NOTICE

The quality of this microfiche is heavily dependent upon the quality of the original thesis submitted for microfilming. Every effort has been made to ensure the highest quality of reproduction possible.

If pages are missing, contact the university which granted the degree.

Some pages may have indistinct print especially if the original pages were typed with a poor typewriter ribbon or if the university sent us a poor photocopy.

Previously copyrighted materials (journal articles, published tests, etc.) are not filmed.

Reproduction in full or in part of this film is governed by the Canadian Copyright Act, R.S.C. 1970, c. C-30. Please read the authorization forms which accompany this thesis.

**THIS DISSERTATION
HAS BEEN MICROFILMED,
EXACTLY AS RECEIVED**

AVIS

La qualité de cette microfiche dépend grandement de la qualité de la thèse soumise au microfilmage. Nous avons tout fait pour assurer une qualité supérieure de reproduction.

S'il manque des pages, veuillez communiquer avec l'université qui a conféré le grade.

La qualité d'impression de certaines pages peut laisser à désirer, surtout si les pages originales ont été dactylographiées à l'aide d'un ruban usé ou si l'université nous a fait parvenir une photocopie de mauvaise qualité.

Les documents qui font déjà l'objet d'un droit d'auteur (articles de revue, examens publiés, etc.) ne sont pas microfilmés.

La reproduction, même partielle, de ce microfilm est soumise à la Loi canadienne sur le droit d'auteur, SRC 1970, c. C-30. Veuillez prendre connaissance des formules d'autorisation qui accompagnent cette thèse.

ABSTRACT

Local mass transfer due to the impingement of a confined laminar two-dimensional air jet on a flat surface has been studied. The influence of the jet Reynolds number and the jet-to-plate spacing on the local mass transfer were investigated. The range of Reynolds number was 100 to 400 with the slot width, b , taken as the characteristic length. The jet-to-plate spacings were $2b$, $4b$ and $12b$. Experimental mass transfer studies were made using a swollen polymer method coupled with laser holography interferometric techniques.

The local Sherwood number along the impingement plate was found to exhibit a local minimum and a local maximum in the region away from the jet centre. The locations of the extrema points were a function of the jet Reynolds number and jet-to-plate spacing.

A two-dimensional numerical study was also made simulating the experimental set-up. The momentum and transport equations were numerically solved using hybrid differencing schemes (upstream-weighted and upstream schemes). The numerical study confirmed the presence of the local extrema in the Sherwood number. Contours of the flow stream function indicated that the presence of the Sherwood number extrema is due to flow recirculation in the region between the confinement plate and the impingement surface.

Excellent agreement was obtained between the measured local Sherwood numbers and those computed using the numerical solution of the transport equations.

ACKNOWLEDGEMENT

The author wishes to acknowledge the assistance given by the following during the course of this work:

1. Professor Jacob H. Masliyah, the author's supervisor, for providing the valuable advice and necessary guidance to complete this work. His effort is deeply appreciated.
2. Dr. K. Nandakumar, for several helpful discussions of the general numerical problem.
3. Jerry Moser, for the design and construction of the hologram-recording system at the initial stage of this work.
4. Keith Faulder and the staff of the workshop, for the invaluable assistance of the experimental equipment throughout this work.
5. Don Sutherland and the staff of the instrument shop, for their contributions throughout this work.

The author would also like to offer his sincere thanks to his officemate, Dr. John Ivory, for his friendship and encouragement during the long course of this work.

10.55	CONTOURS OF EQUAL MASS TRANSFER RATE FOR A CONFINED TWO-DIMENSIONAL JET ($Re_b=306, L=12$) ...	217

1. INTRODUCTION

Jet impingement flows are frequently used for their excellent heat and mass transfer characteristics, where localized and controlled surface transfer is desirable. The drying of textiles, veneer, paper or film material, the annealing of metal and plastic sheets, the tempering of glass, and the cooling of gas turbine blades and miniature electronic components are some of its more important practical applications.

Heat and mass transfer characteristics of the various types of impinging jets have been studied rather extensively. Under technically realistic conditions, these studies have been mainly concerned with relatively high velocities so that the flow, developing from the exit of the nozzle from which the jet issues is turbulent. The case of heat and mass transfer in impinging flow with a jet that is laminar at the nozzle exit has received lesser attention. This is especially true for the case of two-dimensional jet. Within the knowledge of the author, there has been only one publication dealing with the laminar two-dimensional impinging jet in the presence of the confinement plates. Van Heiningen et. al. (96) predicted numerically the flow field and impingement heat transfer due to a laminar two-dimensional jet with an upper confinement plate, including the effect of uniform suction at the impingement

plate. No experimental results of either heat or mass transfer due to a confined laminar impinging two-dimensional jet are available.

Reasonably accurate analogy exists between heat and mass transfer provided that the mass transfer rate is low and the normal surface velocity is nearly zero. In such a case, a single transport process, either heat or mass transfer, can be studied in isolation. Usually determination of local heat transfer coefficients is not very reliable owing to the relatively large errors involved in the heat transfer sensors. Therefore, it is more convenient to resort to mass transfer studies rather than heat transfer experimentation. According to the analogy for stagnation flows, it is possible to use the usual $(Pr/Sc)^{1/4}$ factor to convert the fairly precise mass transfer measurements presented by the Sherwood number, into heat transfer measurements presented by the Nusselt number.

The present work is concerned with a confined two-dimensional jet having an initially laminar fully developed profile at the nozzle exit. Impingement mass transfer due to this jet has been studied both experimentally and numerically in order to emphasize not only the engineering applications but also the macroscopic nature of the transport phenomenon. A set of empirical equations which are obtained from the mass transfer experiments can be used immediately for engineering designs. On the other hand, numerical predictions verified by the

experimental results provide a complete understanding of the flow and mass transfer characteristics.

1.1 OBJECTIVES OF THE WORK

In this work it was desired to:

1. examine experimentally the effects of the jet Reynolds number and jet-to-plate spacing on the local mass transfer due to the impingement of a confined laminar two-dimensional jet,
2. study the effect of the presence of confinement plates by comparing the experimental results from this work to those obtained by other investigators using unconfined two-dimensional jets,
3. develop a numerical model which would predict the flow field and the mass transfer due to a confined laminar two-dimensional jet, and finally
4. investigate numerically the effect of nozzle exit velocity profile, (i.e. flat and parabolic velocity profiles), on the flow and mass transfer characteristics of a confined laminar impinging two-dimensional jet.

1.2 CHAPTER CONTENTS

A brief review of related literature in impinging jet flow, heat and mass transfer is given in Chapter 2. The choice of experimental techniques is discussed in Chapter 3 with experimental set-up and procedure given in Chapter 4. Calibration and validity of the experimental set-up are given in Chapter 5. The theoretical development which leads to the finite difference equations is presented in Chapters 6 and 7. The adopted numerical procedure is given in Chapter 8 and the validity of the numerical solutions are tested in Chapter 9. Both experimental and numerical results are discussed in Chapter 10 where the effects of jet Reynolds number, jet-to-plate spacing, nozzle exit velocity profile and presence of confinement plates are studied.

Finally, conclusions are drawn in Chapter 11 and recommendations for further study are outlined in Chapter 12.

2. LITERATURE REVIEW

Detailed investigations of the flow field, heat and mass transfer due to single as well as multiple impinging jets have been given by numerous authors. Because of the large number of possible governing parameters, it is hardly surprising that disparity exists between the results and correlations of different investigators. A complete list of literature, together with suitable editorial comment, are of themselves a major undertaking. Therefore, no attempt will be made to review all literature in this area in detail. Only the more relevant references dealing with a single laminar impinging jet similar to the one studied in this work will be reviewed in detail.

In general, there are two types of impinging jets:

1. liquid jet (or free jet): liquid to gas, i.e. water to air referred to as "water jet".
2. submerged jet: liquid to liquid or gas to gas, i.e. air to air referred to as "air jet".

The two types of jets differ substantially from each other. For a liquid jet, entrainment is negligible and the jet forms a free surface at ambient pressure imposed by the surrounding gas. This is the reason why it is also called a "free jet". For a submerged jet, entrainment is important and there is a substantial amount of mixing between the jet and the surrounding fluid.

There are only few studies of impinging jets that deal with liquid jets (11,58,63,98). On the other hand, impinging submerged jets are studied in more detail. In particular, turbulent submerged jets are studied in detail due to their wide industrial applications. Although literature survey of turbulent impinging submerged jets is not the main objective in this chapter, a brief review will also be given here.

For a single turbulent impinging submerged jet, numerous investigations have been made for both axisymmetric (12,14,16,18,20,22,23,24,31,33,39,64,66,67,68,70,86,87,95) and two-dimensional (6,9,10,18,19,42,101,102) cases. Different variables such as jet flow rate, size of the nozzle and jet-to-plate spacing have been considered. For more detail on the studies of single turbulent impinging submerged jet, the reader is referred to the literature reviews given by Cartwright and Russell (10), Gauntner et. al. (21) and Martin (48).

For multiple turbulent impinging submerged jets, numerous investigations have been made for both axisymmetric (20,33,41,59) and two-dimensional (19,42) cases. An additional variable to those mentioned above for a single submerged jet is the spacings between adjacent jets. For more detail on the studies of multiple turbulent impinging submerged jets, the reader is referred to the literature review given by Martin (48).

Another interesting topic in the study of turbulent impinging submerged jets is the impingement heat transfer

with crossflow. A few investigators have studied the impingement heat transfer with crossflow for single (8,89), and multiple (17,40,56,57) axisymmetric submerged jets. Their studies were concerned with the effect of jet-to-plate spacing, jet flow rate and controlled crossflow flow rate on the impingement heat transfer.

Turbulent submerged jets have been studied rather extensively as mentioned above. However, laminar submerged jets have received lesser attention. Most studies of laminar submerged jets deal with a single jet.

2.1 FLOW CHARACTERISTICS OF A SINGLE LAMINAR IMPINGING SUBMERGED JET

The flow pattern produced by a single submerged jet (laminar or turbulent, confined or unconfined) impinging normally on a flat plate can generally be subdivided into three characteristic regions: the free jet region, the stagnation flow region and the wall jet region (15,21,48). The flow field of an unconfined laminar impinging submerged jet is shown schematically in Figure 2.1. The flow field of a confined laminar impinging submerged jet is very similar to the one shown in Figure 2.1 and will be discussed later in this Section.

FIGURE 2.1 : FLOW FIELD OF AN UNCONFINED LAMINAR IMPINGING SUBMERGED JET

2.1.1 UNCONFINED SUBMERGED JET

Most of the studies of a laminar impinging submerged jet deal with an unconfined jet. In this case, no confinement plates of any kind are present.

2.1.1.1 FREE JET REGION

The free jet region is defined as a region of the submerged jet not influenced by the impingement plate. A submerged jet has been examined at some length (32,78). In general, near the nozzle exit, the jet is decelerated by tangential shear stress. At the same time, the surrounding still fluid is accelerated producing a "mixing region". The width of the mixing region increases continuously, and at some distance downstream it is wide enough to have penetrated to the centerline of the jet. Up to this point the centerline velocity is practically unaffected by mixing and is substantially equal to the nozzle exit velocity. Beyond the end of the so called "potential core" the centerline velocity decays as the jet shares its momentum with more entrained fluid.

Extensive reviews of literature concerning laminar submerged jets were presented by Schlichting (78). He studied the decay of centerline velocity and the spread of the jet for both axisymmetric and two-dimensional cases by applying the boundary layer theory. For the sake of simplicity, Schlichting assumed the jet exit is infinitely small and the velocity at the exit is infinity in order to

retain a finite volumetric flow rate as well as a finite momentum. For a laminar two-dimensional submerged jet, the decay of centerline velocity, $v|_{x=0}$, and the spread of the jet, ζ , are given by

$$(v/\bar{v}_j)|_{x=0} = d, (y/b)^{-1/2} \quad (2.1)$$

$$\zeta/b = e, (y/b)^{1/2} \quad (2.2)$$

where b is the slot width, and d , and e , are constants. Their values depend on the flux of momentum at the jet nozzle exit. For a laminar axisymmetric submerged jet, the decay of centerline velocity and the spread of the jet are given by

$$(v/\bar{v}_j)|_{r=0} = d, (y/d)^{-1} \quad (2.3)$$

$$\zeta/d = e, (y/d) \quad (2.4)$$

where r is the radial coordinate, d is the nozzle diameter, and d , and e , are constants. Their values are dependent on the flux of momentum at the jet nozzle exit.

The length of potential core has been investigated by several researchers for jets of finite size. The core length in general is defined as the distance from the nozzle exit to a position where the centerline velocity is 98% of its initial value, $(v/\bar{v}_j)|_{x=0}=0.98$ (22), or the centerline pressure head is 95% of its initial value, $(v/\bar{v}_j)^2|_{x=0}=0.95$ (48). Core lengths of about $4b$ for turbulent two-dimensional

submerged jets (48,101), or $4d$ for turbulent axisymmetric submerged jets (15,22,48) are to be expected. For laminar submerged jets, core lengths are expected to be longer and depend upon the jet Reynolds number. Since the behavior of turbulence increases the rate of mixing between the jet and surrounding fluid, the core length decreases sharply. According to Hrycak et. al.'s (32) experiment for an axisymmetric air jet, the core length is about $15d$ at $Re_d = 500$ and increases with jet Reynolds number to a maximum value of about $20d$ at $Re_d = 1000$.

2.1.1.2 STAGNATION FLOW REGION

As the submerged jet approaches the impingement plate, the axial velocity component, v , is decelerated and transformed into an accelerated streamwise velocity, u . At the stagnation point, the velocity is zero and the pressure attains a local maximum. Stagnation flow of this type is a typical boundary layer flow with the influence of viscosity being restricted to a thin layer near the impingement plate.

The axial extent of the stagnation flow region can be measured as the distance from the impingement plate where the axial centerline velocity drops to 98% of that in the undisturbed submerged jet at the same distance from the jet nozzle exit (22). In other words, it is where the submerged jet flow deflection begins. For a turbulent axisymmetric submerged jet, the beginning of stagnation flow region is about $1.2d$ away from the impingement plate (18,22,32).

Within the knowledge of the author, no such measurement has been reported for a laminar submerged jet.

Schlichting (78) studied analytically the stagnation regions of laminar axisymmetric and two-dimensional flows against an infinite plate. The velocity components of the inviscid flow within the stagnation flow region are linearly proportional to the distance from the stagnation point. For two-dimensional stagnation flow, these velocity components are given by

$$v/\bar{v}_j = a_1 (h - y)/b \quad (2.5)$$

$$u/\bar{v}_j = a_1 (x/b) \quad (2.6)$$

where a_1 is a constant value. For axisymmetric stagnation flow, the velocity components are given by

$$v/\bar{v}_j = 2a_1 (h - y)/d \quad (2.7)$$

$$u/\bar{v}_j = a_1 (r/d) \quad (2.8)$$

where a_1 is constant value. The viscous boundary layer thickness, δ_v , is defined as the distance from the impingement plate where the streamwise velocity, u , reaches 99% of the value of the inviscid flow in either Equations 2.6 or 2.8 depending on the geometry of the stagnation flow. The boundary thickness is given by Schlichting (78) as

$$\delta_v/b = 2.38 / (a_1 Re_b)^{0.5} \quad (2.9)$$

for two-dimensional stagnation flow, and

$$\epsilon_0/d = 1.95 / (a, Re_d)^{0.5} \quad (2.10)$$

for axisymmetric stagnation flow.

2.1.1.3 WALL JET REGION

The wall jet is the boundary layer flow formed by deflection of the submerged jet through the stagnation flow region. Due to the exchange of momentum with the surrounding fluid, the fluid which is accelerated in the stagnation flow region must eventually decelerate in the wall jet region. Therefore, the streamwise velocity, u , initially increases linearly in the stagnation region mentioned above must reach a maximum value at a certain distance downstream and finally decreases in the wall jet region. For a laminar axisymmetric jet, this maximum value is located at about $1d$ away from the stagnation point for $Re_d=1$. As the jet Reynolds number increases, this location moves further away from the stagnation point (45).

The wall jet has the characteristic of zero velocity at both the impingement plate and the outer jet edge, and hence it exhibits a maximum velocity. The flow pattern in the wall jet region can be divided into two parts according to the location of the maximum velocity: an inner layer which has features common to the ordinary boundary layer and an outer layer which has features common to a submerged jet.

Important parameters in the analysis of flow characteristics of wall jets are the growth of the wall jet boundary layer and the decay of the maximum velocity. The boundary layer thickness of the wall jet, δ , generally used is defined as the thickness in wall jet outer layer where the streamwise velocity is 50% of the maximum velocity.

