by moderate and substantial hammerstone shaping flakes which moved a portion of the margin on both faces at the same time, therefore substantially changing the outline form in the base area to produce the desired convex shape. As the artifact was by no means finished and because of the need to remove further thining ahd shaping flakes, the same edges (edge units 2 & 3) were straightened, centered, reduced and strengthened by means of a moderate to substantial shear shape with the tip of a pressure flaker. Another edge (edge unit 1) perhaps did not require as much edge work and here the pressure flaker was used to rub the edge of the artifact to blunt and strengthen it. At this point the biface preform is complete and ready for final thinning and shaping.

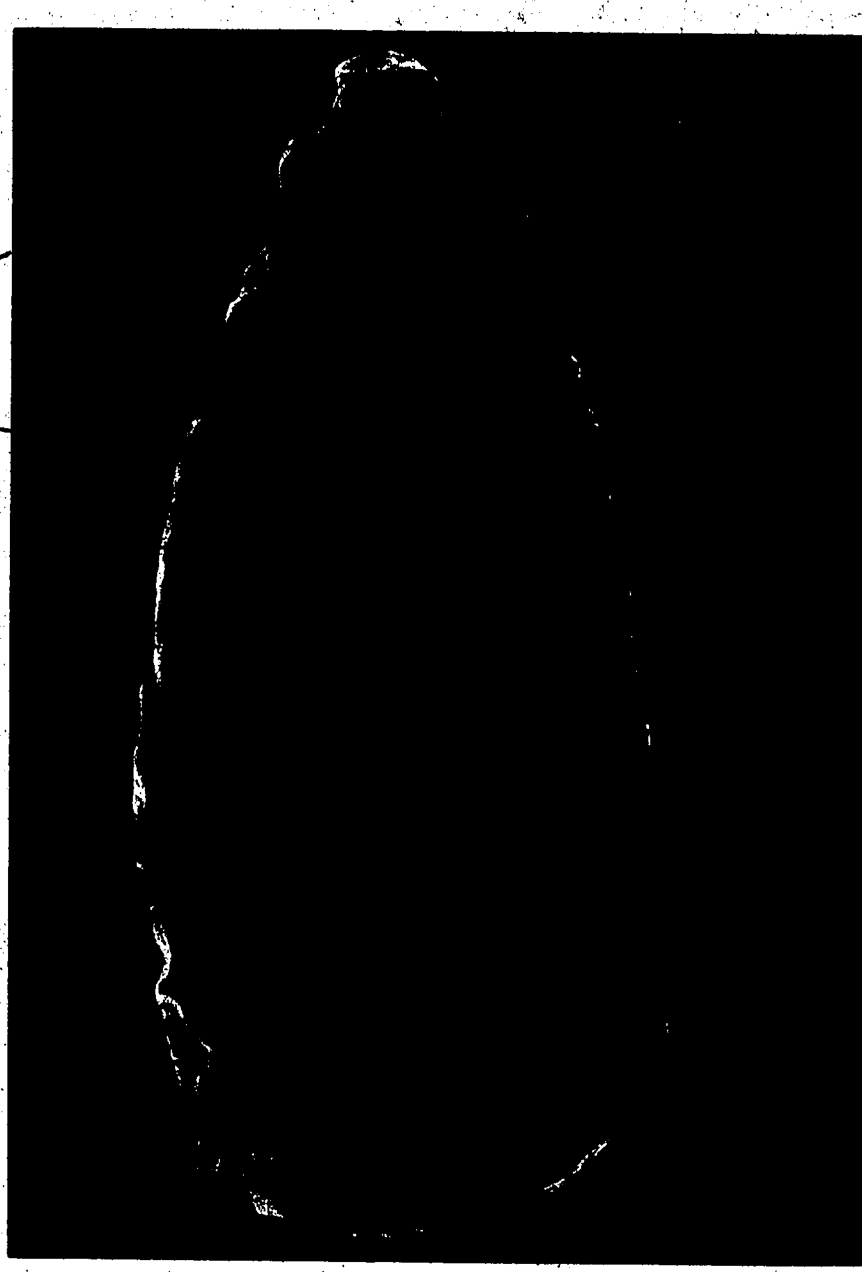

Plate 47: Prehistoric Artifact C01.085, Reverse Face.

Table 61: Form for Coding and Interpreting Prehistoric Artifacts

1.0 Prehistoric Artifact Identification

1.1 Artifact Face: Obverse and Reverse

1.2 Prehistoric Specimen Provenience: DeHa-8

1.3 Specimen Catalogue #: C01079

1.4 Photographic Plate Identification: Roll 4, A5, #34

1.5 Standard Artifact Description:

1.6 Raw Material: Welded Tuff

1.7 Shape/Artifact Class: Biface

1.8 Flaking (Bifacial/Unifacial): Bifacial

1.9 Metric Size: length - 10.2 cm
width - 4.2 cm
thickness - 1.1 cm

1.10 Form/Morphology Description:

This is a well shaped lanceolate biface with thinning and retouch flakes present on both the obverse and reverse faces. It is a broad specimen (4.2 cm) and has a broad but slightly convex base exhibiting several thinning scars on the obverse face. No original cortex or core surfaces remain on this artifact.

3.0 Interpretation of Behavior (Technological) Units

(a) Transforming Behavior Units into Production Units: C01079

3.1 Function of Percussion Thinning/Shaping Units (moderate to very substantial size scars on specimen)

(a) Substantial Indirect Percussion Thinning: Identified on scar 09, this behavior unit is used to remove very large, thin, face paring flakes used to thin the specimen. Production Unit Code is 40:5, 51, 51. Indirect percussion involves placing the edge of a billet on a platform and then hitting it with another billet (billet on billet).

(b) Moderate/Substantial Percussion Thin with Billet: Identified on scars 019 and R8, this unit was used for the majority of face paring or thinning flakes on the artifact. Production Unit Code is 40:4, 41, 51.

(c) Moderate Percussion Shape with Billet: This was the method used to move in the margins and shape the artifact after thining. Production Unit 33:3, 42, 51.

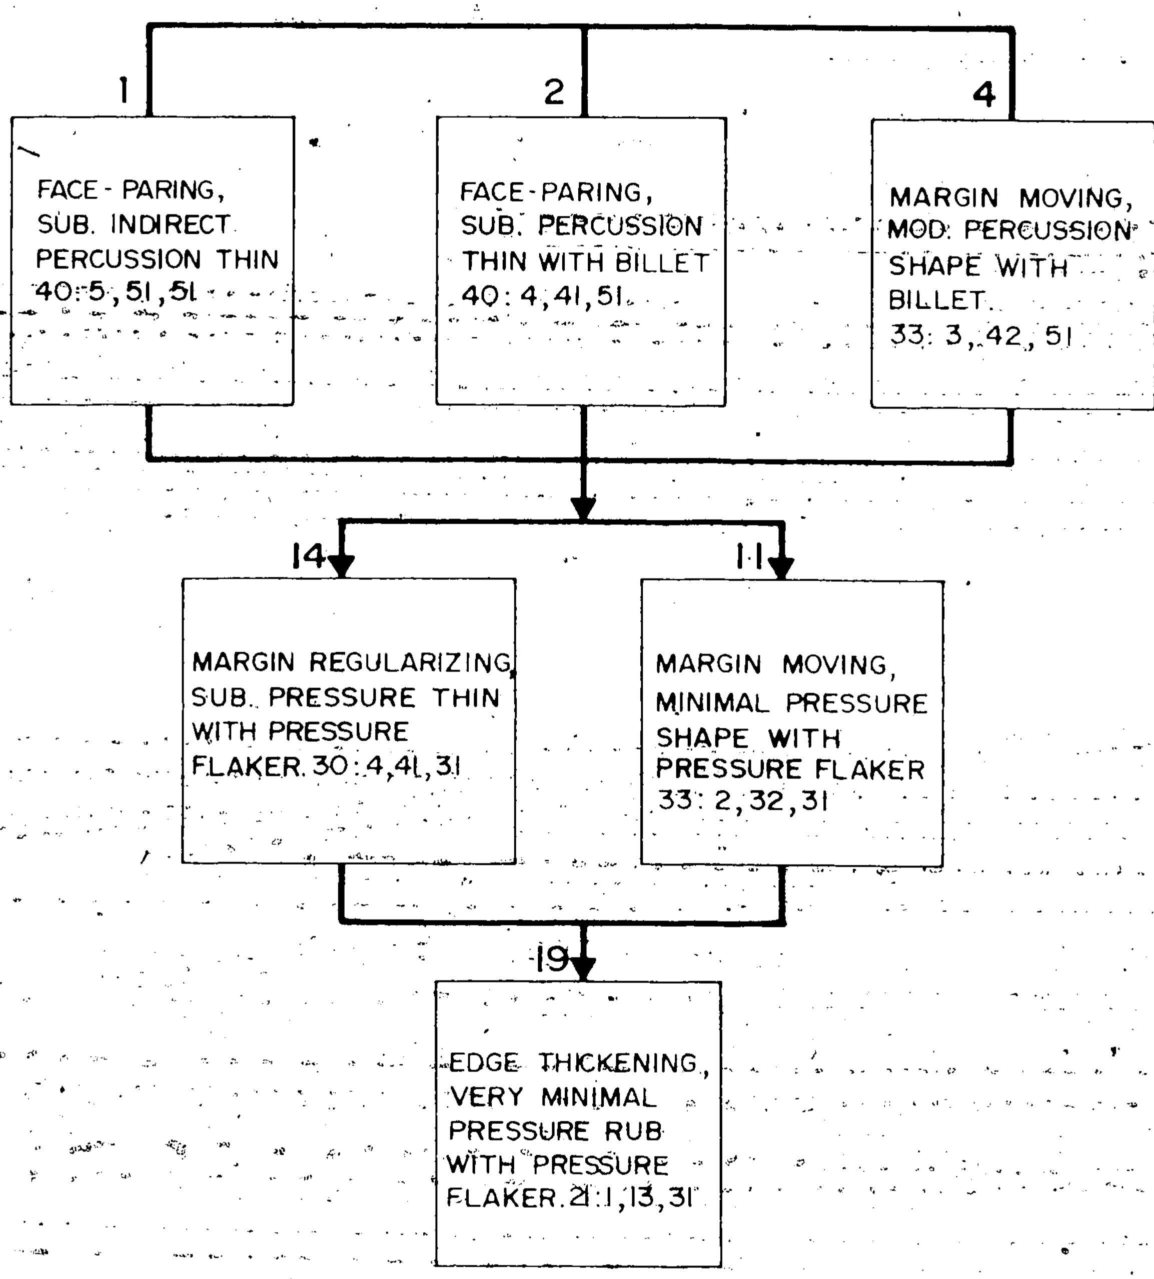
3.2 Function of Pressure Thinning/Shaping Units (minimal to substantial size scars on specimen)

(a) Substantial Pressure Thin with P.F.: Identified from scars R7 and R17, it was used to remove interflake scar ridges and at the same time, face paring and thinning. Scar R18 is a good example. Production Unit Code is 30:4, 41, 31.

(b) Min./Mod. pressure Shape with P.F.: These units are present on the tip and especially the base of the artifact and was used to shape the base and create a bifacial edge angle. Production Code is 31/33:2/3, 32, 31.

3.3 Function of Edge Units (minimal to very minimal size scars on specimen)

(a) Only one edge unit (# 1) is identified on this specimen comprising a minimum pressure rub with the tip of a pressure flaker. This behavior unit executed by rubbing across the artifact edge with the tip of a pressure flaker serves to remove on overly thin edge, thereby thickenin and also straightening it. A relatively small amount of material, in the form of very minimal flakes, was removed and the unit leaves distinct convex projections (04%) and some U-shaped notches from the pressure work (16%). See reference experiment AB2-2(b) for details. Production Unit Code is 21:1, 13, 31.



(b) Reconstructing Sequencing of Production Units: C01079

3.4 Flow Diagram of Production Units (above)

3.5 Description and Discussion of Technological Grammar Found on Artifact

Prehistoric artifact C01079 is a well made symetrical biface in a finished form. Not surprisingly, there is little evidence left of the original shaping flakes, these having been obscured by the extensive thinning found in the finishing stages. Some of the large flakes (i.e., 09) may have been removed by substantial indirect percussion thinning but the majority of the work on the specimen (4 scars identified: 019, R-7, 8, 17) was by substantial billet face paring (or thinning) percussion flakes. Following the percussion thinning which leaves sharp, thin edges and shallow curved notches on the edges, some percussion shaping or margin moving was undertaken to shape the outline form of the artifact. This was followed by pressure margin regularizing to remove interscar flake ridges. As well, pressure shape was used to shape the tip and base.

Following the pressure flaking and billet shaping, a pressure flaker was used to strengthen the overly thin edge and, to some extent, straighten the edge by levelling out the flat curved notches. However, while this does straighten the edge it also leaves a rough edge with many small convex projections and the occasional U-shaped notch. For some reason which is not readily apparent from a technological aspect (which may suggest post-manufacturing breakage), the artifact is broken bi-laterally and has been restored for analysis.

1.0 Prehistoric Artifact Identification

1.1 Artifact Face: Obverse and Reverse

1.2 Prehistoric Specimen Provenience: DeHa-8, Jordan Site

1.3 Specimen Catalogue #: C01067

1.4 Photographic Plate Identification: Roll 1, A2, #37
Roll 1, A1, #31

1.5 Standard Artifact Description:

1.6 Raw Material: Welded Tuff

1.7 Shape/Artifact Class: biface

1.8 Flaking (Bifacial/Unifacial): bifacial

1.9 Metric Size: length - 10.8 cm
width - 6.6 cm
thickness - 1.2 cm

1.10 Form/Morphology Description:

This semi-lunate biface has extensive primary percussion flaking on its obverse and reverse surfaces with less retouching on the obverse face. One lateral margin has a steep working face which may have served as a scraping/cutting edge. Distinctive thinning flakes are also visible on the broad straight base of the specimen.

3.0 Interpretation of Behavior (Technological) Units

(a) Transforming Behavior Units into Production Units: C01067

3.1 Function of Percussion Thinning/Shaping Units (moderate to very substantial size scars on specimen)

(a) Very substantial Indirect Percussion Thinning: This is the most substantial unit on the specimen and was used as the major thinning or face paring behavior. Indirect percussion removes very large thin spatulate (or wide) flakes that usually have rounded or irregular distal edge shapes with a feather termination. Production Unit Code is 40:5, 51, 51. Indirect percussion scars are 08, 09, 016, and 021.

(b) Minimum Percussion Shape with Billet: Identified from scar # R1 (composite scar). This is a unifacial application of margin contouring to create a steep scraping face along the right lateral margin of the reverse face of the artifact. The purpose was to create a substantial edge angle or a very strong working face. Production Unit Code is 31:2, 42, 51.

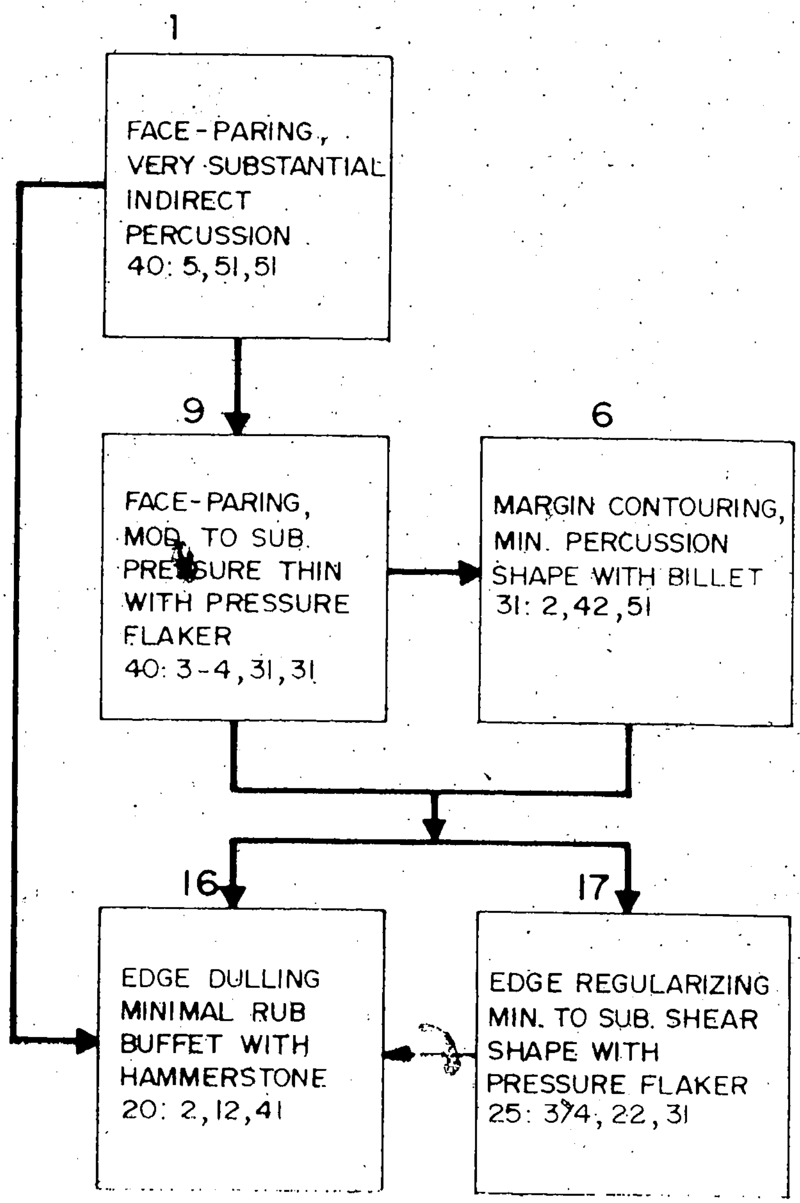
3.2 Function of Pressure Thinning/Shaping Units (minimal to substantial size scars on specimen)

(a) Mod./Substantial Pressure Thinning with Pressure Flaker: This unit is extensive on the specimen especially near the tip on the reverse side where there is a complex of pressure flakes (see scar forms for R25, R26). In fact, there appears to be overlapping pressure scars as scar R26 overlaps earlier pressure scars R27, 28, 29. This behavior unit served a secondary thinning or face paring function. Production Unit Code is 40:3/4, 31, 31.

3.3 Function of Edge Units (minimal to very minimal size scars on specimen)

(a) Minimal Rub/Buffet with Hammerstone: A rub buffet involves rubbing the edge of the artifact while at the same time dragging the tool with minimal force. This removes minimal flakes and blunts or rounds the edge so it will not crush easily. It also serves to smooth the edge somewhat (see edge unit 1 on artifact). Production Unit Code is 20:2, 12, 41.

(b) Mod./Sub Shear Shape with Pressure Flaker: This was the final edge unit applied and served to straighten, center, and regularize the edge. Production Unit Code is 23-25:3-4, 22, 31. This unit is present on the obverse side scars 0-3 to 0-7 and on the reverse side on scar # 1 in front of 03 to 08.



(b) Reconstructing Sequencing of Production Units: C01067

3.4 Flow Diagram of Production Units (above)

3.5 Description and Discussion of Technological Grammar Found on Artifact

This prehistoric specimen has a distinctive semi-lunate outline shape quite different from the other Jordan site bifaces. However, the manufacturing units (behavior units) are essentially the same as other specimens in the collection. The major thinning unit is a very substantial indirect percussion thin which was used for face paring (thinning of the specimen). Following this one edge (Edge Unit 2) received special attention (right lateral margin, reverse face) in that billet percussion shape was used to contour the margins to create a steep angled and strong cutting/scraping edge. Some areas (especially near the curvature zone) were edge straightened, centered and regularized by means of a mod./sub shear shape with a pressure flaker. Some other edges on the artifact, especially near the tip, were thinned by means of moderate/substantial pressure flaking with a pressure flaker (see scars R25, R26). The pressure flaking is particularly prevalent on the tip of the specimen (reverse side scars R20 to R37) and in places, some overlapping is evident (scar R25 overlaps earlier pressure scars R27-29). Edge unit # 1 was applied to most of the pressure thinned areas and has been identified as a possible minimal rub/buffet with hammerstone. The rub/buffet activity involves rubbing the edge of the specimen in a dragging motion, thus blunting or rounding the edge and generally making it stronger and more serviceable (i.e., edge will not crush so easily when used). As in edge unit 2, some portions of this edge were also further treated with a mod./sub shear shape with pressure flaker (see scars R3-R8).

1.6 Raw Material: Welded Tuff

1.7 Shape/Artifact Class: Biface

1.8 Flaking (Bifacial/Unifacial): Bifacial

1.9 Metric Size: length - 25.6 cm
width - 11.2 cm
thickness - 2.0 cm

1.10 Form/Morphology Description:

This specimen (like C01073) is a very large biface (i.e., 25.6 cm long) and, at the same time, is quite thin (2.0 cm) and represents an overall symetrical and well made artifact. The main body thinning flakes are extremely large, thin, and spatulate in shape. Exetnsive thinning and removing of interidge scars has taken place along the lateral margins. As well, the edge has been straightened by smoothing out some of the flat curved notches left by removal of the large thinning flakes. The base is straight but cuts across the artifact at a shallow angle and contains basal thinning flakes. Some water wear is evident on both faces and this may have partially obscured some attributes such as tearing.