The first complete theoretical analysis was performed by Glauert (25) who studied both laminar and turbulent, two-dimensional and axisymmetric wall jets. Since then numerous investigations of turbulent (7,10,14,25,48,60,61,70,83,84) and laminar (25,71,79,82) wall jets have been reported. For a laminar two-dimensional wall jet, the decay of maximum velocity, u_{\max} , and the growth of the wall jet boundary layer, δ , are given by (25,82)

$$u_{\max} / \bar{v}_j = f, (x/b)^{-0.5} \quad (2.11)$$

$$\delta/b = g, (x/b)^{0.5} \quad (2.12)$$

where f , and g , are constants. For a laminar axisymmetric wall jet, the decay of the maximum velocity and the growth of the wall jet boundary layer are given by (25,71,79)

$$u_{\max} / \bar{v}_j = f, (r/d)^{-1.5} \quad (2.13)$$

$$\delta/b = g, (r/d)^{1.5} \quad (2.14)$$

where f , and g , are constants.

2.1.2 CONFINED SUBMERGED JET

The confined two-dimensional submerged jet used in this study is a submerged jet with a confinement plate parallel to and at a distance, h , from the impingement plate. The length of this confinement plate is the same as that of the impingement plate. In addition, two spacers are used to fit between the impingement and the confinement plates so as to form a rectangular channel to which the jet flow would be confined. No such confined submerged jet has been studied. Actually, only a few investigators (34,45,77,96) who studied a laminar impinging submerged jet numerically, considered the effect of the presence of a confinement plate. In all these studies, the submerged jet was only partially confined by a confinement plate parallel to the impingement plate. Such a jet, with no spacers between the impingement and the confinement plates, is referred to as "semi-confined" submerged jet by the investigators.

For a semi-confined submerged jet, the flow field is very similar to that shown in Figure 2.1 for an unconfined submerged jet except a recirculation region is induced between the impingement plate and the confinement plate (45,77,96). This recirculation region can affect the spread of the submerged jet in the free jet region. The inertial effects of the upper part of this recirculation derives the greater part of its momentum from the jet in the wall jet region (96). An interesting result was observed by Van Heiningen et. al. (96) in their study of a semi-confined

laminar two-dimensional air jet is that the jet contracts slightly below the nozzle exit for an initially parabolic jet velocity profile.

The effects of the velocity profile at the nozzle exit on the spread of a submerged jet and the decay of centerline velocity in the free jet region were noted by Van Heiningen et. al. (96) and Li (45) in their numerical studies of semi-confined laminar two-dimensional and axisymmetric submerged jets, respectively. A submerged jet issuing with a flat velocity profile spreads and decays faster than that with a parabolic velocity profile. For the case of flat velocity profile, the momentum just inside the free streamline is an order of magnitude greater than that of the surrounding fluid just outside the free streamline. Therefore interaction occurs immediately between the high momentum fluid at the outer edge of the jet and the still fluid surrounding it, causing a higher rate of spread of the jet. This spreading effect is less important for the submerged jet with a parabolic velocity profile. As mentioned above, the jet actually contracts slightly below the nozzle exit in this case.

2.2 HEAT AND MASS TRANSFER DUE TO A SINGLE LAMINAR IMPINGING SUBMERGED JET

Heat and mass transfer characteristics of laminar

impinging axisymmetric submerged jets have been studied rather extensively. The theoretical and experimental results are well correlated. However, heat and mass transfer characteristics of laminar impinging two-dimensional submerged jets have received lesser attention. In this section, literature related to confined and unconfined submerged jets will be reviewed separately with emphasis on the two-dimensional case.

2.2.1 UNCONFINED SUBMERGED JET

Most of the studies of heat and mass transfer due to unconfined laminar impinging submerged jets cover both the stagnation flow and the wall jet regions. But there are also a few studies which cover the wall jet region only (79,82). In these studies, correlations for heat and mass transfer in terms of simple governing parameters of the flow were obtained. In general, at a given jet Reynolds number, the heat and mass transfer characteristics in the stagnation flow region are very much affected by the jet-to-plate spacing, but those in the wall jet region are not so much affected.

2.2.1.1 UNCONFINED AXISYMMETRIC SUBMERGED JET

Scholtz and Trass (79) studied mass transfer due to a laminar impinging axisymmetric submerged jet both theoretically and experimentally. Their theoretical expression, which has been experimentally verified for mass

transfer in the wall jet region is given by

$$Sh_d = c_1 Re_d^{0.75} (r/d)^{-1.25} \quad (2.15)$$

where $c_1 = c_1 (-g'(0))$ (2.16)

and $(-g'(0)) = \Gamma(Sc + 1/3) / (\Gamma(Sc) \Gamma(1/3))$ (2.17)

$(-g'(0))$ is defined as a dimensionless gradient of concentration at the wall. c_1 is a constant and its value is dependent on the exterior flux of momentum flux defined as by Glauert (25). For a flat velocity profile at nozzle exit, $c_1 = 0.426$. On the other hand, for a parabolic velocity profile, $c_1 = 0.458$. For comparison with the theoretical expression of Equation 2.15, experimental data were obtained by measuring the shrinkage of coatings of acetanilide and benzoic acid in the range of $1000 \leq Re_d \leq 3000$ and $970 \leq Sc \leq 4400$. Agreement with theory was good.

Later, Scholtz and Trass (80,81) have given a theoretical solution in the stagnation flow region of a laminar axisymmetric submerged jet with a parabolic velocity profile at nozzle exit. The solution for inviscid flow in the body of impinging jet was first obtained (80) and then was used as the boundary condition to solve the viscous boundary layer flow near the impingement plate (81). For impinging jet with a parabolic velocity profile at nozzle exit, the Sherwood number in the stagnation flow region was given by

$$\begin{aligned} \text{Sh}_d / \text{Re}_d^{0.5} &= 1.6484 \text{Sc}^{0.333} \\ &- 1.0808 (r/d)^2 \text{Sc}^{0.333} + \dots \quad (2.18) \end{aligned}$$

for $h/d=0.5$, $r/d \leq 0.5$ and $1 \leq \text{Sc} \leq 10$. By setting $r=0$, the stagnation point Sherwood number is given by

$$\text{Sh}_d^* = 1.6484 \text{Re}_d^{0.5} \text{Sc}^{0.333} \quad (2.19)$$

In a similar manner, the mass transfer from the impingement plate in the stagnation flow region using an impinging jet with a flat velocity profile at the nozzle exit was calculated by Scholtz and Trass (81). The results indicated that, at a given jet Reynolds number, the mass transfer at the stagnation point is less than half that observed for a jet with a parabolic velocity profile at nozzle exit. However, no experimental data were obtained to confirm this theoretical finding.

Mass transfer experimental data were obtained by Scholtz and Trass (81) from measurement of the sublimation rates of a naphthalene coating exposed to air jet with a parabolic velocity profile at nozzle exit ($\text{Sc}=2.45$). For the ranges of $570 \leq \text{Re}_d \leq 1970$ and $0.5 \leq h/d \leq 6$, good agreement was reported between the experiment results and the theoretical expression of Equation 2.18. In addition, a smooth transition from the stagnation flow region to the wall jet region was observed in the region of $0.5 \leq r/d \leq 2.25$. Experimental data in this transition region were correlated

in terms of jet Reynolds number as

$$Sh_d = 1.05 Re_d^{0.5} (r/d)^{-0.5} \quad (2.20)$$

for $570 \leq Re_d \leq 1970$ and $Sc = 2.45$.

A typical curve showing the variation of local Sherwood number on the impingement plate for an unconfined laminar axisymmetric submerged jet can be plotted from the correlations for different regions in Equations 2.15, 2.18 and 2.20. Since the dependence of local Sherwood number on Reynolds number differ in the stagnation flow, transition and wall jet regions, the relationship between the local Sherwood number in these regions on a plot of Sh_d versus r/d will depend on Re_d . A typical variation of the local Sherwood number on the impingement plate for an unconfined laminar axisymmetric submerged jet with a parabolic velocity profile at nozzle exit is shown in Figure 2.2 for $Re_d = 1740$ and $Sc = 2.45$.

Kapur and Macleod (36,37,38) have applied the techniques of holographic interferometry to the profilometric measurement of mass transfer rates at solid-fluid surface exposed to an unconfined laminar impinging axisymmetric air jet. Experimental results for the wall jet region in the range of $255 \leq Re_d \leq 1870$ were in excellent agreement with the theoretical predictions of Scholtz and Trass (79). Mass transfer coefficients near the stagnation point were also reported for $Re_d = 1340$ and

FIGURE 2.2 : VARIATION OF LOCAL SHERWOOD NUMBER ON IMPINGEMENT PLATE FOR AN UNCONFINED LAMINAR AXISYMMETRIC SUBMERGED JET WITH INITIAL PARABOLIC PROFILE ($Re_d=1740$, $Sc=2.45$)

$h/d=0.5d, 1d$ and $1.5d$. Within the narrow range of the jet-to-plate spacings used, the mass transfer coefficients in the stagnation flow region were found by Kapur and Macleod to be independent of jet-to-plate spacing.

Masliyah and Nguyen carried out a number of investigations on mass transfer due to laminar axisymmetric (50,51), square (50,51), rectangular (50,52) and two-dimensional (53) air jets by using a laser holography interferometric technique. In their study of axisymmetric jet, experimental results for the wall jet region of $Re_d = 1145$ and 1420 were found to be dependent on $Re_d^{0.75}$ and $(r/d)^{-1.25}$. The exponents of Re_d and (r/d) were in good agreement with the theoretical findings by Scholtz and Trass (79).

2.2.1.2 UNCONFINED TWO-DIMENSIONAL SUBMERGED JET

Schwarz and Caswell (82) studied the heat transfer characteristics of a laminar two-dimensional wall jet by solving the flow equations analytically for a wall jet as developed by Glauert (25). Their correlation for mass transfer in the wall jet region is given by

$$Sh_b = c_1 Re_b^{0.75} (x/b)^{-1.25} \quad (2.21)$$

$$\text{where } c_1 = c_1 (-g'(0)) \quad (2.22)$$

c_1 is a constant whose value is dependent on the exterior flux of momentum flux as defined by Glauert (25). For a flat

velocity profile at nozzle exit, $c_v=0.446$. On the other hand, for a parabolic velocity profile, $c_v=0.465$.

Gardon and Akfirat (19) studied experimentally the heat transfer characteristics of unconfined impinging two-dimensional air jets for both laminar and turbulent cases. Although the nozzle exit velocity profile of the jet was not specified, due to the short nozzles used by Gardon and Akfirat, the nozzle exit velocity profile was most likely flat. In their studies of a single unconfined laminar two-dimensional jet ($Re_b=450, 650$ and 950), their main interest was the effects of jet Reynolds number and jet-to-plate spacing on the stagnation point Nusselt number. For jet-to-plate spacing less than the length of the potential core of the submerged jet ($0.5 < h/b < 5$), Nusselt numbers at the stagnation point depend on the jet Reynolds number only. They are approximately proportional to $Re_b^{0.7}$. At large jet-to-plate spacings, stagnation point Nusselt numbers varied with $(h/b)^{-0.5}$ for $Re_b=450$. However, when Reynolds number was increased to 650 and 950, this monotonic decreasing behavior of stagnation point Nusselt numbers with increasing jet-to-plate spacing does not exist. Instead, a maximum of stagnation point Nusselt numbers occurs when jet-to-plate spacing is in the range of $10 < h/b < 15$. The behavior was explained by Gardon and Akfirat (18) and it is caused by the penetration of mixing induced turbulence to the centerline of initially laminar jets. The interactions between the centerline turbulence and the approaching

centerline velocity in the stagnation flow region is the reason why this non-monotonic behavior of the stagnation point Nusselt numbers was observed. It is because the centerline turbulence increases with increasing jet-to-plate spacing and the approaching centerline velocity decreases with increasing jet-to-plate spacing due to the decay of centerline velocity. Gardon and Akfirat (19) concluded that for small jet-to-plate spacings, it is likely that the potential core velocity will be independent of the jet-to-plate spacing, and the stagnation point Nusselt numbers should show a corresponding trend. Once the core has been engulfed by the mixing region, the decay of the centerline velocity would tend to decrease the heat transfer rate at the stagnation point, but centerline turbulence would have an opposite effect. At lower Reynolds numbers the former should be more important, whereas at the higher Reynolds numbers the influence from centerline turbulence should become more important instead.*

Miyazaki and Silberman (58) have analysed theoretically the flow friction and heat transfer characteristics on a heated or cooled flat plate with unconfined laminar, impinging two-dimensional jet with initial flat profile. A potential flow solution was obtained to provide the distribution of the main-stream velocity. The boundary layer and energy equations were then solved numerically by a finite difference method. The correlation obtained by Miyazaki and Silberman in terms of mass transfer variables

at the stagnation point is given by

$$Sh_b^* = 0.506 Re_b^{0.5} Sc^{0.333} \quad (2.23)$$

for $h/b \geq 1.5$ and $0.7 \leq Sc \leq 10$. Variations of local Nusselt numbers on the impingement plate were also evaluated, though no correlations were given. For $h/b \geq 1.5$, Nusselt number exhibits a maximum at the stagnation point and remains constant within the stagnation flow region. Away from the stagnation flow region, Nusselt number decreases monotonically and finally tends to vary proportionally with $x^{0.5}$ as for the flow over a flat plate.

Sparrow and Wong (91) studied the impingement mass transfer due to an unconfined laminar two-dimensional submerged jet with initial parabolic velocity profile. By using the naphthalene sublimation technique ($Sc=2.5$), variation of the local mass transfer coefficient on the impingement plate was determined for $Re_b = 150, 300, 450, 650$ and 950 , and $h=2b, 5b, 10b, 15b$ and $20b$. In general, the local mass transfer coefficient was found to decrease monotonically with increasing distance from the stagnation point, but correlations were not given. Sparrow and Wong also studied the effect of jet-to-plate spacing on the stagnation point Sherwood number. The non-monotonic behavior of stagnation point transfer coefficients with increasing jet-to-plate spacing mentioned by Gardon and Akfirat (19) for higher Reynolds numbers was again observed. Stagnation

point Sherwood numbers measured by Sparrow and Wong (91) were converted into Nusselt numbers by using the analogy between heat and mass transfer, $Nu_b = (Pr/Sc)^{1/4} Sh_b$, in order to compare with the stagnation point Nusselt numbers measured by Gardon and Akfirat (19). The results of Sparrow and Wong are about 30% higher than those of Gardon and Akfirat. The main cause of this difference is the nature of the initial velocity profiles of these two studies. Similar observation is made by Scholtz and Trass (81) for an unconfined impinging axisymmetric submerged jet that the mass transfer at the stagnation point for a jet with initial flat velocity profile is less than that for a jet with initial parabolic velocity profile.

Sparrow and Lee (90) analysed fluid flow and heat and mass transfer characteristics associated with the impingement of an unconfined laminar two-dimensional submerged jet with an initial parabolic velocity profile. The velocity field within the impinging jet was solved within the framework of an inviscid flow model and the results were used as input for the analysis of the boundary layer heat or mass transfer on the impingement plate. The transfer coefficients were found insensitive to the jet-to-plate spacing within the range investigated, which was $0.375 \leq h/b \leq 1.5$. The dependence of stagnation point Sherwood number on Reynolds number was given as

$$Sh_b = 1.4 Re_b^{0.5} \quad (2.24)$$

for $Sc=2.5$. Fair agreement between Equation 2.24 and the experimental data of Sparrow and Wong (91) for $h/b=2$ was obtained.

In the experimental study of an unconfined laminar impinging two-dimensional air jet with initial parabolic velocity profile by Masliyah and Nguyen (53), a regression equation for the local Sherwood number was given as

$$Sh_D = 0.55 Re_D^{0.55} (x/b)^{-0.73} \quad (2.25)$$

for $Sc=2.85$, $90 \leq Re_D \leq 300$ and $1 \leq x/b \leq 30$. All the experimental data reported were taken with jet-to-plate spacing equal to $4b$. They also pointed out that the experimental results with a jet-to-plate spacing equal to $8b$ gave similar results. An overall general agreement between Equation 2.25 and the experimental results from Sparrow and Wong (91) was obtained. In addition, the exponent, -0.73 , of (x/b) in Equation 2.25 is in fair agreement with the theoretical analysis of Schwarz and Caswell (82) for a two-dimensional wall jet, which is -0.75 . However, their exponents of Reynolds number do not agree.

It would be appropriate to conclude that there are no unified correlations of the variation of local Sherwood number for unconfined two-dimensional submerged jet. In general a typical distribution of local Sherwood number on impingement plate for the two-dimensional case is similar to that for the axisymmetric case. A plot is shown in Figure

2.3 for $Re_D=400$ and $Sc=2.85$ by using the correlations of Equations 2.21 2.24 and 2.25 and assuming that the local Sherwood number in the stagnation flow region remains constant.