Score			+ 80	+ 88	+ 84	+ 96

2.3 Behavior or Morpho-Unit Alternative Chosen from Above:

N.B.

Note that the above units are very close in morphology and it is difficult to separate them or distinguish between them.

As the other two units on edge units 1 and 2 are either min. pressure rub with p.f. or mod./sub. shear shape with p.f., and as min. press. rub with p.f. scored the highest, this unit has been selected here, based on this secondary evidence, highly probable + 96 min. pressure rub with p.f.

R38		Possible	+ 58	Sub. Indirect Percussion	

3.0 Interpretation of Behavior (Technological) Units

(a) Transforming Behavior Units into Production Units:

3.1 Function of Percussion Thinning/Shaping Units (moderate to very substantial size scars on specimen)

(a) Substantial Indirect Percussion Thinning: This unit was the major means of thinning the specimen, and five flakes (015, 031, R15, R33, and R38) have been identified as pertaining to this behavior unit. Indirect percussion is a billet on billet technique which produces flakes having the morphological characteristics between those of hammerstone/pressure and billet. The flakes are extremely large and spatulate, generally with irregular feathered terminations. Production Unit Code is 40:5, 51, 51.

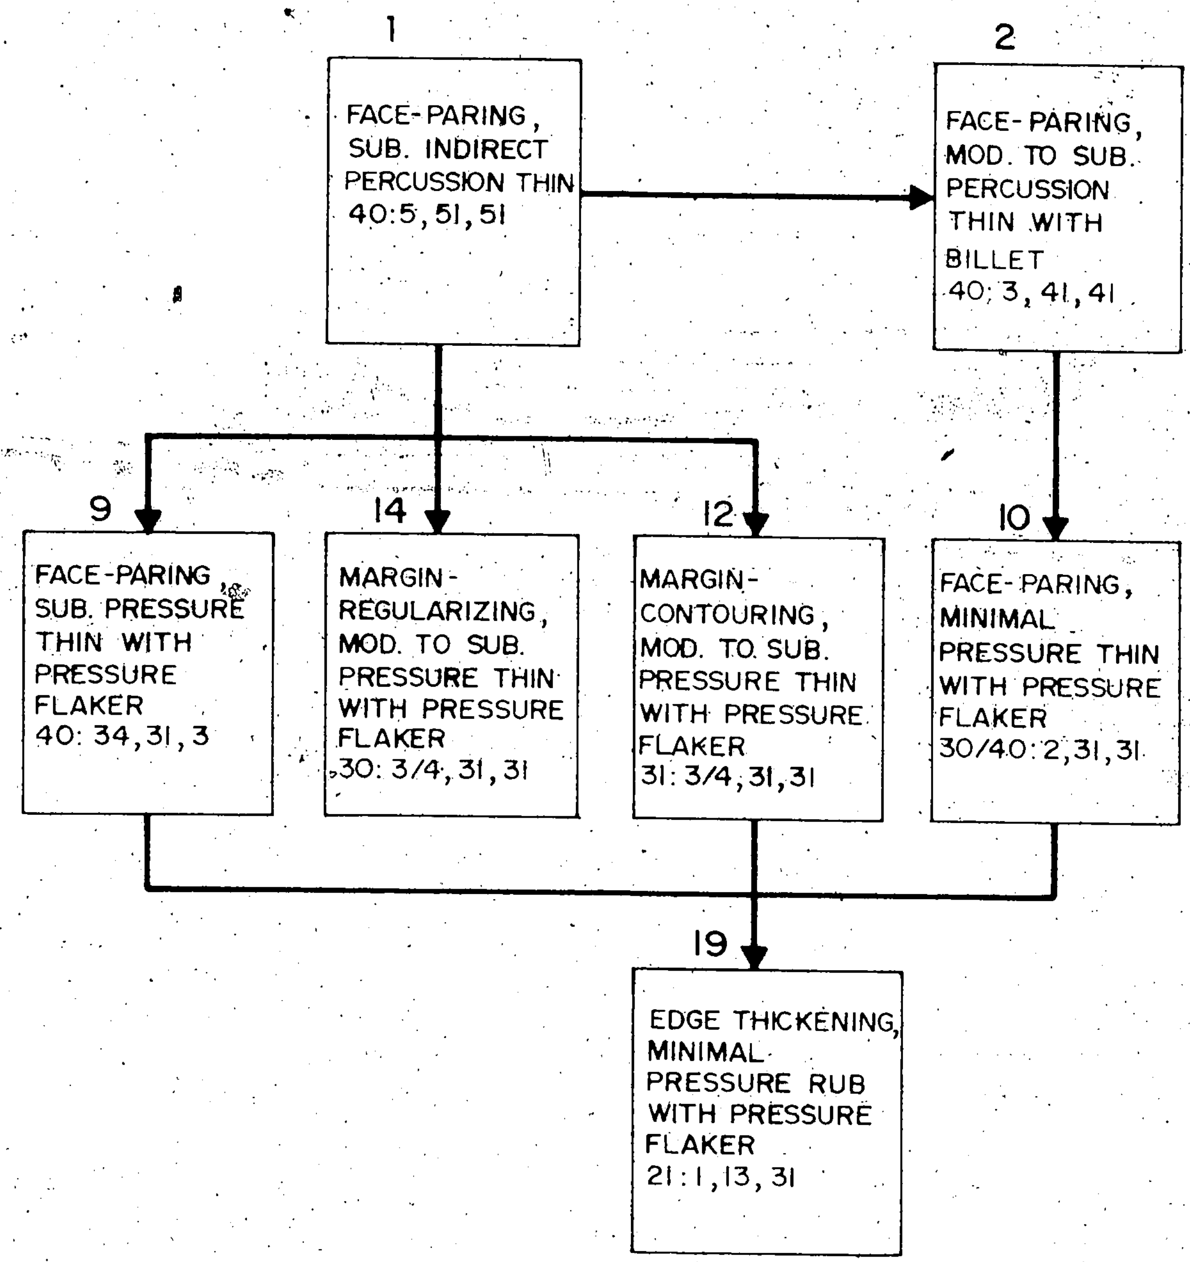
(b) Mod./Sub. Percussion Thin with Billet: Identified from flakes 013 and R5, this unit was sparingly used for face paring or thinning. Production Unit Code is 40:3, 41, 41.

3.2 Function of Pressure Thinning/Shaping Units (minimal to substantial size scars on specimen)

There are extensive isolated or small groups of pressure flakes (mod. to sub.) (see scars 025, R19) on the artifact. The units were used for secondary face paring margin contouring and for removal of inter-ridge scars or margin regularizing. Although most scars coded (03, R17, R19, R4) are substantial, minimum and moderate scars are also present. Production Unit Code is 30/31/40:2/3/4, 31, 31.

3.3 Function of Edge Units (minimal to very minimal size scars on specimen)

(a) Minimum Pressure Rub with Pressure Flaker: This unit, coded and identified from edge units 1, 2 and 3, was applied to all external margins of the artifact. Some areas of mod./sub. shear shaping may also have been undertaken but as the morphology of the two units is very similar, these cannot be readily identified. A pressure rub involves the use of the end of a pressure flaker to rub across the edge of an artifact -- this removes any overly thin material and strengthens the edge. The resulting margin is characteristically rough with small convex projections and some minimal flake removals. Margin damage and micro flakes are two of the morphologies associated with this unit. Production Code Unit is 21:2, 13, 31.



(b) Reconstructing Sequencing of Production Units: C01071

3.4 Flow Diagram of Production Units (above)

3.5 Description and Discussion of Technological Grammar Found on Artifact

This is one of two extremely large bifaces analyzed as part of the Jordan site collection (DeHa-8). The manufacture of this specimen (C01071) is essentially identical to the other specimen (C01073) except that more widespread use is made of pressure flaking units, replacing billet percussion to a minor extent. The technological basis of this specimen consists of six behavior units. The major production unit positively identified from analysis of five scars (015, 031, R15, R33, R38) is substantial indirect percussion face paring. This was the major technique used to reduce (thin) the specimen. Along the right obverse lateral margin some percussion thinning flakes were removed by billet work. Other billet flakes may also be present but they are not concentrated at any one spot. One positive flake scar identification (013) was made regarding this unit. The primary indirect percussion and secondary billet face paring was followed up in places by minimum, moderate and substantial pressure thinning with a pressure flaker. Both types of secondary face paring appear to have served to remove some of the inter-flake scar ridges (margin-regularizing) and perhaps some margin-contouring. Margin contouring involves increasing the edge angle to form a strong bifacial edge. Identified scars are (03, R17, R19, R24). The final step in the manufacture of this specimen was to treat the edges with a minimum pressure rub with a pressure flaker. Like the other large biface, virtually all edges were treated (i.e., Edge Units 1, 2 and 3). Pressure rubbing removes any overly thin material on the edge, blunts and rounds it, thereby adding considerable strength to the margin. The specimen is complete and has not been broken.

	Edge Unit 1	Possible	+ 38	Min. Pressure Rub with P.F.	AB2-2(b)
R37		Possible	+ 40	Mod./Sub. Perc. Thin with Hammerstone	AB16-7(a)

3.0 Interpretation of Behavior (Technological) Units

(a) Transforming Behavior Units into Production Units:

3.1 Function of Percussion Thinning/Shaping Units (moderate to very substantial size scars on specimen)

(a) Moderate and Substantial Percussion Thin with Hammerstone: This behavior unit resulted in face paring (biface thinning flakes) or substantial thinning of the artifact. Production Unit Code is 40:4, 51, 41.

3.2 Function of Pressure Thinning/Shaping Units (minimal to substantial size scars on specimen)

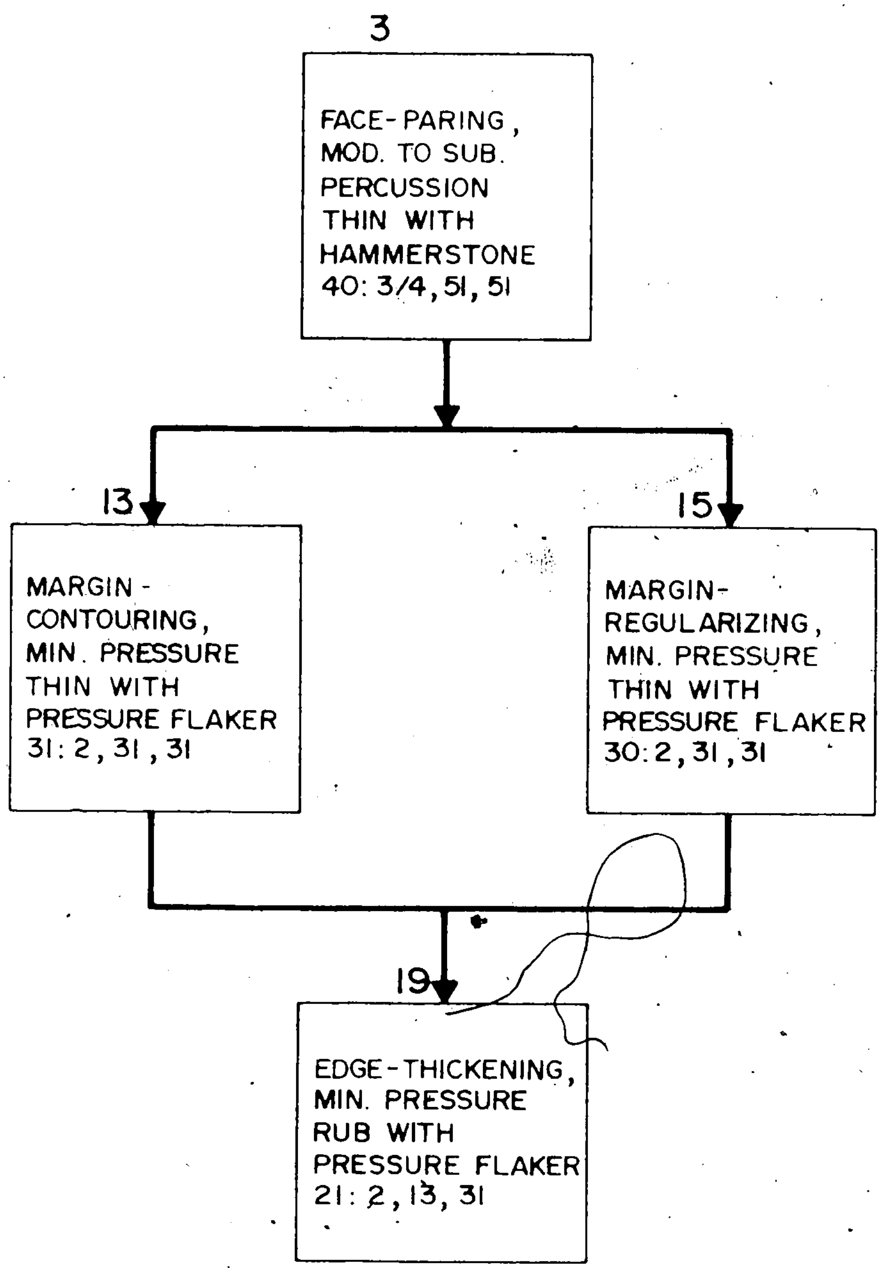
(a) Minimum Pressure Thinning with Pressure Flaker: This unit was identified for some small scars on the base (R24 to R28) and on the tip of the artifact. It was used for margin regularizing (removing inter-flake scar ridges) and margin contouring (increasing the edge angle to make a bifacial edge). Production Unit Code is 30/31:2, 31, 31.

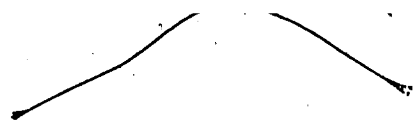
3.3 Function of Edge Units (minimal to very minimal size scars on specimen)

Only one edge unit is apparent from the analysis being a minimal pressure rub with a pressure flaker. This removes or blunts an overly thin edge to allow it to be used as a platform. Some "scalloped flakes," many with tiny platofrms, are removed from the artifact face at the same time (see experiment AB2-2(b) for size and type of flake removal). Production Unit Code is 21:2, 13, 31.

(b) Reconstructing Sequencing of Production Units: C02169

3.4 Flow Diagram of Production Units (below)





3.5 Description and Discussion of Technological Grammar Found on Artifact

This biface was produced by use of moderate and substantial hammerstone thinning flakes. After the substantial thinning the edge was thickened and strengthened by applying the edge of a pressure flaker. This also removed some small thinning flakes. Margin contouring and margin regularizing was accomplished through the use of moderate pressure thinning flakes, especially at the base and tip of the specimen.

Table 65: Form for Coding and Interpreting Prehistoric Artifacts

1.0 Prehistoric Artifact Identification

1.1 Artifact Face: Obverse and Reverse

1.2 Prehistoric Specimen Provenience: DdGw-2

1.3 Specimen Catalogue #: C02357

1.4 Photographic Plate Identification: Roll 3, B3, #13
Roll 4, B4, #9

1.5 Standard Artifact Description:

1.6 Raw Material: Welded Tuff

1.7 Shape/Artifact Class: Biface

1.8 Flaking (Bifacial/Unifacial):

1.9 Metric Size: length - 10.78 cm
width - 3.66 cm
thickness - 1.30 cm

1.10 Form/Morphology Description:

This artifact represents a biface manufactured from a flake core. One side of the specimen has extensive step fracturing, while the other side is unretouched, original flake core surface.

The base is slightly rounded (convex) and has numerous thinning flakes.

2.0 Coding and Identification of Technological Attribute States Found on Individual Flake Scar(s)

2.1 Scar Coding Form for Individual Flake Scars

	Artifact # C02537	Main Flake Scar # 04	Edge Treatment on Same Scar	Notes
1.1	Scar Size	substantial	minimal (1) to moderate	1. Edge Unit 1 - there is extensive edge treatment on one lateral edge of this specimen. The other has none as the notches from percussion flaking are still present and there are many convex projections between scars.
2.1	Edge Sharpness	sharp (2)	predominantly sharp	
2.2	Margin Damage	0	heavy	
2.3	Microflakes	0	light	
2.4	Proximal Edge Morphology	flat curved notch	shallow curved notches	
3.1	Negative Bulb of Force	indistinct		2. Platform intact for coding.
3.2	Bulb to Scar Transition Angle	gradual		
3.3	Flake Thickness	thin		3. Has been truncated by another scar.
4.1	Presence or Absence of Ribs	0		
4.2	Distinctiveness of Ribs	0

2.3 Behavior or Morpho-Unit Alternative Chosen from Above:

Possible + 40 - Mod./Sub. Perc. Thin Hammerstone

The absence of any distinct percussion bulb and the flatness of the flake also support a hammerstone identification.

2.4 Summary of Behavior Units (Morpho-Units) Identified on Artifact, C02357 (Jessup)

Main Scar #	Edge Unit Scar #	Rating on Scoring Scale	Final +/- Score	Behavior Unit	Experimental Control Specimen
04		Possible	+ 64	Mod./Sub. Perc. Thin Hammerstone	AB16-7(a)
	Edge Unit # 1	Highly Probable	+ 72	Moderate/Substantial Shear Shape with Pressure Flaker	AB6-13(b)
018		Possible	+ 66	Mod./Sub. Perc. Thin Hammerstone	AB16-7(a)
R8		Possible	+ 56	Mod./Sub. Perc. Thin Hammerstone	AB16-7(a)
R10		Possible	+ 40	Mod./Sub. Perc. Thin Hammerstone	AB16-7(a)

3.0 Interpretation of Behavior (Technological) Units

(a) Transforming Behavior Units into Production Units:

3.1 Function of Percussion Thinning/Shaping Units (moderate to very substantial size scars on specimen)

(a) Moderate and Substantial Percussion Thin with Hammerstone: Percussion thinning removes face paring flakes which are at least two times longer than the platform at the artifact edge, thinning the specimen much faster than the contour or outline shape is altered. Production Unit Codes for these behavior units are substantial - 40:4, 41, 41; moderate - 40:3, 41, 41.

(b) Because this specimen is made from a flake, another function of the hammerstone thinning was to contour the margin by removing thin flakes near the margin to increase the edge angle and produce a bifacial edge. Production Unit Code is 31:3/4, 41, 41.

3.2 Function of Pressure Thinning/Shaping Units (minimal to substantial size scars on specimen)

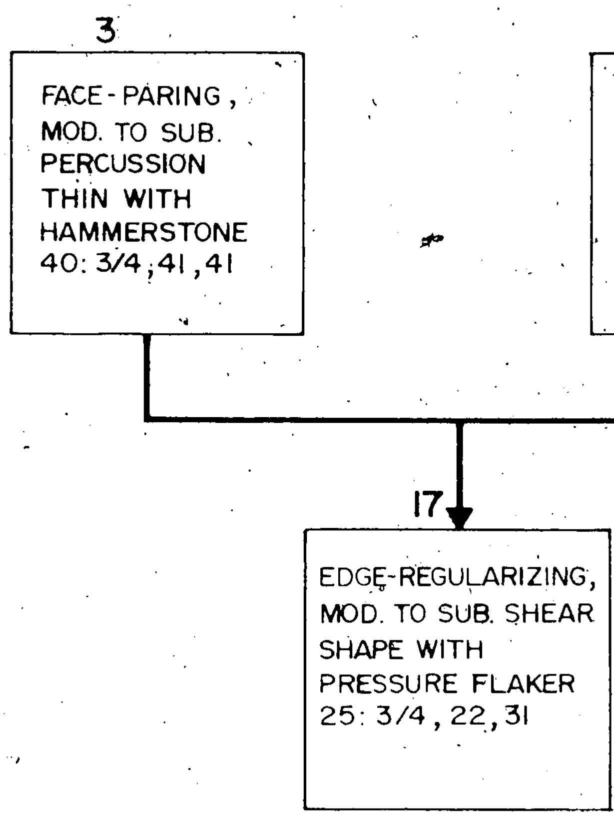
There are no pressure flake scars on the specimen although some flakes look like pressure. These appear to be multiple flake removals from a single blow (as discerned from the platform size and position). Their thinness and small size makes them resemble minimum pressure flakes.

3.3 Function of Edge Units (minimal to very minimal size scars on specimen)

Only one edge unit (unit #1) was identified as moderate to substantial shear shaping with the side and tip of a pressure flaker. Shearing which involves placing the side of the pressure flaker against the edge and moving it diagonally (or in some cases perpendicularly) along the edge producing an irregular surface topography of overlapping scars and platforms in which individual scar outlines are obscure. This production unit serves to center, straighten and regularize the edge all in one operation. Production Unit Code is 23/24/25:3/4, 22, 31.