2.2.2 CONFINED SUBMERGED JET

Heat and mass transfer due to a confined laminar impinging submerged jet have been studied numerically. All studies cover both the stagnation flow and the wall jet regions.

2.2.2.1 CONFINED AXISYMMETRIC SUBMERGED JET

Saad et. al. (77) have simulated the flow and heat transfer characteristics of a semi-confined laminar impinging axisymmetric air jet. The vorticity-stream function formulation of the Navier-Stokes and the energy equations were solved numerically. Effects of uniform suction and nozzle exit velocity profile on the flow and heat transfer characteristics were studied. Saad et. al. also observed the finding of Scholtz and Trass (81) concerning the effect of the initial velocity profile even with the presence of a confinement plate. By comparing their results with the experimental data obtained by Scholtz and Trass (81) who used an unconfined axisymmetric jet, Saad et. al. showed that the presence of a confinement plate has only a minor influence on the stagnation point heat transfer for the range of $2 \leq h/d \leq 4$ and $450 \leq Re_D \leq 2500$.

FIGURE 2.3 : VARIATION OF LOCAL SHERWOOD NUMBER ON IMPINGEMENT PLATE FOR AN UNCONFINED LAMINAR TWO-DIMENSIONAL SUBMERGED JET WITH INITIAL PARABOLIC PROFILE ($Re_b=400$, $Sc=2.85$)

Other numerical studies of semi-confined laminar axisymmetric jets included the studies by Huang et. al. (34) and Li (45). Huang et. al. (34) have numerically solved the Navier-Stokes equations in their primitive form with the energy equation for a semi-confined laminar axisymmetric swirling jet. Li (45) has studied numerically the simultaneous heat and mass transfer under a semi-confined laminar impinging axisymmetric jet.

2.2.2.2 CONFINED TWO-DIMENSIONAL SUBMERGED JET

Only one study of heat transfer due to a laminar impinging two-dimensional submerged jet by Van Heiningen et. al. (96), considered the effect of the presence of a confinement plate. By using the same numerical technique as Saad et. al.'s (77), Van Heiningen studied the effects of uniform suction and nozzle exit velocity profile on the flow and heat transfer characteristics. They found that for a jet-to-plate spacing equal to $4b$ and $100 \leq Re_b \leq 950$, the stagnation point Nusselt number for an initial parabolic velocity profile was between 1.5 and 2 times the value for an initial flat velocity profile. For a flat velocity profile, similar behaviors of skin friction factors and Nusselt numbers along the impingement plate mentioned by Miyazaki and Silberman (58) were also observed, although the results obtained by Miyazaki and Silberman were consistently higher than those obtained by Van Heiningen et. al.. This difference as pointed out by Van Heiningen et. al. is due to

the assumption of potential flow for the flow outside the boundary layer used by Miyazaki and Silberman. For the case of a parabolic velocity profile, Sherwood numbers measured by Sparrow and Wong (91) were converted into Nusselt numbers by using the analogy between heat and mass transfer as mentioned above in order to compare with the numerical results from Van Heiningen et. al.. Good agreement was obtained both in the stagnation flow and in the wall jet regions indicating that the presence of a confinement plate has only a minor effect on the heat and mass transfer characteristics. It is worthwhile to mention that the effect of jet-to-plate spacing was not studied by Van Heiningen et. al. as only one jet-to-plate spacing of $4b$ was used in their study.

3. BASIC EXPERIMENTAL TECHNIQUES

Measurement techniques used to study problems in heat and mass transfer are numerous and often quite complex. Mass transfer techniques have usually been used to avoid the errors inherent in heat transfer measurements; for example, conduction errors in a forced convection heat transfer system even with near-ideal design often cannot be reduced to a sufficiently low level due to the finite conductivity of even the best of insulators. Mass transfer techniques, if properly utilized, do not have an analogous conduction error and for this reason, they are very valuable when precise local measurements are required.

A novel profilometric technique for determining local mass transfer coefficients at solid surface was first described by Macleod and Todd (47). Instead of a volatile or soluble surface coating (i.e., naphthalene coating) customarily employed in profilometric work, the coating used is composed of non-volatile polymer capable of absorbing volatile or soluble swelling agents. Rates of transfer of swelling agent to or from the surface by the experimental fluid stream can then be evaluated from measurements of the swelling or shrinking rate of the coating. In most practical cases, the polymer coating swelling or shrinkage is of order of 10^{-4} m and consequently mechanical means for these measurements are difficult and unreliable. Holographic

interferometry in the conjunction with the swollen polymer technique of Macleod and Todd (47) proposed by Kapur and Macleod (36,37,38) and Masliyah and Nguyen (50,51,52,53) was found to be a powerful and convenient means for measuring such a small change in polymer coating thickness. The unique advantage of this optical method is that it does not influence the process examined. In addition, instead of point by point measurements, information about a whole field of interest can be obtained by the evaluation of photographs.

3.1 SWOLLEN POLYMER TECHNIQUE

The essence of the swollen polymer technique is to coat the flat surface under study with a thin layer of a non-volatile silicon polymer and to swell this coating in a bath of ethylsalicylate. Transfer of ethylsalicylate from the polymer coating when the coating is subjected to an air jet results in local changes in the degree of swelling. These changes cause the polymer coating to shrink (47). It has been shown that the local shrinkage of the polymer coating over a known time within the "constant rate period" provides an accurate measure of the local mass transfer coefficients over the surface (47,51). In other words, in order for the swollen polymer technique to be useful in mass transfer studies, it is essential that a "constant rate

period" is maintained while measurements of mass transfer are taken.

Macleod and Todd (47) have pointed out in their study of this technique that the following important conditions hold within the constant rate period:

1. Swollen polymers having virtually zero heats of mixing, exhibited no total volume change on swelling, i.e., the swollen polymer volume is the sum of the volumes of the dry polymer and that of the pure swelling agent. Thus, the shrinkage of the polymer coating is proportional to the amount of swelling agent transferred from the coating.
2. Although the vapor pressure of the swelling agent over the surface depends both on temperature and on the composition of the coating, and must change as volatilization proceeds at constant temperature, it is reasonable to assume that a change in the partial vapor pressure of up to 5% at the polymer coating during an experiment has a negligible effect on the determination of mass transfer coefficients compared with other sources of error. The so called "constant rate period" is defined as the time period when the vapor pressure remains within 5% of its initial value during volatilization. Within this period, the partial vapor pressure of the swelling agent at the surface can be assumed to be effectively the same as the vapor pressure of the pure swelling agent. Such a constant rate period

was found experimentally and theoretically to be as high as 2500 s.

3. The overall resistance to mass transfer is predominantly in the gas phase.
4. The effect of diffusion of the swelling agent parallel to the surface from regions of low mass transfer to regions of high mass transfer can be neglected. The behavior of the coating at any given point is therefore governed by the local mass transfer in the direction normal to the polymer coating only.

Because of all these conditions mentioned above the swollen technique is a powerful technique in the profilometric determination of local mass transfer coefficients.

The practical advantages of the swollen polymer technique are summarized as follows:

1. The coating itself can be used repeatedly; for each new experiment it can be re-activated by re-immersion in the swelling agent bath.
2. The Schmidt number of the system can be varied; this can be accomplished by a changing the swelling agent alone, without changing the experimental fluid or the polymer coating.
3. Because the mass transfer rate is independent of the coating thickness, no uniformity of thickness other than that implied by the need for hydraulic smoothness at the polymer surface of the coating is required.
4. Unlike the surface of a subliming solid, the surface of

the shrinking polymer maintains a nearly constant optical quality. It is therefore possible to record its shrinkage by fairly standard techniques of holographic interferometry.

It is appropriate to mention that the swollen polymer technique is not suitable for determining local mass transfer coefficients for a curved surface and also when the local mass transfer rate is high.

3.2 LASER HOLOGRAPHY INTERFEROMETRIC TECHNIQUE

Many optical methods have been used in heat and mass transfer studies; reviews of this methods have been presented by Hauf and Grigull (29) and Goldstein (26). Up to a decade ago, the most common methods used were Mach-Zehnder and Michelson interferometry. In 1948, Gabor invented a new optical recording technique which he called "image formation by reconstructed wavefronts" at that time. Not until two years later, the word "holography" was apparently first applied by Roger (43) to describe this new photographic procedure. In contrast to ordinary photography, by which only the amplitude of the reflected light from the object is recorded, holography allows the recording and reconstruction not only the amplitude but also the phase distribution of wavefronts. As holography demands a highly coherent light source, there is a technological break-through after the

invention of the laser about twenty years ago; since then, the holographic techniques have played an important role in the studies of heat and mass transfer (54).

The general theory of holography is so comprehensive that for a detailed description the reader is referred to the literature (13,43,44,73). In this work, only the principles necessary for understanding the holographic measurement techniques are mentioned.

To record a hologram of an object, a beam from a coherent monochromatic light source (usually a laser) is split into two separate beams. One beam, so called the "object beam or wave", illuminates the object, and the reflected scattered light falls directly onto a photographic plate. The other beam, so called "reference beam or wave", travels by a separate path bypassing the object, and falls on the same area of the photographic plate. If both these two waves are mutually coherent, they will interact and form a stable interference pattern. This interference pattern can therefore map an exposure pattern across the surface of the photosensitive emulsion on the photographic plate. When the photographic plate is developed and fixed, the plate with a pattern of dark fringes is called "hologram". The fringe pattern which in general consists of about 1000 lines per millimeter, contains all the visual information about the object. The amplitude of the light from the object is recorded in the form of different contrast of the fringes since the intensity of light incident on the emulsion will

be the square of the sum of the amplitudes from the reference and the object waves. The phase of the light from the object is recorded in the spatial variation of the fringe pattern since when the pathlengths between the reference and the object waves differ by one-half wavelength, interference will be destructive and no light energy will be available to expose the emulsion.

When the hologram is illuminated by the reference wave, the fringe pattern acts like a diffraction grating. A number of light waves are generated by the interaction of the light with the grating. The "zero order" wave propagates in the same direction as the incident light. Beyond the two first order waves, second, third and higher order waves also occur. One of the first order waves travels in the same direction as the original object wave and it is responsible for the virtual image of the original object. The other first order wave is responsible for the real image of the object which usually appears unsharp and highly distorted. Since the scattered light from one point of the object is recorded in each part of the hologram, this point can be seen even through only a small fraction of the plate. It can therefore be observed from various angles, limited only by the size of the hologram. Thus, in the reconstruction stage, a truly three-dimensional picture of the image is obtained.

Making use of these recording properties, several exposures can be made on the same photographic plate. Illuminating this multiple exposed hologram with the

reference wave after processing, the object waves due to different exposures will all be reconstructed and if they differ only slightly from one another they can interfere with each other to form fringes. This is the basic idea of holographic interferometry.

Normally holographic interferometry is made using a double exposure. The interference fringe pattern from the two reconstructed object waves after two different exposures can be photographed and therefore can be analysed at any time.

3.2.1 DOUBLE EXPOSURE HOLOGRAPHIC INTERFEROMETRY

In double exposure holographic interferometry, a hologram of the object, which in this work is the polymer coating, is made before subjecting the polymer coating to the air jet. After the polymer coating is subjected to the air jet, a second exposure is made onto the same photographic plate. After processing the photographic plate, the double exposed hologram is repositioned and illuminated by the reference wave. Now both object waves, the first one is due to the original undisturbed polymer coating and the second is due to the shrunk coating, are reconstructed. The interference from these two object waves forms fringes indicating the change in thickness of the polymer coating between the two exposures. These interference fringes, so called "frozen fringes", are contours of equal coating shrinkage or equal mass transfer and can be photographed

with a 35mm camera.

The main difference of this technique from classical interferometry, such as Mach-Zehnder and Michelson interferometry, is that the object wave is compared to itself. Since both waves pass through the same optical set-up, any imperfections of mirrors and lenses are eliminated. Another advantage of this technique is that it can provide a complete record of the local mass transfer coefficients at all points on the surface. No other technique of heat or mass transfer measurement hitherto reported has this capability. Therefore, mass transfer data can be provided both in precision and completeness.

However, there are also some drawbacks. The photographic process of this technique, particularly at the initial stages, requires a high degree of specialized skill. Its success is greatly dependent on the correct choice of several optical and photographic processing variables, such as ratio of beam intensities, length of exposure and conditions of hologram development. More importantly, in this technique it is difficult to identify the order of any particular fringe. The "frozen fringe" pattern on the double exposed hologram only provides information about differences between the shrinkage of the coating at different points. The actual value of the shrinkage can only be found if the order of fringe at a given point is known. This shortcoming can be overcome by real time holographic interferometry.

3.2.2 REAL TIME HOLOGRAPHIC INTERFEROMETRY

Real time holographic interferometry can be done by using a precise and adjustable hologram mount. After the first exposure, the hologram is processed and replaced in its original position. The "reference image", which is actually the image of the object before the mass transfer experiment, is then reconstructed continuously by illuminating the hologram with the reference wave. Then the mass transfer experiment is started, the reconstructed light can be superimposed onto the changing object wave. The changes of the interference pattern can then be continuously observed and the order of any particular fringe at any given time can be easily determined by counting fringes at a given location as they appear in real time.

Another apparent advantage of this technique is that it is possible to distinguish between a monotonic and a "U" type coating shrinkage between which the double exposure technique fails to distinguish. In double exposure technique, the appearance of "frozen fringes" is simply due to change in depth regardless of whether such a change is a shrinkage or a rise. But in real time technique, the ability to determine the order of each fringe gives a complete information on how the coating shrinkage proceeds. Therefore a "U" type coating shrinkage can be easily observed and recorded.

The optical set-up used in this work which is suitable for both double exposure and real time holographic

interferometry will be discussed in Chapter 4.

4. EXPERIMENTAL SET-UP AND PROCEDURE

The experimental set-up in this work is shown in Figure 4.1 which includes the optical set-up for recording a hologram and also the experimental apparatus for the mass transfer experiment due to an impinging submerged jet. With the hypotenuse surface of a right-angle glass prism as the mass transferring surface, where the polymer coating is applied, it becomes possible to have the entire optical set-up to be located behind the mass transferring surface. Since both the prism and the polymer coating are transparent, the mass transferring surface can be observed from the optical system all the time during the progress of the experiment. Therefore, such an arrangement is suitable not only for double exposure holographic interferometry but also for real time holographic interferometry.

4.1 OPTICAL SET-UP

A concrete table with a concrete slab of size 2.74 x 1.37 x 0.13m is used as the working surface for the optical set-up. The function of heavy slab is to prevent floor vibration from being transmitted to the optical components.

The optical components include:

1. a Spectra Physics model 125A 50mW He-Ne laser which is

FIGURE 4.1 : ARRANGEMENT FOR THE EXPERIMENTAL SET-UP

used as the source of the monochromatic coherent light of wavelength equal to $632.8 \times 10^{-9} \text{m}$,

2. a Prontor-Press shutter which is used to set the exposure time for making a hologram,
3. an Elomag beam splitter-attenuator, model VBA-200, which is a variable reflectivity aluminum mirror for use in splitting the laser beam into the reference and the object beams and in adjusting the ratio of the beam intensities,
4. a Spectra Physics model 332 spatial filter and expanding lens assembly (expanding lens L3, aperture A3) mounted on a Spectra Physics model 306A precision optical mount with base and vertical post which is used to eliminate spatial noise and produce a smooth intensity profile across the expanded object beam,
5. two Spectra Physics model 386-11 utility mirror mounts (includes model 564 mirrors) which are used to reflect the reference beam in order that the reference beam can travel bypassing the object,
6. a Spectra Physics model 332 spatial filter and expanding lens assembly (expanding lens L4, aperture A4) mounted on a Spectra Physics model 306A precision optical mount with base and vertical post which is used to eliminate spatial noise and produce a smooth intensity profile across the expanded reference beam,
7. a piece of $0.3 \times 0.2 \text{m}$ frosted glass mounted on a heavy metal base, of which its reconstructed image from the

hologram is used as a white background for the interference fringes,

8. a photographic plate holder which is designed to hold a half size Agfa-Gevaert 10E75 AH (0.1016 x 0.0635m) photographic plate for double exposure holographic technique, or an Elomag immersion-type X-Y micropositionable photographic plate holder, model MPH-45W, including PC-45 plate carriage which is used to hold and to reposition a full size Agfa-Gevaert 10E75 (0.1016 x 0.127m) photographic plate for real time holographic technique. Photographs of these holographic plate holders are shown in Plate 4.1.