(b) Reconstructing Sequencing of Production Units: C02357

3.4 Flow Diagram of Production Units (below)



3.5 Description and Discussion of Technological Grammar Found on Artifact

This biface preform is manufactured from a large flake core substantial remnants of which remain on both the obverse (scar 01) and reverse faces (scar R20). The bifacial edge on the flake core was produced by moderate and substantial percussion thinning with a hammerstone which also contoured the margin. Subsequently, the side of an antler pressure flaker was used to shear shape the edge and resulted in centering, straightening and regularizing the margin. Some flakes were also removed during this process [as demonstrated in Experiment AB6-13(b)]. This has regularized or straightened the margin by slightly smoothing over some of the flat curved notches left from the percussion flaking.

1.5 Standard Artifact Description:

1.6 Raw Material: Welded Tuff

1.7 Shape/Artifact Class: Pointed Biface

1.8 Flaking (Bifacial/Unifacial): Bifacial

1.9 Metric Size: length - 10.28 cm
width - 3.50 cm
thickness - 1.72 cm

1.10 Form/Morphology Description:

This artifact consists of a bi-pointed bifacial preform that was abandoned prior to the final thinning process. Such specimens are common at the Jessup Quarry site and could be considered rejects from the production process. This one has been analyzed in order to determine the production units in use at the site just prior to final biface completion. The reason for the loss of the specimen by aboriginal knappers is the large hump of material left on the reverse face. In attempting to remove this central mass, the biface broke bilaterally and was abandoned.

3.0 Interpretation of Behavior (Technological) Units

(a) Transforming Behavior Units into Production Units: C02135

3.1 Function of Percussion Thinning/Shaping Units (moderate to very substantial size scars on specimen)

(a) Substantial and Moderate Percussion Thin with Billet: This behavior unit was used for face paring the specimen on both the obverse and reverse faces. Face paring produces the familiar biface thinning flakes. Production Unit Code is 40:3/4, 41, 51.

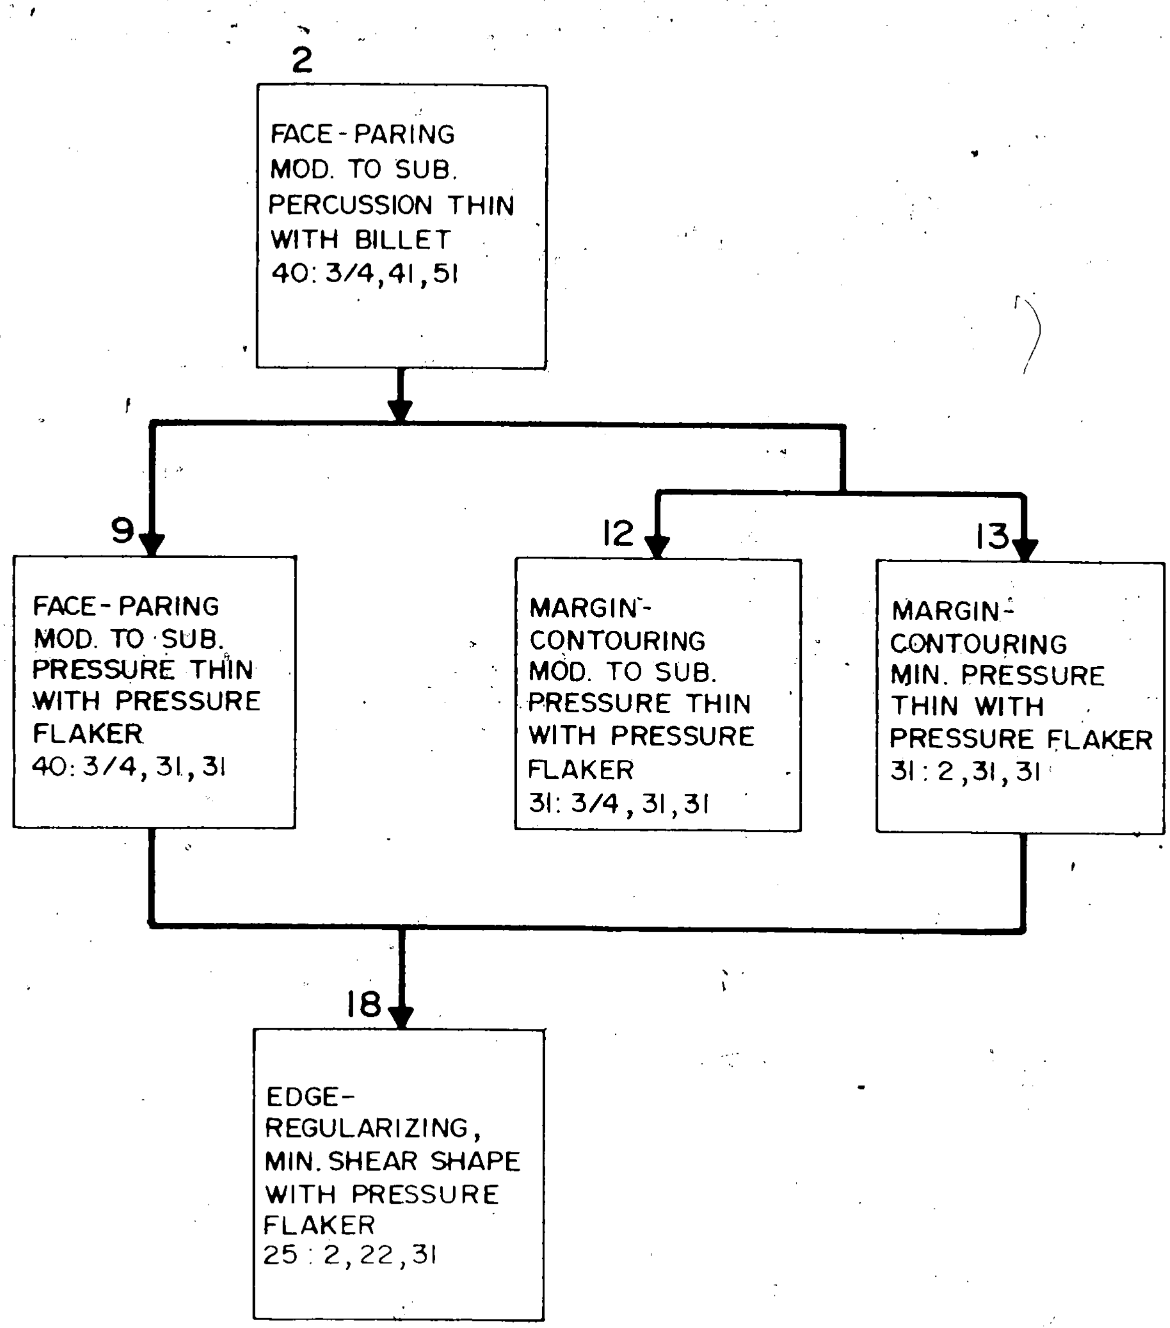
3.2 Function of Pressure Thinning/Shaping Units (minimal to substantial size scars on specimen)

(a) Minimum to Substantial Pressure Thin with Pressure Flaker: These behavior units were used for face paring. Production Unit 40:2/3/4, 31, 31.

(b) The same behavior units (above) were also used for margin contouring - in this case it involved removing material from an overly thick edge. Production Unit Code is 31:2/3/4, 31, 31.

3.3 Function of Edge Units (minimal to very minimal size scars on specimen)

One edge unit was identified, minimal shear shape with a pressure flaker. This unit was used at the top of the specimen to straighten the edge primarily by reducing the U-shaped pressure notches (found on all pressure flaking platforms) to very shallow indistinct notches. The unit also strengthens and reduces the edge although the secondary reducing effect on this specimen was very minimal. Production Unit Code is 23/24/25:2, 22, 31.



(b) Reconstructing Sequencing of Production Units: C02135

3.4 Flow Diagram of Production Units (above)

3.5 Description and Discussion of Technological Grammar Found on Artifact

The above biface rough out comprising a bi-pointed preform, broke before completion and was abandoned by the aboriginal flint knappers prior to completion. The primary thinning on the specimen consists of substantial and moderate percussion thinning with an antler billet (see flake scars 05, 012, and R6). The face paring produces the familiar biface thinning flakes. Following and overlying the percussion work (see scar R12 overlaid on scar R14) is substantial pressure thinning with a pressure flaker. The purpose of this thinning (face paring) unit may have been margin contouring (i.e., removing thin flakes on the margin to produce the desired curvature and reduce an overly thick edge). At the tip of the specimen, minimal pressure thinning with a pressure flaker was used to remove a series of identifiable parallel pressure flakes on both faces. This created the desired bifacial edge. As pressure flaking always leaves U-shaped notches and percussion flaking always leaves flat curved notches (see experiments), in order to straighten the edge, an edge unit was utilized. Both in areas of percussion flaking and substantial pressure flaking a sporadically applied minimal shear shape with pressure flaker was used for edge centering, straightening and regularizing. At the tip of the specimen and overlying the minimal pressure flaking a more uniform but very minimal moderate shear shape with pressure flake was used. At this point the artifact was still far from being a completed biface and required further percussion thinning to remove a large lump of material (flakes R23, 25, 10, 11). An attempt to do this from the opposite or obverse side failed and broke the specimen. It is interesting to note that part of the original platform from the flake that broke the specimen is still present and attached to scar 0-12.

Table 67: Form for Coding and Interpreting Prehistoric Artifacts

1.0 Prehistoric Artifact Identification

1.1 Artifact Face: Obverse and Reverse

1.2 Prehistoric Specimen Provenience: Jessup, DdGw-2

1.3 Specimen Catalogue #: C02082

1.4 Photographic Plate Identification: Roll 3, B3, #4
Roll 3, B4, #29

1.5 Standard Artifact Description:

1.6 Raw Material: Welded Tuff

1.7 Shape/Artifact Class: Bi-pointed Biface

1.8 Flaking (Bifacial/Unifacial): Bifacial

1.9 Metric Size: length - 13.70 cm
width - 3.63 cm
thickness - 1.19 cm

1.10 Form/Morphology Description:

This bi-pointed biface snapped at mid-section due to removal of an overly thick thinning flake that resulted in a hinged step fracture which broke the specimen. The overall artifact is rather narrow and tapers at each end to a blunted slightly convex points and/or bases. Only a small portion of the original flake core surface remains on the reverse side.

3.0 Interpretation of Behavior (Technological) Units, C02082

(a) Transforming Behavior Units into Production Units:

3.1 Function of Percussion Thinning/Shaping Units (moderate to very substantial size scars on specimen)

(a) Mod./Sub. Percussion Thin with Hammerstone: Thinning or face paring was also accomplished with a hammerstone (scars 021, 041, R2, R3). Production Unit Code is 40:3/4, 41, 41.

(b) Moderate Percussion Shape with Hammerstone: The shape units were used for margin moving (i.e., to control its outline form rather than having thinning as the primary objective). Some of the shaping flakes may be thinning flakes as these are also present (see below). Production Unit Code is 33:4, 42, 41.

3.2 Function of Pressure Thinning/Shaping Units (minimal to substantial size scars on specimen)

There are no pressure flaking behavior units on this prehistoric artifact.

3.3 Function of Edge Units (minimal to very minimal size scars on specimen)

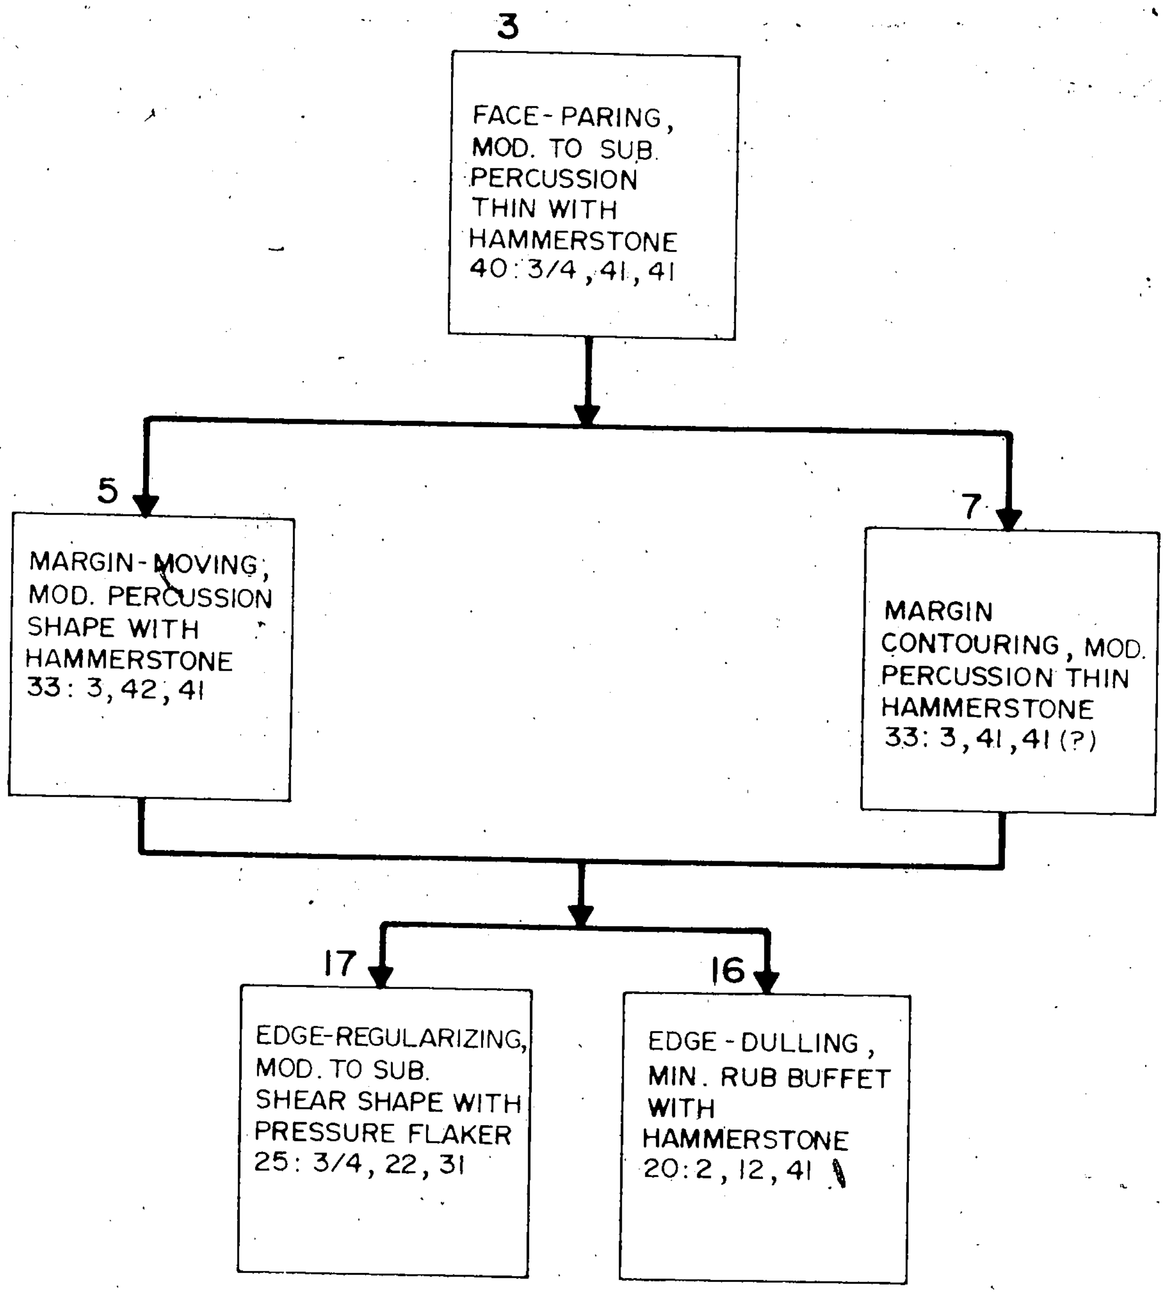
(a) Minimum to Moderate Shear Shape with Pressure Flaker: This unit was used (see edge unit 1) to straighten, center, and reduce the edge. Edge straightening was undertaken by smoothing out the flat curved notches left by percussion work. Shearing is accomplished by moving the tip of the pressure flaker across the edge of the artifact in a twisting motion. Production Unit Code is 23/24/25:2/4, 22, 31.

(b) Minimum Rub/Buffet with Hammerstone: Rub buffet involves edge dulling achieved by rubbing the edge of the artifact, while at the same time, dragging the tool with minimal force. This removal of little, flat (often square ended) flakes blunts or rounds the edge so it will not crush easily when used as a platform. An alternative purpose would be to smooth the edge (see edge unit 2). Production Unit Code is 20:2, 12, 41.

(c) Hypothetical Unit - Moderate Percussion Thin with Hammerstone: Due to overlapping behavior unit and scars, it was not possible to code this unit directly. The hammerstone work scored a + 52 along with the hammerstone rub/buffet (see coding of edge unit #2). Such thinning units are used for margin contouring which is accomplished by removing short, flat flakes on artifact margins to lessen the edge angle. The edge would be subsequently strengthened if this was followed by the rub/buffet as coded. Production Unit Code for minimal hammerstone thinning used for margin contouring is 33:3, 41, 41.

(b) Reconstructing Sequencing of Production Units: C02082

3.4 Flow Diagram of Production Units (below)



3.5 Description and Discussion of Technological Grammar Found on Artifact

This prehistoric biface was manufactured from a flake core (scar R26 exhibits the original core surface). The flake core was shaped, utilizing substantial percussion face paring flakes with a hammerstone followed by moderate margin moving percussion shaping. This initial percussion work shaped the bi-pointed specimen and thinned it to a reasonable thickness, but not to a finished state. In order to undertake the final thinning work the edge was prepared by means of minimal shear shaping with a pressure flaker (see edge unit 1) which straightened, centered and strengthened the edge. Other edges (edge unit 2) may have been too thick for shearing (i.e., scar 015) and instead, a minimum percussion thin with hammerstone was used for margin contouring (i.e., removing short flat flakes on the artifact margin to reduce the edge angle). This was followed by a minimum rub/buffet with the hammerstone to blunt or round the edge and strengthen it. Subsequent to this work, one of the finishing thinning flakes (possibly 09/R18) was too powerful and caused a bilateral transverse fracture which broke the artifact in half causing it to be abandoned.

Table 68: Form for Coding and Interpreting Prehistoric Artifacts

1.0 Prehistoric Artifact Identification

1.1 Artifact Face: Obverse and Reverse

1.2 Prehistoric Specimen Provenience: Jessup Site, DdGw-2

1.3 Specimen Catalogue #: C02070

1.4 Photographic Plate Identification: Roll 4, B4, #7

1.5 Standard Artifact Description:

1.6 Raw Material: Welded Tuff

1.7 Shape/Artifact Class: Biface

1.8 Flaking (Bifacial/Unifacial):

1.9 Metric Size: length - 9.31 cm
width - 4.24 cm
thickness - .94 cm

1.10 Form/Morphology Description:

This specimen comprises a broad bifacial tool with a broad but shallow convex to straight base with rounded corners. During final thinning the specimen broke bilaterally and has been glued back together for analysis. It appears that it may have been manufactured from a flake core as a small portion of the original surface remains on the obverse face and an original detachment platform on the base of the flake core.

3.0 Interpretation of Behavior (Technological) Units

(a) Transforming Behavior Units into Production Units:

3.1 Function of Percussion Thinning/Shaping Units (moderate to very substantial size scars on specimen)

(a) Moderate to Substantial Percussion Thin with Hammerstone: Face paring removes flakes which are a minimum of twice the size of the paltform at the artifact edge which has the effect of thinning the specimen rather than moving in the overall outline shape or outer edge. Production Unit Code is 40:4, 51, 41.

(b) Moderate Percussion Shape with Hammerstone: These flakes differ from the larger hammerstone face paring flakes in that they are used to control the overall shape of the specimen during the reduction process through margin moving. Production Unit Code is 33:3, 42, 41. In some cases the margin moving may have been used to prepare solid platforms on the edge for further substantial face paring.

3.2 Function of Pressure Thinning/Shaping Units (minimal to substantial size scars on specimen)

(a) Minimum Pressure Shape with Pressure Flaker: These margin moving flakes were used on the base (scars R12 to R18) to shape the convex base. Production Unit Code is 33:2, 32, 31.

(b) Minimum, Moderate and Substantial Pressure Thin with Pressure Flaker: These units were used for face paring and margin contouring (on the tip) to thin the edge angle. Production Unit Codes are 40:2/3/4, 41, 31 and 31:2, 41, 31 (on tip).