The positions of the optical components and the polymer coating surface are determined according to the Holo-Diagram technique (1,2,3,4). The polymer coating is placed along the ellipse whose foci are the beam splitter and the center of the photographic plate and away from the line joining the two foci. In this work, the distance between the beam splitter and the center of the photographic plate is fixed at approximately 1.2m. The length of the object surface, which is the hypotenuse of a right-angle glass prism is 0.125m. Because of the geometry of the optical set-up in this work, the angle of illumination and observation of the object surface is restricted to 45° by use of the right-angle prism. Abramson (1) has mentioned that in holographic interferometry, if the object is illuminated and looked upon in a direction that makes an angle β , to the

(a) DOUBLE EXPOSURE HOLOGRAPHY

(b) REAL TIME HOLOGRAPHY

PLATE 4.1 : PHOTOGRAPHS OF HOLOGRAPHIC PLATE HOLDERS

object surface, the distance between two dark fringes will correspond to a difference in thickness of half the wavelength of the light used multiplied by a constant k . Abramson defined the constant k , as the reciprocal of $\cos \beta$. In this work, the value of k , can be easily evaluated as 1.414 or the reciprocal of $\cos 45^\circ$. According to the Holo-Diagram, the object in this work must be placed along the ellipse passing through the point at which the k , value is 1.414 and the distances to both the two foci are equal. Due to the finite length of the object surface, the light that is reflected from its different parts must travel different distances. In other words, the k , values along the object surface at different parts are always different. Consequently, the pattern of fringes moves relatively to the object when viewed from different directions (2). In this work, the length of the object is only 0.125m compared to the distance which is 1.2m between the two foci, therefore the movement of the fringe pattern is not serious. In addition, this shortcoming can be overcome by looking at and photographing the fringe pattern at a fixed direction all the time. This can be accomplished by mounting an aluminum plate with a 0.013m diameter hole at the center on the photographic plate holder (see Plate 4.1). The fringe pattern is then viewed through the circular hole.

The positions of the two mirrors are adjusted so that the path lengths of the object and the reference beams, measured from the beam splitter to the center of the

photographic plate have the same value. Consequently, the maximum coherent length of the laser is utilized so as to give the maximum object field of depth.

An overall view of the optical set-up is shown in the photographs in Plate 4.2.

To record a hologram of the polymer coating from this optical set-up, the laser beam with diameter about 0.002m is split into a reference and a object beams. The ratio of beam intensities can be altered at any time by rotating the mirror of the beam splitter-attenuator to different surface reflectivities. The reference beam is directed by two mirrors bypassing the polymer coating and is expanded by the spatial filter and expanding lens assembly. The expanded reference beam falls on the photographic plate. The object beam is expanded by the spatial filter and expanding lens assembly so that it is wide enough to cover the whole object. The object beam travels through the prism and the polymer coating and it experiences a total internal reflection at the surface of the coating. Finally, the object beam leaves the prism and falls on the photographic plate. The interference pattern generated by overlapping object and reference beams is recorded to form the hologram.

In both the double exposure holographic technique and the real time holographic technique, on reconstruction of the hologram, the object images recorded before and after the change in coating thickness interfere with each other to form fringes. The absolute magnitude of the change of

(a)

(b)

PLATE 4.2 : OVERALL VIEW OF THE OPTICAL SET-UP

coating thickness is given by

$$r' = n B \lambda \quad (4.1)$$

where r' is the displacement of a given object point from a fixed point, λ is the wavelength of light, and n is the fringe order of the point under consideration. B is, in general, a function of spatial position of the object point relative to the beam splitter and the photographic plate. In this work, all the positions of the optical components remained the same, therefore B is considered a constant. By simple geometrical manipulations, B can be easily evaluated from the optical set-up by calculating the difference in the path lengths of a light ray before and after a change of coating thickness. Figure 4.2 shows the paths of a light ray before and after a mass transfer experiment for a given change of coating thickness, r' . The change in the light path length between a-a and b-b is the same between c-c and d-d, and is given by

$$2r'(n_s - n_p \sin \beta_1 \sin \beta_2) / \cos \beta_1 \quad (4.2)$$

where n and n are refractive index of the swollen polymer and the glass prism respectively ($n_s=1.428$ and $n_p=1.5$). The angle β_1 , as shown in Figure 4.2 is equal to 45° . The angle $\beta_2 = \sin^{-1}(n_p \sin \beta_1 / n_s)$ is calculated as $47^\circ 58'$. As the appearance of a fringe is due to a change of light path

FIGURE 4.2 : LIGHT PATH LENGTH BEFORE AND AFTER MASS TRANSFER EXPERIMENT

lengths of $n\lambda/2$, then the change of coating thickness r' for n th fringe is given by

$$r' = n\lambda \cos \beta_1 / 4(n_s - n_p \sin \beta_1 \sin \beta_2) \quad (4.3)$$

Comparing Equations 4.1 and 4.3, the constant B is given by

$$B = \cos \beta_1 / 4(n_s - n_p \sin \beta_1 \sin \beta_2) \quad (4.4)$$

Hence, by knowing the incident angle β_1 and the refractive angle β_2 , the value of B can be calculated by using Equation 4.4. If the value of B is known and the fringe order n is determined, the absolute magnitude of the polymer coating shrinkage at a given point can be evaluated.

4.2 MASS TRANSFER EXPERIMENTAL SET-UP

The mass transfer experimental set-up is shown in the photographs in Plate 4.3 and it includes the following: an impingement plate, a confinement plate from which a slot jet issues, a top spacer and also a bottom spacer.

1. The mass transferring surface is the hypotenuse surface of a right-angle glass prism (0.089 x 0.125m) which is fitted into a window cutting of an aluminum plate. The aluminum plate, 0.149 x 0.625m, has a thickness of 0.012m. The surface of the prism together with the

(a)

(b)

**PLATE 4.3 : THE OVERALL VIEW OF THE MASS TRANSFER
EXPERIMENTAL SET-UP**

aluminum plate form one flat surface. This surface is then coated with a thin layer of silicone rubber to form the impingement plate. The front and top views of this impingement plate are shown in Figure 4.3.

2. An aluminum plate having a thickness of 0.012m and the same size as the impingement plate is attached normally to the nozzle of an aluminum slot tube. The aluminum tube with dimensions 0.0015 x 0.132 x 0.4m is long enough to provide a fully developed parabolic velocity profile at the nozzle exit for the highest Reynolds number used in this work. The large ratio of plate span (0.132m) to nozzle width (0.0015m) minimizes end effects and leads to a situation of nearly a two-dimensional jet. The front and top views of the confined plate and the aluminum tube are shown in Figure 4.4.
3. Three sets of spacers are used so as to obtain three different jet-to-plate spacings. A set of spacers includes two aluminum plates of the equal width. One aluminum plate is mounted on top of the impingement plate and the confinement plate, so called top spacer. Another aluminum plate is mounted on the bottom, so called bottom spacer. The gaps between the impingement plate and the confinement plate for these three sets of spacers are 0.003m, 0.006m, and 0.018m, respectively. These correspond to jet-to-plate spacings of $2b$, $4b$ and $12b$.

(a) FRONT VIEW

(b) TOP VIEW

FIGURE 4.3 : FRONT AND TOP VIEWS OF IMPINGEMENT PLATE

FIGURE 4.4 : FRONT AND TOP VIEWS OF CONFINEMENT PLATE WITH SLOT TUBE

The mass transfer experimental set-up is mounted on a heavy metal base as shown in Plate 4.3. The spacers are used to fit between the impingement and the confinement plates so as to form a rectangular channel in which the jet flow would be confined. With such an arrangement of the aluminum slot tube and the impingement plate, the air impinges normally on the impingement surface at a line which is 0.043m from one edge of the glass prism and 0.082m from the other. Since only the mass transfer on the hypotenuse surface of the prism can be studied by holographic interferometry, the location of the slot nozzle allows the effective downstream distance for which mass transfer can be measured to be 55b.

Before each experiment, the impingement plate is easily repositioned with the help of the top and bottom spacers. The impingement plate and the top spacer can be removed after each experiment while the confinement plate and the bottom spacer remained on the heavy metal base.

4.3 EXPERIMENTAL PROCEDURE

The experimental procedure for double exposure holographic interferometry is discussed in Sections 4.3.1 to 4.3.4, while the experimental procedure for real time holographic interferometry is discussed in Section 4.3.5.

4.3.1 PREPARATION OF POLYMER COATING

The polymer coating is formed as follows:

1. Liquid silicone primer, SS-4120, from General Electric is applied by bushing uniformly on the cleaned mass transferring surface. It is important to allow the primer to dry in air for at least one hour before the polymer is applied.
2. Ten parts of liquid polymer rubber, RTV-615A silicone rubber, and one part of catalyst RTV-615B (both from General Electric) are mixed throughly in a styrofoam cup to about 0.1 kg of mixture.
3. The polymer mixture is poured evenly on the mass transferring surface with the mass transferring surface being horizontal.
4. In order to obtain a uniform coating thickness, the freshly coated surface is allowed to semi-harden at room temperature for about ten hours.
5. The semi-harden surface is then cured in the oven at 65°C for three hours.

For complete swelling of a fresh polymer coating with ethylsalicylate it took at least ten hours, while re-swelling a partially exhausted coating after an experimental run required about three hours of immersion in the swelling agent bath.

The refractive index of silicone rubber swollen to various degrees was found by Masliyah and Nguyen (51). It is evident that the refractive index is a weak function of the

degree of swelling when the swollen polymer is near its equilibrium value.

4.3.2 MAKING OF DOUBLE EXPOSURE HOLOGRAM

Each full sized Agfa-Gevaert 10E75 AH photographic plate (0.1016 x 0.127m) is cut into two halves (0.1016 x 0.0635m) in the dark room by using a glass cutter and an aluminum guiding plate. To avoid damage to the emulsion side of the photographic plate, an incision is made only on the back side with minimum stress.

The 50 mW He-Ne laser is turned on at least half an hour before an experimental run. By rotating the mirror of the beam splitter-attenuator to the reading of 110, the intensity of the object beam is selected as about three times the intensity of the reference beam. The shutter is then set at 1/30 s. The selections of the exposure time and the intensity ratio between the two beams were found by trial and error, and remained the same for all the experimental runs.

The impingement plate is removed from the swelling bath and is dried carefully by using clean tissue paper. The impingement plate is then placed on top of the bottom spacer and is mounted with the confinement plate and the top spacer to form a rectangular channel. The laboratory temperature and pressure are measured, and the laboratory lights are then switched off. The photographic plate is placed in the plate holder.

Since handling the mounting of the rectangular channel and the photographic plate can create a temperature gradient, the equipment is left for several minutes in order to equilibrate with the laboratory. The shutter is then activated with an exposure time of $1/30$ s and the first exposure is made on the photographic plate. The mass transfer experiment is then started. Air is supplied from a compressed air cylinder and its volumetric flow rate is measured by a rotameter. Two rotameters are used in this work, Fischer & Porter Co. Rotameter and Brook Rotameter. Each rotameter covers a different range of volumetric air flow rate. The calibrations of these two rotameters are given in Appendix B. After a given period of time, the air flow is stopped. The shutter is reactivated with the same exposure time to obtain a second exposure on the photographic plate.

4.3.3 PROCESSING OF HOLOGRAM

The exposed photographic plate is removed from the plate holder for processing. The processing sequence is as follows:

The photographic plate is

1. developed with Kodak D-19 developer solution for 2 to 3 minutes,
2. stopped with Kodak indicator stop bath for half a minute,
3. fixed with Kodak rapid fixed solution for 2 minutes,

4. washed with tap water,
5. and finally dried by spraying methanol on the photographic plate.

4.3.4 PHOTOGRAPHING OF RECONSTRUCTED IMAGE

To record the virtual image of a double exposed hologram, the following procedure is used.

1. The double exposed hologram, after processing, is repositioned in the photographic plate holder.
2. The intensity of the reference beam is selected as about one half of that of the object beam by rotating the mirror of the beam splitter-attenuator to the reading of 60. In other words, the intensity of the reference beam is higher than that when the double exposed hologram was made.
3. The object beam is then blocked off.
4. A Nikon F2A Photomic camera with Nikon Motor Drive MD-3 and Micro-Nikkor 105mm f/4 Lens is placed behind the hologram and the view guiding aluminum plate. The lens aperture is normally set at f/4 and exposure time varied from 8 to 20 seconds. Focusing the camera on the reconstructed virtual image, the photograph of this image can then be taken.
5. Kodak Tri-X pan film (TX 402) with ASA speed of 400, a fast black and white film, is used.

The processing of the Tri-X pan film is proceeded in room temperature as follows:

The film is

1. developed with Kodak D-76 developer solution for 7 minutes,
2. stopped with Kodak indicator stop bath for half a minute,
3. fixed with Kodak fixer solution for 4 minutes,
4. washed with running tap water,
5. and finally dried by hanging in a dust free room.

4.3.5 PROCEDURE FOR REAL TIME HOLOGRAPHIC INTERFEROMETRY

In this work, real time holographic interferometry is used for qualitative study only. This technique is used for determining the order of a particular fringe of the "frozen fringe" pattern obtained from double exposed hologram.

For real time holographic interferometry, an immersion-type X-Y micropositionable photographic plate holder, model MPH-45W, is used instead of the simple plate holder used in double exposure holographic interferometry. A full size Agfa-Gevaert 10E75 (0.1016 x 0.127m) photographic plate is placed in the PC-45 plate carriage and is allowed to normalize in the plate holder water cell for approximately 15 minutes. This operation pre-sensitizes the emulsion and also allows strain release, swelling, or other emulsion excursions to occur prior to exposure. The mass transfer set-up is prepared as previously discussed. The shutter is activated with an exposure time of 1/60 s. This exposure time is half of that of the double exposure

holographic interferometry because the photographic emulsion becomes more sensitive while soaking in water. But the intensity ratio between the reference and the object beams is maintained the same as that of the double exposure holographic interferometry. The plate carriage with the photographic plate is then removed from the water cell for processing. The processing sequence is as previous Section 4.3.3 except in this case the developing time is shorter.

The hologram after processing is placed back into the water cell to within one fringe alignment by using the precision X-Y controls on the plate holder. With both the reference and object beams striking the hologram, the fringes which occur between the holographic virtual image and the actual subject image can be eliminated by adjusting the plate position with the precision X-Y controls. When no interference fringes on the object are observed, this indicates that the photographic plate is repositioned in its original position. The mass transfer experiment is then proceeded with. The shrinkage of the polymer coating can be viewed behind the hologram as real time interference fringes across the image. The order of any particular fringe can be determined by counting fringes at a given location on the impingement plate as they appear in real time.

5. CALIBRATION AND VALIDITY OF THE EXPERIMENTAL SET-UP

Mass transfer characteristics due to an unconfined laminar impinging two-dimensional air jet is studied by measuring the local Sherwood number along the impingement plate. Local Sherwood number in this work is defined by

$$Sh_b = k b / D \quad (5.1)$$

$$\text{or } Sh'_b = k' b / D \quad (5.2)$$

where k and k' are the local mass transfer coefficients, and D is the diffusion coefficient. The local mass transfer coefficients k and k' are defined by

$$N = k (p_s - p_j) \rho^0 Mw / P \quad (5.3)$$

$$\text{and } N = k' (p_s - p_b) \rho^0 Mw / P \quad (5.4)$$

where N is mass flux, ρ^0 is the molar density of the gas mixture, Mw is the molecular weight of swelling agent, and P is the total pressure. The partial vapor pressures of the swelling agent, p_s , p_j and p_b are located at the coating surface, the jet nozzle exit and in the bulk flow, respectively.

For an unconfined air jet, the partial vapor pressures of the swelling agent at the jet nozzle exit and in the bulk flow are equal to zero ($p_j = p_b = 0$). It leads to $k = k'$ from

Equations 5.3 and 5.4. However, for an confined air jet, p_0 is no longer equal to zero and it is not easy to measure in the experimental set-up of this work. Therefore, only the Sherwood numbers evaluated from Equation 5.1 are investigated in the experimental study for confined air jet. On the other hand, p_0 can be evaluated numerically. Both the Sherwood numbers evaluated from Equations 5.1 and 5.2 are investigated in the numerical study.

For both confined and unconfined air jet, $p_1 = 0$ and the partial vapor pressure of the swelling agent at the coating surface, p_s , is that of its vapor pressure, P^* , during the "constant rate period" and Equation 5.3 simplifies to

$$N = k P^* \rho^* M_v / P \quad (5.5)$$

The mass flux, N , can also be given as

$$N = r' \rho_s / T \quad (5.6)$$

where r' is the change of coating thickness given by Equation 4.1, ρ_s is the density of the swollen polymer and T is the duration of the mass transfer experiment. The product $r' \rho_s$ is the mass of swelling agent transferred per unit area, since the swollen polymer volume is the sum of the volume of the dry polymer and that of the pure swelling agent (47). Substituting Equation 4.1 into Equation 5.6, one obtains

$$N = n B \lambda \rho_s / T \quad (5.7)$$

Define $A = B \lambda \rho_s$, then Equation 5.7 becomes

$$N = A (n / T) \quad (5.8)$$

where A is a constant for a given mass transfer experimental and optical set-up. Constant A is also referred to as the calibration constant of the experimental set-up. Combining Equations 5.1, 5.5 and 5.8, one obtains

$$\begin{aligned} Sh &= (A P / \rho^* P^* M_w) (b / D) (n / T) \\ &= G (n / T) \end{aligned} \quad (5.9)$$

where G is dependent only on the physical properties of working fluids.