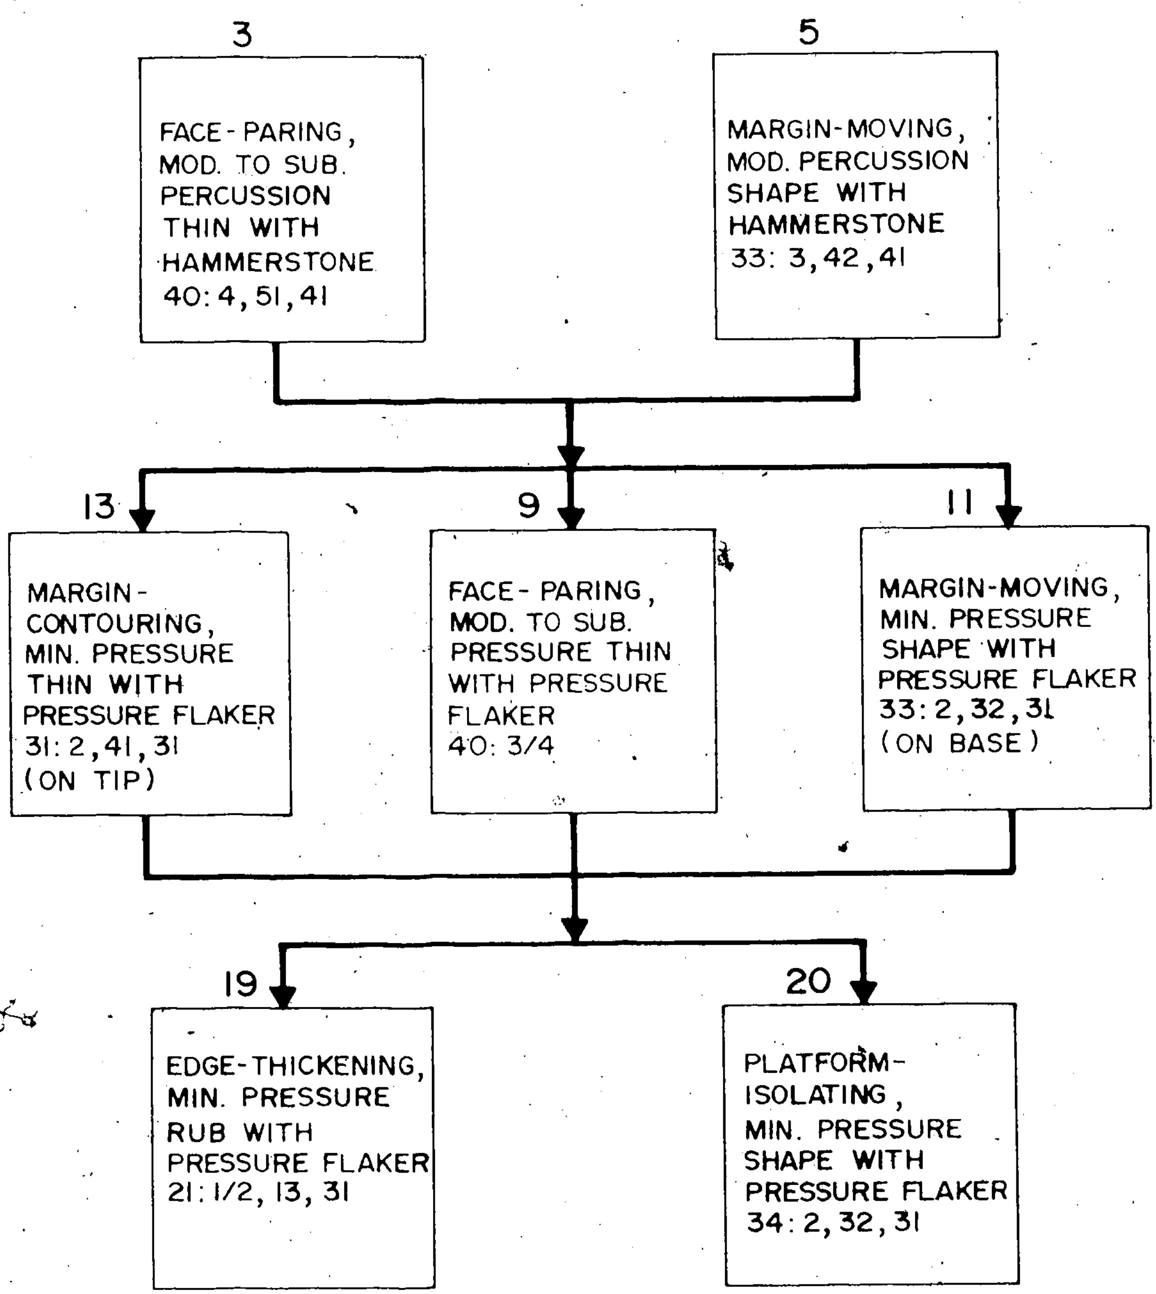
3.3 Function of Edge Units (minimal to very minimal size scars on specimen)

(a) Minimum Platform Isolating with Pressure Flaker: This unit may be present on scars 03, 04, 05, and 06 as they most closely resemble the experimental morphology [see experiment AB2-2(c)]. Platform isolating consists of removing small notches on either side of an edge area to be used as a platform for a thinning flake. By isolating the platform in this way, the thinning flake tends to travel inwards further in a more confined scar pattern rather than spreading out. Production Unit Code is 34:2, 32, 31.

(b) Minimum Pressure Rub with Pressure Flaker: This edge unit is present and has dulled the edge of all of edge unit #3 and the lower portion of edge unit #1 and perhaps, to a very minimal extent, the base (edge unit 2). This behavior unit thickens and strengthens the edge and allows for the edge to be more effectively used as a platform for further flake removals. Production Unit Code is 21:1/2; 13, 31.

(b) Reconstructing Sequencing of Production Units: C02070

3.4 Flow Diagram of Production Units (below)



3.5 Description and Discussion of Technological Grammar Found on Artifact

Manufactured from a flake core, this artifact still has the original flake core platform intact on the obverse face (see scar 013) and several original flake core surfaces remain, namely scars 030, 031, 032 and R25. The core was face pared using moderate to substantial percussion thinning flakes with a hammerstone. Shaping or margin moving was accomplished by means of moderate percussion flaking with a small pebble (small hammerstone). Some of these shaping flakes also overlap into thinning flakes and are concentrated along the right lateral margin of the obverse face and the left lateral margin of the reverse face and were used to trim the edges back and set up solid platforms. One of the thinning or shaping flake removals had excessive force or an improperly prepared platform (possibly scar 07 which is a substantial hammerstone thinning scar) and subsequently caused a bilateral transverse snap, breaking the artifact in half. Prior to this breakage and abandonment of the specimen, edge preparation work had been completed to prepare the margin for further thinning treatments. These edge units consist of a notable one in the form of minimum platform isolating with a pressure flaker. Good examples of this behavior unit are scars 03, 04, 05 and 06, showing the characteristic U-shaped notches placed on either side of a potential platform area. By isolating the platform in this way, a more compact and longer thinning flake can be detached travelling inwards rather than sideways along the margin. This helps to control the thinning process. A second edge unit was a minimum pressure rub with a pressure flaker. This unit was used to dull the edge by removing overly thin material and also helped to blunt and strengthen the edge for further flaking activity. The behavior unit is present in all of edge unit #3 and the lower portions of edge unit #1 and, as well, minimally on the base overlying edge unit 2. Edge unit 2, the final behavior unit here, comprises a minimum pressure shaping with an antler pressure flaker. The unit has been applied in one small area (scars R12 to R18) on the base of the artifact. The unit is applied unifacially to the platform of the original flake core with the obverse side being used as the platform to remove flakes on the reverse side. The purpose was to move the margin in to form a convex base.

1.4 Photographic Plate Identification: Roll 2, B2, #21A and 27A

1.5 Standard Artifact Description:

1.6 Raw Material: Welded Tuff

1.7 Shape/Artifact Class: Biface

1.8 Flaking (Bifacial/Unifacial): Bifacial

1.9 Metric Size: length - 10.88 cm
width - 4.72 cm
thickness - 1.54 cm

1.10 Form/Morphology Description:

This is a rough preform consisting of a broad ovoid blade with a broad but shallow convex base. It is manufactured from a bifacially worked flake, with the striking platform of the flake preform still present. Unsuccessful thinning at mid section has caused a bilateral traverse fracture snapping the specimen in half. The two sections have been glued back together for analysis.

2.0 Coding and Identification of Technological Attribute States Found on Individual Flake Scar(s)

2.1 Scar Coding Form for Individual Flake Scars

	Artifact # C02071	Main Flake Scar # 03	Edge Treatment on Same Scar	Notes
1.1	Scar Size	very sub. (1)	Min. or very minimal (2)	1. Because of scar size it must be substantial force.
2.1	Edge Sharpness		intermediate	
2.2	Margin Damage		light	2. All sub. perc. or indirect perc., have curved notches - this one is straight. Therefore, some form of edge treatment is present.
2.3	Microflakes		light	
2.4	Proximal Edge Morphology		straight with convex projections	
3.1	Negative Bulb of Force	indistinct		3. There is a single undulation connected with the flow of force that may be a rib or an undulation.
3.2	Bulb to Scar Transition Angle	gradual		
3.3	Flake Thickness	thick		
4.1	Presence or Absence of Ribs	0 (3)		4. This is a failed scar because it took out too much material.
4.2	Distinctiveness of Ribs	n/a		
4.3	Rib Spacing And Distribution	n/a		5. This Edge Unit (#1) covers scars 1-3, 22-23 on obverse face and scars 1-4 on the reverse face (see scar R4).
4.4	Tearing	heavy		
5.1	Scar Shape at Distal Edge	rounded	1/2 straight 1/2 curved	
5.2	Scar Termination at Distal Edge	step/ feather (4)	step/ feather	

2.2 Interpretation of Individual Flake Scar(s) in Terms of Behavior Units (Morpho-Units) Responsible for Flake Scar 03, Main Scar, C02071

	Prehistoric C02071 Scar 03	AB16-17(a) Mod./Sub. Perc. Thin Hammerstone	AB11-11 Sub. Indirect Percussion	AB7-10 Sub. Perc. Thin Billet
1.1	very sub.	+ 1	+ 1	+ 1

Total	+	+ 4.8	+ 4.67	+ 5
	-	- 3.2	- 3.33	- 3
%	+	+ 60	+ 58	+ 63
	-	- 40	- 42	- 37
Score		+ 20	+ 16	+ 26

2.3 Behavior or Morpho-Unit Alternative Chosen from Above:

Indeterminate + 20 - Mod./Sub. ~~Perc.~~ Thin Hammerstone

N.B.
This scar is very difficult to code as it represents a failed scar - the flatness and lack of a distinct percussion bulb favour a hammerstone identification.

2.2 Interpretation of Individual Flake Scar(s) in Terms of Behavior Units (Morpho-Units) Responsible for Flake Scar, C02071, Edge Unit 1 (see note 5) (coded 03)

	Prehistoric C02071 Edge Unit 1	AB10-1 Min. Rub/Buffet with Hammerstone	AB10-1 Min. Rub/Buffet Antler Billet	AB6-13(a) Min. Shear Shape with P.F.	AB2-2(c) Min. Platform Isol. with P.F.	AB14-16(b) Min. Perc. Shape Hammer.