Therefore, to evaluate the local Sherwood number it is necessary to know the physical properties under the operating conditions, the local fringe order and the duration of the experimental run.

5.1 CALIBRATION PROCEDURE

In order to evaluate the mass flux of the swelling agent, it is necessary to know the value of the constant A

of Equation 5.8. The calibration constant A can be obtained by studying the mass transfer due to an unconfined laminar impinging axisymmetric air jet with initial parabolic velocity profile using the same optical set-up as shown in Figure 4.1.

This calibration is made using the theoretical expression obtained by Scholtz and Trass (79) for an unconfined laminar impinging axisymmetric submerged jet in the wall jet region given by Equation 2.15 as

$$Sh_d = c_1 Re_d^{0.75} (r/d)^{-1.25} \quad (5.10)$$

where $c_1 = 0.458 \Gamma(Sc + 1/3) / \Gamma(Sc) \Gamma(1/3)$ (5.11) for initial parabolic velocity profile. Equation 5.10 has been shown by Scholtz and Trass (79) to be fairly accurate in the wall jet region. Equating Equations 5.9 and 5.10 by using the nozzle diameter, d , instead of the slot width, b , as the characteristic length in Equation 5.9 for the case of axisymmetric and rearranging, yields

$$n = (c_1 D \rho^* P^* M_w / d A P) (T Re_d^{0.75} (r/d)^{-1.25}) \quad (5.12)$$

If a mass transfer experiment is performed using an unconfined impinging axisymmetric air jet with initial parabolic velocity profile, then a plot of n versus $(T Re_d^{0.75} (r/d)^{-1.25})$ in the wall jet region gives as its

slope ($c, D \rho^* P^* M_w / d A P$). The constant A can then be evaluated from the knowledge of the physical properties of the system.

The experimental set-up and procedure for an unconfined axisymmetric jet are similar to those for a confined two-dimensional jet mentioned in Chapter 4. Here, the confinement plate and slot tube referred to in Chapter 4 is replaced by a circular tube with a diameter equal to 0.003m. This tube is mounted on a heavy stand. The tube is set perpendicular to the mass transferring surface with a jet-to-plate spacing of $1.5d$. Double exposure holographic interferometry is used throughout this calibration. Experimental runs with durations equal to 90s, 180s and 360s and for $Re_d = 1210$ and 1470 are made. The average operating temperature and pressure of the experimental runs were 20.7°C and 93.87kPa , respectively.

The "frozen fringe" pattern for run no. CJ14-1.5B for $Re_d = 1470$ and $T = 90\text{s}$ is shown in Plate 5.1a. The "frozen fringe" pattern for run no. CJ14-6A for $Re_d = 1470$ and $T = 360\text{s}$ is shown in Plate 5.1b. Determination of fringe order of these "frozen fringe" patterns is rather simple. In Plate 5.1a, the outer bright region is considered to be the zeroth order fringe where no mass transfer as yet has occurred. Since in this case the zeroth order fringe is known, the determination of the order of other fringes is straightforward. By counting the fringe order from the outer zeroth order fringe towards the stagnation point, it is

(a) $T = 90s$

(b) $T = 360s$

PLATE 5.1 : CONTOURS OF EQUAL MASS TRANSFER RATE FOR AN UNCONFINED AXISYMMETRIC AIR JET ($Re_d=1470$)

possible to label all the fringes. It is thus this short duration experiment that gives the base on which the long duration experiment, such as the one shown in Plate 5.1b, are interpreted. In each experimental run, the variation of the local fringe order, n , with dimensionless radial distance, r/d , is determined. Experimental results of local fringe order, n , and dimensionless radial distance, r/d , are given in Appendix C.

A confirmation of the "constant rate period" can be obtained by combining all the experimental runs for a given Reynolds number in the form of n/T (51). A plot of n/T versus r/d for $Re_d = 1470$ is shown in Figure 5.1. Here, the data for different duration collapse onto one curve indicating that the driving force, in this case, the swelling agent vapor pressure at the coating surface, P^* , is the same for both the shortest and for the longest mass transfer experiment.

A plot of Equation 5.12 is given in Figure 5.2. The slope of the least squares linear regression is $634.08s^{-1}$ which gives A as $1.614 \times 10^{-4} \text{ kg/m}^2$ using physical properties in Appendix A evaluated at average operating conditions of 20.7°C and 93.87kPa .

It is possible to proceed in a different manner to obtain a calibration constant A . Using the appropriate data, Equation 4.4 gives $B = 0.2615$. Since the calibration constant, A , is defined as $B\lambda\rho_s$, by using the values of swollen coating density, ρ_s , and the wavelength of the light, λ , in

FIGURE 5.1 : VARIATION OF n/T WITH DIMENSIONLESS RADIAL DISTANCE FOR $Re_d = 1470$

FIGURE 5.2 : CALIBRATION PLOT USING AN UNCONFINED, AXISYMMETRIC AIR JET

Appendix A, A becomes 1.67×10^{-4} kg/m³.

The agreement between the two methods for evaluating the constant A is within 3.3%. This agreement confirms the success of the method based on optical analysis mentioned in Section 4.1. This also indicates that the coating surface is reasonably smooth throughout the region of interest during the experimental period. The value of A as obtained from an unconfined axisymmetric air jet is used for the evaluation of local Sherwood number throughout the experimental study of this work

5.2 TEST OF CALIBRATION VALIDITY

The validity of the value of calibration constant A evaluated in Section 5.1 is tested by studying the mass transfer due to an unconfined laminar impinging two-dimensional air jet with an initial parabolic velocity profile. The same optical set-up as shown in Figure 4.1 is used. Local Sherwood numbers in the wall jet region evaluated by using Equation 5.9 with $A = 1.614 \times 10^{-4}$ kg/m³ are compared with the regression equation given by Masliyah and Nguyen (53)

$$Sh_b = 0.55 Re_b^{0.5} (x/b)^{-0.5} \quad (5.13)$$

for an unconfined impinging two-dimensional air jet

($Sc=2.85$).

The experimental set-up and procedure for an unconfined two-dimensional jet are similar to those for an unconfined axisymmetric jet mentioned in Section 5.1, except a plexiglass slot tube with dimensions $0.0015 \times 0.075 \times 0.35\text{m}$ is used. This tube is mounted on a heavy stand and set perpendicular to the mass transferring surface with a jet-to-plate spacing of $4b$. Double exposure holographic interferometry is used. Experimental runs with durations equal to 120s, 240s and 480s and for $Re_b=94$ and 204 are made. The average operating temperature and pressure of the experimental runs were 20.7°C and 93.98kPa , respectively. Under these operating conditions, $Sc=2.74$.

The "frozen fringe" pattern for run no. SJ1-2A for $Re_b=94$ and $T=120\text{s}$ is shown in Plate 5.2a. The "frozen fringe" pattern for run no. SJ1-4F for $Re_b=94$ and $T=240\text{s}$ is shown in Plate 5.2b. In both cases, the zeroth order fringes are no longer on the mass transferring surface. A simple trial and error method introduced by Masliyah and Nguyen (51) when the zeroth order fringe cannot be identified is used to determine the fringe order in this case. In their study of unconfined axisymmetric air jet, Masliyah and Nguyen pointed out that, according to Equation 5.12, a plot of $\log(n)$ versus $\log(r/d)$ for experiments with various durations of a given Reynolds number gave curves which are parallel to each other. Similar behavior of fringe order with dimensionless streamwise distance for the

a T = 120s

(b) T = 240s

PLATE 5.2 : CONTOURS OF EQUAL MASS TRANSFER RATE FOR AN UNCONFINED TWO-DIMENSIONAL AIR JET ($Re_b=94$)

two-dimensional case is expected. By choosing the correct local fringe order, the curves from a plot of $\log(n)$ versus $\log(x/b)$ for experiments with various durations of a given Reynolds number should therefore parallel to each other. Such a plot for an unconfined two-dimensional air jet is shown in Figure 5.3 for $Re_b = 94$. Using such trial and error method, the outer darken regions in both Plates 5.2a and 5.2b are determined to be the first order fringes. By counting the fringe order from the outer first order fringe towards the stagnation point, it is possible to label all the fringes. As soon as the local fringe order is known, local Sherwood number can be easily determined by using Equation 5.9. In each experimental run, the variation of local Sherwood number, Sh_b , with dimensionless streamwise distance, x/b , are determined. Experimental results of local Sherwood number, Sh_b , and dimensionless streamwise distance, x/b , are given in Appendix D.

It is worthwhile to mention that the regression equation given by Masliyah and Nguyen (53), Equation 5.13, is only valid for $Sc=2.85$ which is slightly different from the $Sc=2.74$ of this work. Considering the effect of Schmidt number on local Sherwood number by using the correlation given by Scholtz and Trass, Equation 5.11, Equation 5.13 becomes

$$Sh_b = 0.54 Re_b^{0.5} (x/b)^{-0.75} \quad (5.14)$$

FIGURE 5.3 : VARIATION OF FRINGE ORDER WITH DIMENSIONLESS STREAMWISE DISTANCE FOR $Re_b = 94$

for $Sc=2.74$.

A plot to test the validity of the experimental local Sherwood numbers for an unconfined two-dimensional air flow is shown in Figure 5.4. For a perfect fit with Equation 5.14, all data points should lie on a straight line having a slope of unity. From Figure 5.4, although it is observed that the data points are consistently above the perfect fit line, there are still within the scattered range ($\pm 9\%$) of the experimental data obtained by Masliyah and Nguyen (53). Therefore, the validity of the calibration constant A is reaffirmed.

FIGURE 5.4 : COMPARISON OF MASS TRANSFER DATA DUE TO AN UNCONFINED IMPINGING TWO-DIMENSIONAL AIR JET WITH EQUATION 5.14

6. NUMERICAL MODEL-MATHEMATICAL FORMULATION

A two-dimensional numerical model is used to simulate the experimental set-up. The impinging jet system considered in this work is shown in Figure 6.1. The air jet issues from a two-dimensional slot tube of width b with an average velocity of \bar{v}_j . The confinement plate is located parallel to and at a distance h from the impingement plate. The impingement is normal to the impingement plate. For the description of the flow and the concentration fields, a two-dimensional rectangular coordinate system is used with the origin at the center of the jet nozzle exit. The x -coordinate is parallel to the impingement plate and the y -coordinate is normal to it. The outflow region is chosen at a location sufficiently far away from the stagnation flow region to ensure that the velocity and the concentration profiles at this location are developing as those for parallel plates.

The governing equations for this two-dimensional impinging jet system are presented in Section 6.1. The boundary conditions for this system are presented in Section 6.2.

FIGURE 6.1 : COORDINATE SYSTEM AND BOUNDARIES OF THE IMPINGING JET SYSTEM

6.1 GOVERNING EQUATIONS

The pressure gradient is so small that the change of density at each point in the system can be neglected. Therefore, air can be treated as an incompressible Newtonian fluid, even though it is a compressible fluid itself. The two-dimensional momentum and transport equations can be reduced to the corresponding vorticity-stream function form with the assumption of steady state, incompressible viscous Newtonian fluid flow with constant physical properties. The pertinent equations are (69):

$$\frac{\partial(u \omega)}{\partial x} + \frac{\partial(v \omega)}{\partial y} = \left(\frac{\partial^2 \omega}{\partial x^2} + \frac{\partial^2 \omega}{\partial y^2} \right) \quad (6.1)$$

$$\frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} = \omega \quad (6.2)$$

$$\frac{\partial(u c)}{\partial x} + \frac{\partial(v c)}{\partial y} = D \left(\frac{\partial^2 c}{\partial x^2} + \frac{\partial^2 c}{\partial y^2} \right) + R \quad (6.3)$$

where ω is the vorticity and is defined by

$$\omega = \frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} \quad (6.4)$$

ψ is stream function and is defined by

$$\frac{\partial \psi}{\partial y} = u \quad \text{and} \quad \frac{\partial \psi}{\partial x} = -v \quad (6.5)$$

c is the molar concentration of the swelling agent, and R is the molar rate of production of the swelling agent per unit volume. For a system without chemical reaction, $R=0$.

When dimensionless variables are introduced as follows:

$$\begin{aligned} L &= h / b \\ U &= u / \bar{v}_j \\ V &= v / \bar{v}_j \\ X &= x / b \\ Y &= y / b \\ C &= (c - c_j) / (c_s - c_j) \\ \Omega &= \omega (b / \bar{v}_j) \\ \Psi &= \psi / (b \bar{v}_j) \\ Re_b &= b \bar{v}_j / \nu \\ Sc &= \nu / D \end{aligned} \quad (6.6)$$

then the above equations becomes:

$$\frac{\partial(U \Omega)}{\partial X} + \frac{\partial(V \Omega)}{\partial Y} = \frac{1}{Re_b} \left(\frac{\partial^2 \Omega}{\partial X^2} + \frac{\partial^2 \Omega}{\partial Y^2} \right) \quad (6.7)$$

$$\frac{\partial^2 \Psi}{\partial X^2} + \frac{\partial^2 \Psi}{\partial Y^2} = \Omega \quad (6.8)$$

$$\frac{\partial(U C)}{\partial X} + \frac{\partial(V C)}{\partial Y} = \frac{1}{Re_b Sc} \left(\frac{\partial^2 C}{\partial X^2} + \frac{\partial^2 C}{\partial Y^2} \right) \quad (6.9)$$

$$\text{where } \frac{\partial \Psi}{\partial Y} = U \quad \text{and} \quad \frac{\partial \Psi}{\partial X} = -V \quad (6.10)$$

The objective of the numerical study is to solve Equations 6.7, 6.8 and 6.9 for Ω , Ψ and C .

6.2 BOUNDARY CONDITIONS

Because the governing equations are elliptic in nature, boundary conditions must be specified at all the boundaries. The boundaries are classified in five regions: the nozzle exit, the confinement plate, the impingement plate, the axis of symmetry and the outflow region.

6.2.1 NOZZLE EXIT

For an initial parabolic velocity profile at the nozzle exit, the velocity components are

$$\begin{aligned} V &= 1.5 (1 - 4 X^2) \\ U &= 0 \end{aligned} \quad (6.11)$$

From these velocity components, one can show that

$$\Psi = -1.5 X + 2 X^3 \quad (6.12)$$

$$\Omega = .12 X$$

(6.13)

where the stream function, ψ , at the axis of symmetry ($X=0$) is taken as zero.

For an initial flat velocity profile at nozzle exit, the velocity components are

$$V = 1$$

$$U = 0$$

(6.14)

From these velocity components, one can show that

$$\psi = -X$$

(6.15)

$$\Omega = 0$$

(6.16)

The boundary condition for the concentration at the nozzle exit is

$$C = 0$$

(6.17)

for an air jet.

6.2.2 CONFINEMENT PLATE

Because the confinement plate is impermeable, the value of the stream function does not change along the plate. This value can be determined by substituting $X=0.5$ in Equations 6.12 and 6.15 for the case of parabolic and flat velocity

profile, respectively. For both cases, the boundary condition of the stream function at the confinement plate is

$$\psi = -0.5 \quad (6.18)$$

The boundary condition for the vorticity at the confinement plate is evaluated by using no-slip boundary condition (96). This boundary condition is given in finite difference form and will be discussed in Chapter 7.

The boundary condition for the concentration is

$$\partial C / \partial Y = 0 \quad (6.19)$$

due to no mass transfer occurring at the plate.

6.2.3 IMPINGEMENT PLATE

Again, because the impingement plate is impermeable, the value of stream function does not change along the plate. The stream function can be arbitrary set to zero to give

$$\psi = 0 \quad (6.20)$$

The boundary condition for the vorticity at the impingement plate is the same as that of the confinement plate.

The boundary condition for the concentration is given by

$$C = 1 \quad (6.21)$$

6.2.4 AXIS OF SYMMETRY

The axis of symmetry is given by $X=0$ and the stream function is a constant along it. Arbitrarily the constant is set to zero to give

$$\psi = 0 \quad (6.22)$$

The boundary condition of vorticity can be easily determined by setting $U = \partial V / \partial X = \partial U / \partial Y = 0$ and noting that $V(X, Y) = -V(-X, Y)$. The vorticity along $X=0$ is then given by

$$\Omega = 0 \quad (6.23)$$

Since the concentration is also symmetric on both sides of the axis, it leads to

$$\partial C / \partial X = 0 \quad (6.24)$$

along the axis of symmetry.

6.2.5 OUTFLOW REGION

This boundary is located sufficiently far from the jet such that the flow is nearly fully developed where the influence of the impinging zone is not felt. Usually, a fully developed flow is assumed at this boundary (96). If, instead a developing flow profile for the parallel plates channel is assumed, the outflow boundary can then be located anywhere in the x-direction as long as it is far enough and not influenced by the impinging jet flow. With an assumption of a developing flow profile at the outflow boundary, this boundary can be located closer to the stagnation point than that with an assumption of a fully developed flow profile. In other words, the number of grid points in x-direction can then be minimized.

The developing stream function and vorticity profiles are derived from the developing velocity profile given by Sparrow et. al. (92) for their study of velocity development for the parallel-plate channel. By using only the most dominant term in their solution series, the stream function and the vorticity at the outflow region are given by

$$\psi = \psi_{fd} + \frac{1}{\alpha_1^2 L} \left\{ \frac{\sin [\alpha_1 (2(Y/L) - 1)]}{\cos \alpha_1} \left(\frac{L}{2\alpha_1} - Y + \frac{L}{2} \right) - 8\alpha_1^2 (X/L) / Re_D \right\} e^{-\alpha_1 X/L} \quad (6.25)$$

and

$$\Omega = \Omega_{fd} - \frac{2}{\alpha_1 L^2} \left\{ \frac{\sin [\alpha_1 (2(Y/L) - 1)]}{\cos \alpha_1} \right\} e^{-8\alpha_1^2 (X/L) / Re_b} \quad (6.26)$$

where $\alpha_1 = 4.49341$. The subscript "fd" denotes fully developed flow, where

$$\Psi_{fd} = 1.5 (Y/L)^2 - (Y/L)^3 - 0.5 \quad (6.27)$$

$$\Omega_{fd} = 3 (1 - 2 (Y/L)) / L^2 \quad (6.28)$$

The developing concentration profile is analogous to the developing temperature profile for parallel plates given by McCuen (62) and Shah and London (85). The boundary conditions used in this work are similar to those of the fundamental solution of the third kind in their work. The concentration at the outflow region is given by

$$C = C_{fd} + \sum_{i=1}^{\infty} E_i Y_i e^{-\lambda_i^2 (X/2L) / (Re_b Sc)} \quad (6.29)$$

where Y_i 's are functions of Y . E_i 's and λ_i 's are eigenconstants and eigenvalues, respectively and they are evaluated at the confinement plate for the first four terms in the series as (62,85):

$$\lambda_1 = 3.117 \quad \text{and} \quad E_1 Y_1 = -1.2480$$

$$\lambda_2 = 9.714 \quad \text{and} \quad E_2 Y_2 = +0.3831$$

$$\begin{aligned} \lambda_1 &= 16.260 & \text{and} & & E_1 Y_1 &= -0.2263 \\ \lambda_2 &= 22.810 & \text{and} & & E_2 Y_2 &= +0.1605 \end{aligned} \quad (6.30)$$

Due to the oscillating behavior of the series in Equation 6.29 (from the values of $E_i Y_i$'s), there is no dominant term in this series. The fully developed concentration profile is given by

$$C_{fd} = 1 \quad (6.31)$$

The finite difference form of the boundary conditions in the outflow region will be discussed in Chapter 7.

The location of the outflow region boundary is chosen depending on the jet Reynolds number and jet-to-plate spacing. It is given in Table 6.1.

TABLE 6.1 : LOCATION OF OUTFLOW REGION BOUNDARY

L	Re_b	X
2	100 - 400	74
4	100 - 400	74
12	100 - 300	170
	400	186

7. NUMERICAL FORMULATION

Initially the numerical technique used in this work was similar to the method introduced by Joseph, Smith and Adler (35) which is that of the Marker-and-Cell (MAC) method used by other investigators dealing with numerical studies (5,28,30,65,72, 93,99). The method is to solve the unsteady state primitive equations. A steady state solution is obtained by advancing the velocities and pressure from one time interval to another until the solution no longer changes with time. This numerical technique was later abandoned due to the failure to obtain a converged solution for higher Reynolds number unless the time interval was steadily reduced. Large CPU time was required in order to obtain a steady state solution.

The second numerical technique used in this work was the central finite-difference representation of the steady state vorticity transport equation. This numerical technique was again abandoned due to the failure to obtain a converged solution for $Re_b > 100$. Severe under-relaxation was required for the run of $Re_b = 100$. Converged solution for $Re_b = 100$ was not obtained until after 2700 iterations.

The third and successful numerical technique used in this work is the hybrid differencing schemes, so called "upstream-weighted" and "upstream" differencing schemes, introduced by Raithby and Torrance (69). The detail of

derivations of the general finite-difference equations is given in Section 7.1. The derivations of the finite-difference equations at the boundaries are given in Section 7.2. The finite-difference equations for "upstream-weighted" and "upstream" differencing schemes is discussed in Section 7.3. Finally, the stability properties of the finite-difference equations are discussed in Section 7.4.

7.1 FINITE-DIFFERENCE EQUATIONS

The governing equations are:

$$\frac{\partial(U\phi)}{\partial X} + \frac{\partial(V\phi)}{\partial Y} = a \left(\frac{\partial^2\phi}{\partial X^2} + \frac{\partial^2\phi}{\partial Y^2} \right) \quad (7.1)$$

$$\frac{\partial^2\psi}{\partial X^2} + \frac{\partial^2\psi}{\partial Y^2} = \Omega \quad (7.2)$$

$$\text{where } \frac{\partial\psi}{\partial Y} = U \quad \text{and} \quad \frac{\partial\psi}{\partial X} = -V \quad (7.3)$$

Equation 7.1 is a more general equation than Equations 6.7 and 6.9. The variable ϕ represents vorticity, Ω , in Equation 6.7 and concentration, C , in Equation 6.9. The coefficient a for these two cases becomes $(Re_b)^{-1}$ and $(Re_b Sc)^{-1}$, respectively.

The region of interest is represented by a rectangular grid network shown in Figure 7.1 with grid lines parallel to the X and Y coordinates. Grid lines in X and Y directions are designated by i and j, respectively. As shown in Figure 7.1, the total numbers of node (the intersection of the grid lines) in X and Y directions are n_x and n_y , respectively. The numbers of node cover the jet nozzle exit is n_j .

For the time being, let us restrict our attention to the region surrounding the typical node (i,j) shown in Figure 7.2. The variables ρ , ψ and C are defined at each node, while the velocity components, U and V, are defined at points midway between these nodes. In other words, the velocity components are on the boundaries of the control volume. The control volume of a node is the region bounded by the dashed lines shown in Figure 7.2, the sides of which lie midway between the neighbouring nodes. One of the advantages of using such a finite-difference grid is that it simplifies the computation of mass flux into and out of the control volume, since the velocity components are located at the control volume boundary itself.

The finite-difference equations of the velocity components are obtained as follows

$$\begin{aligned} & [\psi(i+1, j+1) + \psi(i, j+1) - \psi(i+1, j-1) - \psi(i, j-1)]/4 \\ & = U(i+1/2, j) \Delta Y(j) \end{aligned} \quad (7.4)$$

$$\begin{aligned} & [\psi(i+1, j+1) + \psi(i+1, j) - \psi(i-1, j+1) - \psi(i-1, j)]/4 \\ & = -V(i, j+1/2) \Delta X(i) \end{aligned} \quad (7.5)$$

FIGURE 7.1 : GRID NETWORK OF THE IMPINGING JET SYSTEM

FIGURE 7.2 : GRID NETWORK AND CONTROL VOLUME SURROUNDING TYPICAL NODE (i, j)

such that $U(i+1/2, j)$ is the mean velocity in the X-direction in the region bounded by grid lines passing through nodes $(i+1, j+1)$, $(i, j+1)$, $(i, j-1)$ and $(i+1, j-1)$, and $V(i, j+1/2)$ is the mean velocity in the Y-direction in the region bounded by the grid lines passing through nodes $(i+1, j+1)$, $(i-1, j+1)$, $(i-1, j)$ and $(i+1, j)$. With these approximate equations, the mass balance is satisfied exactly over the control volume. From Equations 7.4 and 7.5, one obtains

$$\begin{aligned} & [U(i+1/2, j) - U(i-1/2, j)] \Delta Y(j) \\ & + [V(i, j+1/2) - V(i, j-1/2)] \Delta X(i) = 0 \end{aligned} \quad (7.6)$$

Dividing by $\Delta X(i) \Delta Y(j)$, Equation 7.6 becomes the central finite-difference representation of the equation of continuity over the control volume of node (i, j) .

The convective term $\partial(U\phi)/\partial X$ of Equation 7.1 is represented as the difference between two fluxes, one through the right hand side boundary, the $(i+1/2)$ face, and one through the left hand side boundary, the $(i-1/2)$ face, of the control volume shown in Figure 7.2. The flux, $U\phi$, through the right hand side boundary is approximated by $U(i+1/2, j)\phi(i+1/2-\alpha_\bullet, j)$, where $\phi(i+1/2-\alpha_\bullet, j)$ is equal to the "true" value of the variable ϕ half-way between nodes (i, j) and $(i+1, j)$ and is located at $(i+1/2-\alpha_\bullet, j)$ if one linearly interpolates between $\phi(i, j)$ and $\phi(i+1, j)$ (69). Since both $\phi(i, j)$, $\phi(i+1/2-\alpha_\bullet, j)$ and $\phi(i+1, j)$ lie on the same straight line, therefore

$$\begin{aligned}
 (0.5 + \alpha_e) \phi(i, j) + (0.5 - \alpha_e) \phi(i+1, j) \\
 = \phi(i+1/2 - \alpha_e, j)
 \end{aligned} \tag{7.7}$$

Proceeding similarly at the left hand side boundary, using the parameter α_w , the flux, $U\phi$, is approximated by $U(i-1/2, j)\phi(i-1/2 - \alpha_w, j)$ where

$$\begin{aligned}
 (0.5 + \alpha_w) \phi(i-1, j) + (0.5 - \alpha_w) \phi(i, j) \\
 = \phi(i-1/2 - \alpha_w, j)
 \end{aligned} \tag{7.8}$$

Therefore, the convective term in X-direction becomes

$$\begin{aligned}
 \frac{\partial(U\phi)}{\partial X} &= [U(i+1/2, j) \phi(i+1/2 - \alpha_e, j) \\
 &- U(i-1/2, j) \phi(i-1/2 - \alpha_w, j)] / \Delta X(i) \tag{7.9}
 \end{aligned}$$

The convective term $\partial(V\phi)/\partial Y$ of Equation 7.1 is represented as the difference between fluxes, one through the top boundary, the $(j-1/2)$ face, and one through the bottom boundary, the $(j+1/2)$ face, of the control volume shown in Figure 7.2. Similarly, the convective term in the Y-direction becomes

$$\begin{aligned}
 \frac{\partial(V\phi)}{\partial Y} &= [V(i, j+1/2) \phi(i, j+1/2 - \beta_s) \\
 &- V(i, j-1/2) \phi(i, j-1/2 - \beta_n)] / \Delta Y(j) \tag{7.10}
 \end{aligned}$$

$$\begin{aligned} \text{where } (0.5 + \beta_s) \phi(i, j) + (0.5 - \beta_s) \phi(i, j+1) \\ = \phi(i, j+1/2-\beta_s) \end{aligned} \quad (7.11)$$

$$\begin{aligned} (0.5 + \beta_n) \phi(i, j-1) + (0.5 - \beta_n) \phi(i, j) \\ = \phi(i, j-1/2-\beta_n) \end{aligned} \quad (7.12)$$

Note that all α 's and β 's are unknowns and are to be determined.

The finite-difference equations for the diffusion terms $a(\partial^2\phi/\partial X^2)$ and $a(\partial^2\phi/\partial Y^2)$ of Equation 7.1 were introduced by Raithby and Torrance (69) as follows:

$$\begin{aligned} a \frac{\partial^2\phi}{\partial X^2} = \frac{a}{\Delta X(i)} \left\{ (1 - \gamma_e) \left[\frac{\phi(i+1, j) - \phi(i, j)}{\bar{\Delta X}(i)} \right] \right. \\ \left. - (1 - \gamma_w) \left[\frac{\phi(i, j) - \phi(i-1, j)}{\bar{\Delta X}(i-1)} \right] \right\} \end{aligned} \quad (7.13)$$

in the X-direction, and

$$\begin{aligned} a \frac{\partial^2\phi}{\partial Y^2} = \frac{a}{\Delta Y(j)} \left\{ (1 - \delta_s) \left[\frac{\phi(i, j+1) - \phi(i, j)}{\bar{\Delta Y}(j)} \right] \right. \\ \left. - (1 - \delta_n) \left[\frac{\phi(i, j) - \phi(i, j-1)}{\bar{\Delta Y}(j-1)} \right] \right\} \end{aligned} \quad (7.14)$$

in the Y-direction, where γ 's and δ 's are weighting factors to be determined. The advantage of using these weighting factors is that they retain flexibility similar to that for

the convective terms.

Considering the flux crossing the common boundary between two adjacent control volumes, conservation requires that α_e and γ_e for the control volume of node (i, j) must equal α_w and γ_w for the control volume of the node $(i+1, j)$. Similarly, β_s and δ_s for the control volume of the node (i, j) must equal β_n and δ_n for the control volume of the node $(i, j+1)$. Therefore, α_e , γ_e , α_w , γ_w , β_s , δ_s , β_n and δ_n in the previous expressions can be replaced by the notations $\alpha(i+1, j)$, $\gamma(i+1, j)$, $\alpha(i, j)$, $\gamma(i, j)$, $\beta(i, j+1)$, $\delta(i, j+1)$, $\beta(i, j)$ and $\delta(i, j)$, respectively.

By introducing all the foregoing flux terms into Equation 7.1, one obtains the following explicit equation at each interior node

$$\begin{aligned} \phi(i, j) = & \{m_1 \phi(i-1, j) + m_2 \phi(i+1, j) \\ & + m_3 \phi(i, j-1) + m_4 \phi(i, j+1)\} / m, \quad (7.15) \end{aligned}$$

The coefficients of Equation 7.15 are defined by

$$\begin{aligned} m_1 = & [1 - \gamma(i, j)] \xi(i, j) + 0.5 [U(i-1/2, j) \Delta Y(j)] \\ & + \alpha(i, j) |U(i-1/2, j) \Delta Y(j)| \\ m_2 = & [1 - \gamma(i+1, j)] \xi(i+1, j) - 0.5 [U(i+1/2, j) \Delta Y(j)] \\ & + \alpha(i+1, j) |U(i+1/2, j) \Delta Y(j)| \\ m_3 = & \{|U(i+1/2, j) \Delta Y(j)| \alpha(i+1, j) \\ & + |U(i-1/2, j) \Delta Y(j)| \alpha(i, j) \\ & + |V(i, j+1/2) \Delta X(i)| \beta(i, j+1) \end{aligned}$$

$$\begin{aligned}
& \alpha(i, j-1/2) \Delta X(i) | \beta(i, j) \} \\
& + \{ [1 - \gamma(i+1, j)] \xi(i+1, j) + [1 - \gamma(i, j)] \xi(i, j) \\
& + [1 - \delta(i, j+1)] \eta(i, j+1) + [1 - \delta(i, j)] \eta(i, j) \} \\
m. = & [1 - \delta(i, j)] \eta(i, j) + 0.5 [V(i, j-1/2) \Delta X(i)] \\
& + \beta(i, j) |V(i, j-1/2) \Delta X(i)| \\
m. = & [1 - \delta(i, j+1)] \eta(i, j+1) - 0.5 [V(i, j+1/2) \Delta X(i)] \\
& + \beta(i, j+1) |V(i, j+1/2) \Delta X(i)| \quad (7.16)
\end{aligned}$$

with

$$\xi(i, j) = \frac{a \Delta Y(j)}{\bar{\Delta X}(i-1)} \quad \text{and} \quad \eta(i, j) = \frac{a \Delta X(i)}{\bar{\Delta Y}(j-1)} \quad (7.17)$$

As mentioned above, the sign of both elements in the products $\alpha(i, j) U(i-1/2, j)$, $\alpha(i+1, j) U(i+1/2, j)$, $\beta(i, j) V(i, j-1/2)$, and $\beta(i, j+1) V(i, j+1/2)$ must be the same.

Therefore the products are all positive quantities and can be written as noted in Equation 7.16 with the understanding that all α 's and β 's used in this work are positive number.