5.1	rounded	+ 40 - 60	- 1	+ 40 - 60	+ 42.9 - 57.1
5.2	feather	+ 40 - 60	+ 33.3 - 67.7	+ 50 - 50	+ 71.4 - 28.6
Total	+	+ 5.20	+ 5.33	+ 5.30	+ 5.86
	-	- 2.80	- 2.67	- 2.70	- 2.14
%	+	+ 65	+ 67	+ 66	+ 73
	-	- 35	- 33	- 34	- 27
Score		+ 30	+ 34	+ 32	+ 46

2.3 Behavior or Morpho-Unit Alternative Chosen from Above:

Possible + 34 - Moderate Percussion Shape Hammerstone

The thinness and flatness of the flake scar, plus the indistinct percussion bulb, favour a hammerstone identification even though the billet scored slightly higher due to flake termination which, in this case, may be determined by the very steep working face and the smooth original flake core surface.

2.0 Coding and Identification of Technological Attribute States Found on Individual Flake Scar(s)

2.1 Scar Coding Form for Individual Flake Scars

	Artifact # C02071	Main Flake Scar # R4	Edge Treatment on Same Scar	Notes
1.1	Scar Size	very sub.	(2)	1. Attribute 2.1 immediately indicates overlapping technological behaviors as no sub. or mod. percussion flakes leave an intermediate sharp edge.
2.1	Edge Sharpness			
2.2	Margin Damage			
2.3	Microflakes			
2.4	Proximal Edge Morphology			2. Edge Unit 1 - scars 1-4 reverse face and 1-3, 22-23 obverse face (see scar 03).
3.1	Negative Bulb of Force	indistinct		
3.2	Bulb to Scar Transition Angle	gradual		3. The ribs are difficult to discern - some faint ones may be evenly distributed.
3.3	Flake Thickness	thin		
4.1	Presence or Absence of Ribs	present		
4.2	Distinctiveness of Ribs	indistinct		
4.3	Rib Spacing And Distribution	rel. far apart on dist. half (3)		
4.4	Tearing	0		
5.1	Scar Shape at Distal Edge	straight		
5.2	Scar Termination at Distal Edge	step/ feather		

2.2 Interpretation of Individual Flake Scar(s) in Terms of Behavior Units (Morpho-Units) Responsible for Flake Scar R4, Main Scar, C02071

	Prehistoric C02071 Main Scar R4	AB7-10 Sub. Perc. Thin Billet	AB11-11 Sub. Indirect Percussion	AB16-7(a) Mod./Sub. Perc. Thin Hammerstone
1.1	very sub.	+ 1	+ 1	+ 1
2.1				
2.2				
2.3				
2.4				
3.1	indistinct	+ 75 - 25	+ 66.6 - 33.3	+ 1
3.2	gradual	+ 75 - 25	+ 1	+ 1
3.3	thin	+ 50 - 50	+ 1	+ 80 - 20
4.1	present	+ 50 - 50	+ 33.3 - 66.7	+ 80 - 20
4.2	indistinct	+ 1	+ 1	+ 1
4.3	rel. far apart on distal 1/2	+ 1	+ 1	- 1
4.4	0	+ 75 - 25	+ 66.6 - 33.3	+ 60 - 40

5.1	straight	- 1	- 1	+ 60 - 40
5.2	step/ feather	+ 1	+ 1	+ 1
Total	+	+ 7.25	+ 7.67	+ 7.80
	-	- 2.75	- 2.33	- 2.20
%	+	+ 73	+ 77	+ 78
	-	- 27	- 23	- 22
Score		+ 46	+ 54	+ 56

2.3 Behavior or Morpho-Unit Alternative Chosen from Above:

Possible + 56 - Mod./Sub. Perc. Thin Hammerstone

If the rib attribute (which is doubtful) were removed, the hammerstone score would be much higher again then the billet.

2.0 Coding and Identification of Technological Attribute States Found on Individual Flake Scar(s)

2.1 Scar Coding Form for Individual Flake Scars

Artifact # C02071	Main Flake Scar # R10	Edge Treatment on Same Scar	Notes
1.1 Scar Size	substantial	very minimal (1)	1. Edge Unit 2 coded from scars 8-12 reverse face and 9-20 obverse face (see scar 0-18)
2.1 Edge Sharpness		intermediate to dull	
2.2 Margin Damage		heavy	
2.3 Microflakes		heavy	
2.4 Proximal Edge Morphology		straight with convex projections	
3.1 Negative Bulb of Force	indistinct		
3.2 Bulb to Scar Transition Angle	gradual		
3.3 Flake Thickness	thin		
4.1 Presence or Absence of Ribs	present		
4.2 Distinctiveness of Ribs	indistinct		
4.3 Rib Spacing And Distribution	far apart on distal 1/2		
4.4 Tearing	light		
5.1 Scar Shape at Distal Edge	rounded	straight	
5.2 Scar Termination at Distal Edge	feather	step

Total	+	+ 4.33	+ 3.83	+ 4.66	+ 4.84	+ 5
	-	- 2.67	- 3.17	- 2.34	- 2.16	- 2
%	+	+ 62	+ 55	+ 67	+ 69	+ 71
	-	- 38	- 45	- 33	- 31	- 29
Score		+ 24	+ 10	+ 34	+ 38	+ 42

2.3 Behavior or Morpho-Unit Alternative Chosen from Above:

* Possible + 42 - Min. Rub/Buffet Hammerstone
Possible + 38 - Min. Pressure Rub with P.F.
Possible + 34 - Mod. Shear Shape with P.F.

* Rub/buffet produces the flat little scars found on the specimen. As well, the min. rub/buffet with hammerstone was used on the other edge unit (#1).

2.4 Summary of Behavior Units (Morpho-Units) Identified on Artifact C02071

Main Scar #	Edge Unit Scar #	Rating on Scoring Scale	Final +/- Score	Behavior Unit	Experimental Control Specimen
03		Indeterminate	+ 20	Mod./Sub. Percussion Thin Hammerstone (represents a failed scar)	AB16-17(a)
	Edge Unit 1	Possible	+ 36	Min. Rub Buffet Hammerstone	AB10-1
021		Possible	+ 34	Mod. Perc. Shape Hammerstone	AB3-17
R4		Possible	+ 56	Mod./Sub. Perc. Thin Hammerstone	AB16-7(a)
R10		Possible	+ 56	Mod./Sub. Perc. Thin Hammerstone	AB16-7(a)
R10	Edge Unit 2	Possible	+ 42	Min. Rub/Buffet Hammerstone	AB10-1(a)

3.0 Interpretation of Behavior (Technological) Units

(a) Transforming Behavior Units into Production Units:

3.1 Function of Percussion Thinning/Shaping Units (moderate to very substantial size scars on specimen)

(a) Moderate Percussion Shape Hammerstone: This margin moving unit was used to shape the edge, probably with a small hammerstone. Flake scar 021 is an example. Production Unit Code is 33:3, 42, 41.

(b) Substantial/Moderate Percussion Thin with Hammerstone: This behavior unit was used to thin the specimen. Biface thinning or face paring is designed to remove face material rather than alter the outline form of the artifact. Production Unit Code is 40:3/4, 41, 41.

3.2 Function of Pressure Thinning/Shaping Units (minimal to substantial size scars on specimen)

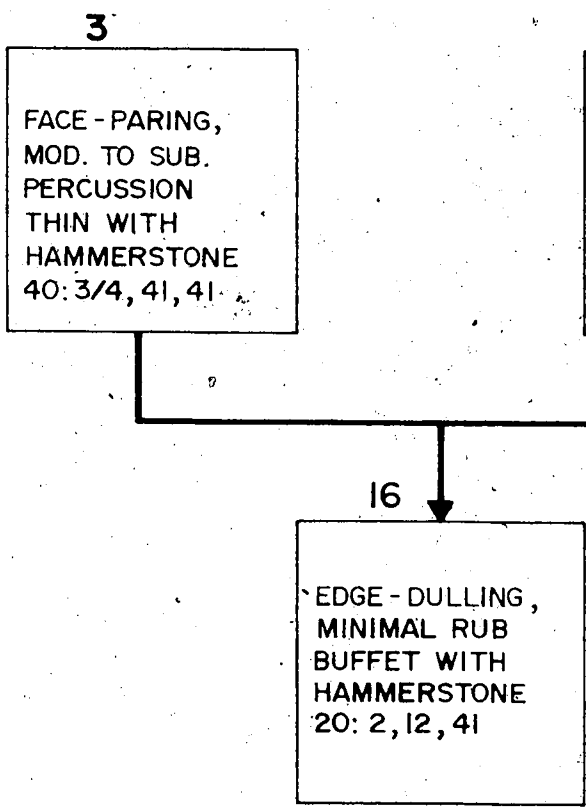
There are no pressure units on this specimen.

3.3 Function of Edge Units (minimal to very minimal size scars on specimen)

(a) Minimum Rub/Buffet with Hammerstone: The rub/buffet behavior unit involves a unifacial rubbing of the edge while at the same time using minimal force to drag or bite into the edge. This results in very small flat flake removals and rounds or blunts the edge so it has an intermediate degree of sharpness between sharp and dull. Such an edge is strengthened and smoothed and is more suitable for use as a platform for further thinning/shaping work (see edge units 1 and 2). Production Unit Code is 20:2, 12, 41.

(b) Reconstructing Sequencing of Production Units: C02071

3.4 Flow Diagram of Production Units (below)



3.5 Description and Discussion of Technological Grammar Found on Artifact

Analysis of this biface "rough out" or preform was made difficult due to the lack of scars suitable for coding and scoring. There are relatively few scars on this specimen and even fewer ones that are not severely obscured by overlapping and admixture with the original flake core surface, making precise identification of the particular scar's attributes difficult. An example would be scar #018. The termination of this scar is very difficult to define as it appears to blend in or is part of the original flake core surface.

The specimen was manufactured from a flake core as scars 023 and R1 exhibit original core surface. The original platform for the core also remains (see reverse face note on diagram). The flake core was shaped utilizing moderate hammerstone percussion shaping flakes followed by substantial/moderate hammerstone thinning in a few cases (see scars R4, R10). Each artifact face has one or more significant failed scar (i.e., 04 to 08, R5 to R6) and one of these failed thinning/shaping attempts caused a bilateral transverse fracture which broke the specimen causing it to be abandoned during this initial reduction stage. Prior to abandonment, the edges (edge units 1 & 2) were treated with a minimal rub/buffet with a hammerstone. This involves rubbing the edge of the artifact while also dragging the tool so that a very minimal amount of material is removed. This rounds or blunts the edge to an intermediate sharpness, therefore making it stronger and more suitable for a platform for further flake removals.