The finite-difference approximations of the vorticity-stream function relation are derived from the central difference approximations for non-uniform grid network, where

$$\begin{aligned}
\frac{\partial^2 \psi}{\partial X^2} = & 2 \left\{ \frac{\bar{\Delta X}(i-1) \psi(i+1, j) + \bar{\Delta X}(i) \psi(i-1, j)}{\bar{\Delta X}(i) \bar{\Delta X}(i-1) [\bar{\Delta X}(i) + \bar{\Delta X}(i-1)]} \right. \\
& \left. - \frac{[\bar{\Delta X}(i) + \bar{\Delta X}(i-1)] \psi(i, j)}{\bar{\Delta X}(i) \bar{\Delta X}(i-1) [\bar{\Delta X}(i) + \bar{\Delta X}(i-1)]} \right\} \quad (7.18)
\end{aligned}$$

$$\text{and } \frac{\partial^2 \Psi}{\partial Y^2} = 2 \left\{ \frac{\bar{\Delta}Y(j-1) \Psi(i, j+1) + \bar{\Delta}Y(i) \Psi(i, j-1)}{\bar{\Delta}Y(j) \bar{\Delta}Y(j-1) [\bar{\Delta}Y(j) + \bar{\Delta}Y(j-1)]} \right. \\ \left. - \frac{[\bar{\Delta}Y(j) + \bar{\Delta}Y(j-1)] \Psi(i, j)}{\bar{\Delta}Y(j) \bar{\Delta}Y(j-1) [\bar{\Delta}Y(j) + \bar{\Delta}Y(j-1)]} \right\} \quad (7.19)$$

By introducing Equations 7.18 and 7.19 into Equation 7.2, one obtains the following explicit equation for the stream function at each interior node

$$\Psi(i, j) = \{n_1 \Psi(i-1, j) + n_2 \Psi(i+1, j) \\ + n_3 \Psi(i, j-1) + n_4 \Psi(i, j+1) - \Omega(i, j)\} / n_5 \quad (7.20)$$

The coefficients of Equation 7.20 are defined by

$$n_1 = 2 / \{ \bar{\Delta}X(i-1) [\bar{\Delta}X(i) + \bar{\Delta}X(i-1)] \} \\ n_2 = 2 / \{ \bar{\Delta}X(i) [\bar{\Delta}X(i) + \bar{\Delta}X(i-1)] \} \\ n_3 = 2 \left\{ \frac{1}{\bar{\Delta}X(i) \bar{\Delta}X(i-1)} + \frac{1}{\bar{\Delta}Y(j) \bar{\Delta}Y(j-1)} \right\} \\ n_4 = 2 / \{ \bar{\Delta}Y(j-1) [\bar{\Delta}Y(j) + \bar{\Delta}Y(j-1)] \} \\ n_5 = 2 / \{ \bar{\Delta}Y(j) [\bar{\Delta}Y(j) + \bar{\Delta}Y(j-1)] \} \quad (7.21)$$

The distributions of vorticity, stream-function and concentration inside the region of interest can then be obtained by solving Equations 7.15 and 7.20 using an iterative method. The values of the parameters α , β , γ and δ can be specified depending on the differencing scheme used.

These values will be given later in this chapter. Procedure of the iterative method is discussed in Chapter 8. Since the variables Ω , Ψ and C are evaluated at nodes, for consistency in analysing the numerical results, the velocity components U and V are also evaluated at the nodes by using the following equations:

$$U(i, j) = [\Psi(i, j+1) - \Psi(i, j-1)] / 2 \Delta Y(j) \quad (7.22)$$

$$V(i, j) = -[\Psi(i+1, j) - \Psi(i-1, j)] / 2 \Delta X(i) \quad (7.23)$$

The velocity components obtained from Equations 7.22 and 7.23 are used instead of those evaluated from Equations 7.4 and 7.5 during the iterations.

7.2 BOUNDARY CONDITIONS

The finite-difference equations at the boundaries will be discussed for the five different regions mentioned above separately.

7.2.1 NOZZLE EXIT

This boundary is defined as $1 \leq i < n_j$ and $j=1$ in Figure 7.2. For an initial parabolic velocity profile,

$$V(i, 1) = 1.5 (1 - 4 X(i)^2)$$

$$U(i, 1) = 0$$

$$\begin{aligned}\psi(i,1) &= -1.5 X(i) + 2 X(i)^2 \\ \Omega(i,1) &= 12 X(i)\end{aligned}\quad (7.24)$$

and for an initial flat velocity profile,

$$\begin{aligned}U(i,1) &= 1 \\ V(i,1) &= 0 \\ \psi(i,1) &= -X(i) \\ \Omega(i,1) &= 0\end{aligned}\quad (7.25)$$

The boundary condition for the concentration for both parabolic and flat velocity profiles are

$$C(i,1) = 0 \quad (7.26)$$

7.2.2 CONFINEMENT PLATE

This boundary is defined as $n_j \leq i < n_x$ and $j=1$ in Figure 7.2. The boundary condition for the stream-function at the confinement plate is

$$\psi(i,1) = -0.5 \quad (7.27)$$

The boundary condition of the vorticity at the confinement plate is approximated by a finite-difference expression with truncation error less than $O(\Delta Y)^2$ which embodies the no-slip conditions, $\partial\psi/\partial Y=U=0$ and $\partial^2\psi/\partial Y^2=-\partial U/\partial Y = \Omega(i,1)$ at the boundary. The finite-difference equation at

this boundary is derived using Taylor series as

$$\Omega(i,1) = 2 \left\{ \frac{[\Psi(i,2) - \Psi(i,1)] [\bar{\Delta Y}(2) + \bar{\Delta Y}(1)]^2}{\bar{\Delta Y}(1)^2 \bar{\Delta Y}(2) [\bar{\Delta Y}(1) + \bar{\Delta Y}(2)]^2} - \frac{[\Psi(i,3) - \Psi(i,1)] [\bar{\Delta Y}(1)]^2}{\bar{\Delta Y}(1)^2 \bar{\Delta Y}(2) [\bar{\Delta Y}(1) + \bar{\Delta Y}(2)]^2} \right\} \quad (7.28)$$

The boundary condition for the concentration at the confinement plate is approximated by using a forward finite-difference expression with truncation error less than $O(\bar{\Delta Y})^2$. For $\partial C/\partial Y=0$ at the boundary, the finite-difference equation becomes:

$$C(i,1) = \left\{ \frac{[\bar{\Delta Y}(1) + \bar{\Delta Y}(2)]^2 C(i,2) - \bar{\Delta Y}(1)^2 C(i,3)}{[\bar{\Delta Y}(1) + \bar{\Delta Y}(2)]^2 - \bar{\Delta Y}(1)^2} \right\} \quad (7.29)$$

7.2.3 IMPINGEMENT PLATE

This boundary is defined as $1 \leq i < n_x$ and $j = n_y$ in Figure 7.2. The boundary condition of stream-function is given by

$$\Psi(i, n_y) = 0 \quad (7.30)$$

The boundary condition of the vorticity is similar to that at the confinement plate. The finite-difference equation for vorticity at this boundary is derived using

Taylor series as

$$\Omega(i, n_y) = 2 \left\{ \frac{[\Psi(i, n_y-1) - \Psi(i, n_y)] [\bar{\Delta Y}(n_y-1) + \bar{\Delta Y}(n_y-2)]^2}{\bar{\Delta Y}(n_y-1)^2 \bar{\Delta Y}(n_y-2) [\bar{\Delta Y}(n_y-1) + \bar{\Delta Y}(n_y-2)]^2} - \frac{[\Psi(i, n_y-2) - \Psi(i, n_y)] \bar{\Delta Y}(n_y-1)^2}{\bar{\Delta Y}(n_y-1)^2 \bar{\Delta Y}(n_y-2) [\bar{\Delta Y}(n_y-1) + \bar{\Delta Y}(n_y-2)]^2} \right\} \quad (7.31)$$

The boundary condition of the concentration is given by

$$C(i, n_y) = 0 \quad (7.32)$$

7.2.4 AXIS OF SYMMETRY

This boundary is defined as $i=1$ and $1 < j < n_y$ in Figure 7.2. The boundary conditions of stream-function and vorticity are given by

$$\begin{aligned} \Psi(1, j) &= 0 \\ \Omega(1, j) &= 0 \end{aligned} \quad (7.32)$$

For the boundary condition of the concentration, a boundary control volume surrounding a boundary node $(1, j)$ is introduced. Referring to Figure 7.2, the node (i, j) becomes $(1, j)$ and $\bar{\Delta X}(1) = \bar{\Delta X}(0) = \Delta X(1)$. The index $i \geq 1$ will refer to the variables inside the system, and $i < 1$ will refer to the variables outside the system. Equation 7.15 is now applied

to the nodes on this boundary. Variables such as $V(1, j+1/2)$, $\beta(1, j+1)$, $\delta(1, j+1)$ and $n(1, j+1)$ can be evaluated at the boundary. Due to the fact that this boundary can be considered as a plane of symmetry, the variables outside the field can be evaluated as follows

$$\begin{aligned}\psi(0, j) &= -\psi(2, j) \\ U(1/2, j) &= -U(3/2, j) \\ C(0, j) &= C(2, j)\end{aligned}\quad (7.34)$$

Therefore the concentration at this boundary, $C(1, j)$, can be evaluated from Equation 7.15 similarly to that of the interior node.

7.2.5 OUTFLOW REGION

This boundary is defined as $i=n_x$ and $1 < j < n_y$ in Figure 7.2. The finite-difference equations for fully developed stream-function, vorticity and concentration are given by

$$\begin{aligned}\psi_{fd}(j) &= 1.5 (Y(j)/L)^3 - (Y(j)/L)^3 - 0.5 \\ \omega_{fd}(j) &= 3 [1 - 2 (Y(j)/L)] / L^2 \\ \text{and } C_{fd}(j) &= 1\end{aligned}\quad (7.35)$$

The finite-difference equations for the stream-function and vorticity at this boundary can be obtained from Equations 6.25 and 6.26. After rearrangement, they become, respectively

$$\Psi(nx, j) = \Psi_{fd}(j) + [\Psi(nx-1, j) - \Psi_{fd}(j)] z, \quad (7.36)$$

$$\Omega(nx, j) = \Omega_{fd}(j) + [\Omega(nx-1, j) - \Omega_{fd}(j)] z, \quad (7.37)$$

$$\text{with } z_1 = \exp \{-8 \alpha_1^2 [\bar{\Delta} X(nx-1)] / (L Re_b)\} \quad (7.38)$$

The finite-difference equation for the concentration at this boundary can be obtained from Equation 6.29 by approximating the ratio of the series for $X=X(nx)$ and $X=X(nx-1)$ as the ratio of the first term of these series, where

$$C(nx, j) = C_{fd}(j) + [C(nx-1, j) - C_{fd}(j)] z, \quad (7.39)$$

$$\text{with } z_2 = \exp \{-\lambda_1 [\bar{\Delta} X(nx-1)] / (2 L Re_b Sc)\} \quad (7.40)$$

7.3 FINITE-DIFFERENCING SCHEMES

Three finite-differencing schemes are used in this work, namely, a central differencing scheme (C.D.S.), an upstream differencing scheme (U.D.S.) and an upstream-weighted differencing scheme (U.W.D.S.).

7.3.1 CENTRAL DIFFERENCING SCHEME (C.D.S.)

Setting $\alpha(i, j) = \beta(i, j) = \gamma(i, j) = \delta(i, j) = 0$ in the finite-difference equations of Section 7.1 results in a central differencing scheme with truncation error $O(\Delta X^2, \Delta Y^2)$.

7.3.2 UPSTREAM DIFFERENCING SCHEME (U.D.S.)

Setting $\alpha(i,j)=\beta(i,j)=0.5$ and $\gamma(i,j)=\delta(i,j)=0$ in the finite-difference equations in Section 7.1 results in an upstream differencing scheme. This differencing scheme was used by Torrance (94) and Raithby and Torrance (69), and is similar to the "upwind differences" used by Runchal et. al. (74,75,76). In this case, the variables Ω , Φ and C in the system are determined to a large extent by the values of the corresponding variables prevailing immediately upstream.

7.3.3 UPSTREAM-WEIGHTED DIFFERENCING SCHEME (U.W.D.S.)

In this case, the parameters $\alpha(i,j)$, $\beta(i,j)$, $\gamma(i,j)$ and $\delta(i,j)$ are determined from the exact solution to the local one-dimensional transport equations between nodes. Consider the transport equation of the variable ϕ in the X -direction between nodes $(i-1,j)$ and (i,j) , the one-dimensional equation governing the variation of the variable ϕ with X between nodes $(i-1,j)$ and (i,j) is

$$U(i-1/2,j) \frac{d\phi}{dX} = a \frac{d^2\phi}{dX^2} \quad (7.41)$$

The exact solution of Equation 7.41 is given by

$$\frac{\phi - \phi(i-1,j)}{\phi(i,j) - \phi(i-1,j)} = \frac{\exp \{U(i-1/2,j) [X-X(i-1)]/a\} - 1}{\exp \{U(i-1/2,j) [\bar{\Delta}X(i-1)]/a\} - 1} \quad (7.42)$$

Locally exact solutions of the form of Equation 7.42 were introduced by Spalding (88) and Raithby and Torrance (69). The value of ϕ at $(i-0.5, j)$, where $X=X(i-1)+(\bar{\Delta}X(i-1)/2)$, can be evaluated from Equation 7.42. This "true" value of the variable ϕ is equal to $\phi(i-1/2-\alpha(i, j), j)$ of Equation 7.8. Therefore, from Equations 7.8 and 7.42, with $\alpha_w = \alpha(i, j)$, one obtains

$$\alpha(i, j) = \frac{1}{2} - \frac{\exp(Rw/2) - 1}{\exp(Rw) - 1} \quad (7.43)$$

$$\text{where } Rw = |U(i-1/2, j)| \bar{\Delta}X(i-1) / a \quad (7.44)$$

Similarly,

$$\beta(i, j) = \frac{1}{2} - \frac{\exp(Rs/2) - 1}{\exp(Rs) - 1} \quad (7.45)$$

$$\text{where } Rs = |V(i, j-1/2)| \bar{\Delta}Y(j-1) / a \quad (7.46)$$

The absolute signs are introduced since α 's and β 's are always positive numbers, and for stability reasons are chosen to match the signs of local mean velocities. From Equation 7.13, the first derivative of ϕ in X-direction at $(i-1/2)$ is given by

$$\left. \frac{d\phi}{dx} \right|_{i-1/2} = [1 - \gamma(i, j)] \frac{[\phi(i, j) - \phi(i-1, j)]}{\bar{\Delta}X(i-1)} \quad (7.47)$$

Since by introducing the parameter $\gamma(i,j)$, the finite-difference equation should yield the same result as the locally exact solution. The right hand side of Equation 7.47 can be evaluated from Equation 7.42. After rearrangement, one obtains

$$\gamma(i,j) = 1 - \frac{R_w \exp(R_w/2)}{\exp(R_w) - 1} \quad (7.48)$$

Similarly,

$$\delta(i,j) = 1 - \frac{R_s \exp(R_s/2)}{\exp(R_s) - 1} \quad (7.49)$$

Clearly, in the limit of R_w approaching zero both $\alpha(i,j)$ and $\gamma(i,j)$ approach zero and the finite-difference equations reduce to central differencing scheme. On the other hand, for large R_w , $\alpha(i,j)$ approaches 0.5 and $\gamma(i,j)$ approaches 1. This limit implies that upstream differencing scheme is used for the convection term and that the diffusion term is dropped. Similarly, $\beta(i,j)$ and $\delta(i,j)$ approach the same value with respect to the value of R_s .

7.4 STABILITY OF THE FINITE-DIFFERENCE EQUATIONS

The finite-difference equations derived in Section 7.1 are a set of non-linear algebraic equations to be solved iteratively.

For a set of linear algebraic equations with constant coefficients such as

$$K(i) = \sum_{\text{all } j} f(i,j) K(j) + g(i) \quad (7.50)$$

The matrix theory states that such a set will converge to a solution in a successive substitution method when the matrix $f(i,j)$ is "diagonally dominant" (45,74). This condition can be expressed as $\sum_{\text{all } j} |f(i,j)| \leq 1$, for all i , and for at least one i such that the inequality holds.

For non-linear equations, the above conditions are often sufficient, although they may not be the necessary conditions (27). Therefore, in order for Equation 7.15 to satisfy the conditions for convergence, the following

$$\left| \frac{a_1}{a_2} \right| + \left| \frac{a_2}{a_3} \right| + \left| \frac{a_3}{a_4} \right| + \left| \frac{a_4}{a_5} \right| \leq 1 \quad (7.51)$$

must hold for all the interior nodes and with strict inequality for at least one node.

The stability of the finite-difference equations for the three finite differencing schemes will be discussed

separately.

7.4.1 CENTRAL DIFFERENCING SCHEME (C.D.S.)

For the central differencing scheme, $\alpha(i,j)=\beta(i,j)=\gamma(i,j)=\delta(i,j)=0$, one can immediately observe from Equation 7.16 that convergence of Equation 7.15 is not always assured: the sum of the terms on left hand side of Equation 7.51, because of the presence of the velocity terms in the numerator, is not bounded. As long as all the coefficients in Equation 7.16 are positive, the sum of these terms is unity. However, once this is not true, the sum of these terms may well exceed unity. In the region near the jet nozzle exit, the velocity in the Y-direction, V , is large. For the case of high Reynolds numbers, the coefficient m , in Equation 7.16 becomes negative. Such a coefficient may lead to non-convergence or numerical instabilities.

7.4.2 UPSTREAM DIFFERENCING SCHEME (U.D.S.)

For the upstream differencing scheme, $\alpha(i,j)=\beta(i,j)=0.5$ and $\gamma(i,j)=\delta(i,j)=0$, one can immediately observe from Equation 7.16 that all the coefficients are always positive and hence the sum of the terms on the left hand side of Equation 7.51 will always be unity. Therefore, the upstream differencing scheme has a better chance of convergence.

7.4.3 UPSTREAM-WEIGHTED DIFFERENCING SCHEME (U.W.D.S.)

For the upstream-weighted differencing scheme, $\alpha(i,j)$, $\beta(i,j)$, $\gamma(i,j)$ and $\delta(i,j)$ are unknowns and are depended on the local velocity components and the grid size by studying Equations 4.43, 4.45, 4.48 and 4.49. The limit values of these parameters were shown in Section 7.3, where $\alpha(i,j)$ and $\beta(i,j)$ vary from 0 to 0.5 and $\gamma(i,j)$ and $\delta(i,j)$ vary from 0 to 1 with R_w and R_s increasing.

In order to have a better chance of convergence, all the coefficients in Equation 7.16 should be positive such that the sum of the terms on the left hand side of Equation 7.51 is unity. Since a negative coefficient occurs only when the local velocities are large, let us examine the coefficients for such cases. In the region of interest, the largest U occurs near the stagnation flow region and the largest V occurs near the jet nozzle exit. Therefore the values of $\alpha(i,j)$ and $\gamma(i,j)$ are close to 0.5 and 1 near the stagnation flow region, respectively. On the other hand, the values of $\beta(i,j)$ and $\delta(i,j)$ are close to 0.5 and 1 near the jet nozzle exit, respectively. From Equation 7.16, all the coefficients should be positive for both cases with m_1 approaching zero for the first case and m_2 approaching zero for the second case.

Once again, all the coefficients in Equation 7.16 are always positive. The convergence properties of this differencing scheme should be similar to those for the upstream differencing scheme.

8. COMPUTATIONAL PROCEDURE

The grid design used for the numerical computations is discussed in Section 8.1, followed by a detailed presentation of the method of solution in Section 8.2. The selection of the convergence criteria is discussed in Section 8.3. Finally, the construction of the computer program is given in Section 8.4.

8.1 GRID DESIGN

A non-uniform grid is used in the numerical computations. The grid size and the arrangement are known to be important factors in determining not only the accuracy of the solution, but also the convergence characteristics.

Due to relatively large gradients of velocity and concentration along the impingement plate, the gridlines parallel and adjacent to this plate must be very closely spaced. On the other hand, gridlines parallel and adjacent to the axis of symmetry are also closely spaced in order to ensure accurate calculation of the variables within the stagnation flow region.

In this work, different grid networks are designed for the numerical runs for the three different jet-to-plate spacings ($L=2, 4$ and 12). These grid networks are results of

numerous trials and are given in Table 8.1 Tests for the accuracy of these grid networks will be given in Chapter 9.

TABLE 8.1 : GRID NETWORKS FOR DIFFERENT L AND Re

L	Re _b	nx	ny
2	100 - 400	55	25
4	100 - 400	55	25
12	100 - 300	67	25
	400	69	25

8.1.1 GRID ARRANGEMENT IN X-DIRECTION

The finest grid spacings are adjacent to the axis of symmetry. In such a region, nine nodes are used to cover a distance $b/2$ ($n_j=9$). The grid spacings are then increased in steps a factor of 2 in the X-direction. The largest grid spacings appear in the outflow region which are 128 times the finest one. The grid arrangement in X-direction are listed in Table 8.2.

The distance in X-direction which is covered by grid network is a function of n_x , the total number of nodes in X-direction used. In other words, the location of the outflow region boundary is a function of n_x . For the grid networks with $n_x=55$, 67 and 69 as shown in Table 8.1, the outflow region boundaries are located at $X=74$, 170 and 186,

respectively (see Table 8.2). These locations of the outflow region boundaries are also mentioned above in Table 6.1.

8.1.2 GRID ARRANGEMENT IN Y-DIRECTION

Since finer grid spacings must be located adjacent to the impingement plate, this can be achieved with a coordinate stretching transformation of some kind. One of the most commonly used transformation is that of an exponential stretch. Choose

$$Y = \frac{[1 - \exp(-b, Y')]}{[1 - \exp(-b, L)]} L \quad (8.1)$$

such that the Y' -coordinate is transformed into the stretched Y -coordinate. b , is an arbitrary constant used to adjust the "stretch". Equation 8.1 satisfies the boundary conditions of $Y(1)=0$, $Y'(1)=0$ and $Y(ny)=L$, $Y'(ny)=L$.

In this work, b , is chosen as 0.75, 0.25 and 0.075 for numerical runs of $L=2$, 4 and 12, respectively. Numerical runs with $b=1.0$ for $L=2$ and $b=0.75$ for $L=4$ are also made for the case of an initial parabolic velocity profile. The grid arrangements in Y -direction for three different jet-to-plate spacings are listed in Tables 8.3, 8.4 and 8.5 for $L=2$, 4 and 12, respectively. A total of 25 nodes are used in Y -direction ($ny=25$) throughout all the numerical runs. Sample runs with $ny=17$ for $L=2$ and 4, and also with $ny=33$ for $L=12$ are only used for the purpose of testing the

accuracy of the numerical solutions using a particular grid network.

8.2 METHOD OF SOLUTION

The finite-difference equations used to discretize the governing equations and the associated boundary conditions shown in Chapter 7 constitute a system of strongly non-linear algebraic equations. For a $n_x \times n_y$ grid network, there are $(n_x-2) \times (n_y-2)$ algebraic equations for each of the three variables, ψ , Ω and C making a total of $3 \times (n_x-2) \times (n_y-2)$ equations to be solved. Because of the difficulty in solving a strongly non-linear system of equations, a linear algorithm is used such that the non-linear coefficients are updated periodically. The Gauss-Seidel iteration method coupled with the conventional successive over relaxation (SOR) method is used. This method has been established that an optimum relaxation factor exists which yields the maximum rate of convergence for linear problems. However, for a non-linear problem the relaxation factor varies not only from node to node but also with every iteration. An estimation of this relaxation factor is not worthwhile from a computational efficiency point of view. In such cases a constant value is used which is chosen based on numerical experimentation. In this work, the proper relaxation factors for the stream-function and

the concentration are 1.7 and 0.7, respectively. While for the vorticity, the relaxation factor is in the range of 0.1 to 0.4.

A modified scheme of calculations, presented by Wilkes (100) is used during the iteration procedure. This modified scheme has been observed by Masliyah and Nandakumar (49) to have a stabilizing effect on the convergence characteristics and it is twice as fast as the conventional SOR method. The depiction of this scheme is shown in Figure 8.1. The grid network is divided into two subgrids. The circles refer to subgrid 1 and the crosses refer to subgrid 2. The iteration is carried out in two steps, one subgrid being covered first and the other next. In the first half of iteration, the nodes of the subgrid 1 are computed using the neighbouring four nodes of the subgrid 2 as given by Equations 7.15 and 7.20, together with

$$S_n^{(1)}(i,j) = S_{n-1}^{(1)}(i,j) + w [S_n^{(2)}(i,j) - S_{n-1}^{(1)}(i,j)] \quad (8.2)$$

where $S_n^{(1)}(i,j)$ is the value of $S(i,j)$ (represented variables Ω , Ψ and C) at the n th iteration belonging to subgrid 1, $S_n^{(2)}(i,j)$ is the value of $S(i,j)$ computed using the four neighbouring nodes of subgrid 2 and w is a constant relaxation factor. Therefore, all the nodes in subgrid 1 are computed first and only points belonging to subgrid 2 are used.

o subgrid 1
x subgrid 2

FIGURE 8.1 : SUBGRIDS USED FOR THE ITERATIVE SCHEME

In the next half of iteration, nodes of subgrid 2 are evaluated using the neighbouring four nodes which belong to subgrid 1. The values of these four nodes in subgrid 1 computed in the first half iteration are used. In this second half iteration, the same relaxation factor, w , is used. This completes one full iteration.

Equations 7.4, 7.5, 7.15 and 7.16 are solved simultaneously to obtain the velocity, vorticity and stream-function distributions. The summary of the procedure used in solving the stream-function and vorticity transport equations is listed below

1. For a low Reynolds number case ($Re_b=1$), arbitrary constant values are used for the starting values of stream-function and vorticity. For the cases of higher Reynolds number the converged solution obtained for a lower Reynolds number is used as the initial starting values.
2. Any variable which is a constant is computed before entering the iteration loop.
3. Within the iteration loop, $U(i+1/2, j)$ and $V(i, j+1/2)$ are computed from Equations 7.4 and 7.5 using the guessed values of the stream-function.
4. The parameters α , β , γ and δ for upstream-weighted differencing scheme (U.W.D.S.) are then evaluated. One may notice that these parameters for central differencing scheme (C.D.S.) and upstream differencing scheme (U.D.S.) are constants and can be evaluated

before entering the iteration loop. Even for the case of U.W.D.S., the values of these parameters do not need frequent updating (69). In this work, these parameters are updated after every 50 iterations.

5. The non-linear coefficients m_1 , m_2 , m_3 , m_4 and m_5 are updated using Equation 7.16. Then the vorticity at each interior node is iterated in the manner mentioned above using Equation 7.15.
6. Next, the stream-function is iterated in the same manner at all interior nodes using Equation 7.20. This iteration is carried out three times in order to get a smooth solution in the manner suggested by Masliyah and Nandakumar (49).
7. The vorticity boundary conditions at both the impingement and confinement plates are updated. The vorticity and stream-function boundary conditions at the outflow region are also updated.
8. The modified variables are treated as improved guesses and steps 3 to 7 are then repeated until the process satisfied specified convergence criteria.

One cycle for steps 3 through 7 is referred to being one iteration. The convergence criterion is tested at the end of each iteration.

It is found that a relatively large number of iterations is required for a converged solution. For example, for $Re_b = 100$ and $L = 4$, 1353 iterations are needed to obtain the converged solution. In this case, the converged

solution of $Re_b=1$ and $L=4$ is used as the initial guess. The CPU time used for this run is approximately 110 s on Amdahl 470/V8 computer.

After the converged solutions of vorticity and stream-function are obtained, the velocity components are evaluated at each interior node using Equations 7.22 and 7.23. In addition, an important variable, the local skin friction factor, is evaluated along the impingement plate from the flow field. The local skin friction factor, C_f , is defined as

$$C_f = \tau_s / (0.5 \rho \bar{v}_j^2) \quad (8.3)$$

where ρ is the density of air and τ_s is the shear stress at the impingement plate. The shear stress at the impingement plate ($y=h$) is given by

$$\tau_s = - \left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \right) \Big|_{y=h} \quad (8.4)$$

Since the impingement plate is impermeable, implies that $v=(\partial v/\partial x)=0$ at the impingement plate. Introducing the dimensionless variables of Equation 6.6 and combining Equations 8.3 and 8.4, yields

$$C_f = - \frac{2}{Re_b} \left(\frac{\partial U}{\partial Y} \right) \Big|_{Y=L}$$

$$C_f = - \frac{2}{Re_b} \Omega \Big|_{Y=L} \quad (8.5)$$

By using Equation 8.5, the local skin friction factor can then be evaluated from the vorticity at the impingement plate and the jet Reynolds number.

The transport equation of the swelling agent is solved to obtain the concentration distribution. The procedure is mainly the same as mentioned above except in this case the velocity components are known, therefore the coefficients m_1 , m_2 , m_3 , m_4 , and m_5 do not vary with iteration. In other words, the system of algebraic equations to be solved is linear.

After the converged solution of concentration is obtained, the bulk flow concentration is evaluated. The bulk flow concentration, c_b , is defined as

$$c_b = \left(\int_0^h u c \, dy \right) / (\bar{u} \cdot h) \quad (8.6)$$

where \bar{u} is the average velocity in the outflow region and is equal to $0.5\bar{v}_j b/h$ for the jet system in this work. Introducing the dimensionless variables of Equation 6.6, yields

$$c_b = 2 \int_0^L U C \, dY \quad (8.7)$$

In addition, the local Sherwood number is also evaluated

along the impingement plate from the concentration field. The definitions of the Sherwood number are given in Equations 5.1 and 5.2. Rewriting the definitions of the local mass transfer coefficients k and k' in Equations 5.3 and 5.4 using ideal gas law and Dalton's law, yields

$$N = k (c_g - c_l) Mw \quad (8.8)$$

$$\text{and } N = k' (c_g - c_g) Mw \quad (8.9)$$

According to Fick's law, the mass transfer of swelling agent from the impingement plate is described by

$$N = -D Mw \left. \frac{\partial c}{\partial y} \right|_{y=h} \quad (8.10)$$

Introducing the dimensionless variables of Equation 6.6 and combining Equations 8.8 and 8.10, and also Equations 8.9 and 8.10, yield

$$Sh_b = - \left. \frac{\partial C}{\partial Y} \right|_{Y=L} \quad (8.11)$$

$$Sh'_b = - \left. \frac{\partial C}{\partial Y} \right|_{Y=L} / (C_g - C_g) \quad (8.12)$$

By using Equations 8.11 and 8.12, the local Sherwood numbers can then be evaluated from the gradient of concentration at

the impingement plate.

8.3 CONVERGENCE CRITERION

Convergence of the numerical results is assumed when the maximum absolute difference between two consecutive iterations, defined as

$$\epsilon = \max_{i,j} |S_n(i,j) - S_{n-1}(i,j)| \quad (8.13)$$

is less than 10^{-4} for vorticity and stream-function, and 10^{-6} for concentration. The suitability of these convergence criteria is confirmed by numerical experimentation. Once the convergence criterion is met, further iterations have no significant effect on the local skin friction factor and local Sherwood number along the impingement plate.

8.4 OUTLINE OF THE COMPUTER PROGRAM

A main program with four subroutines is used in the numerical study. The first subroutine, ITER1, is used to compute the stream-function and the vorticity distributions. After the converged solutions of the stream-function and the vorticity are obtained from ITER1, the second subroutine, CALC1; is used to compute the velocity components at all the nodes instead of midway points. In this subroutine, the

local skin friction factor along the impingement plate is also evaluated. The third subroutine, ITER2, is used to compute the concentration distribution. After the converged solution of the concentration is obtained from ITER2, the fourth subroutine, CALC2, is used to compute the bulk flow concentration and the local Sherwood number along the impingement plate.

Only the computational procedure of subroutine ITER1 is shown in Figure 8.2 in the form of a flow diagram. The computational procedure of subroutine ITER2 is very similar to that of subroutine ITER1. The computational procedures of subroutines CALC1 and CALC2 are straightforward calculations only.

The program is listed in Appendix F, together with a typical output listing.

FIGURE 8.2 : COMPUTATIONAL FLOW DIAGRAM FOR SUBROUTINE ITER1

9. VALIDITY OF THE NUMERICAL SOLUTION

Accuracy of numerical solution is dependent on the choice of grid network and differencing scheme. The influences of grid network and differencing scheme on the numerical solution are studied separately in Sections 9.1 and 9.2, respectively.

9.1 INFLUENCE OF GRID NETWORK

The influences of the grid network on the numerical solutions for three different jet-to-plate spacings ($L=2, 4$ and 12) are studied separately.

For $L=2$, numerical runs for different Reynolds number using two different grid networks of 55×17 and 55×25 with $b_0=0.75$ are made. The differencing scheme used is U.W.D.S.. The skin friction factor evaluated along the impingement plate from these two grid networks are plotted in Figure 9.1 for $Re_b=100, 200, 300$ and 400 with an initial parabolic velocity profile. There is little difference between the values of $C_f Re_b$ obtained from the two different grid networks for $Re_b=100$ and 200 . For $Re_b=300$ and 400 , disagreement between the values of $C_f Re_b$ obtained from these two grid networks is found only in a small region near the stagnation flow region with a maximum difference of

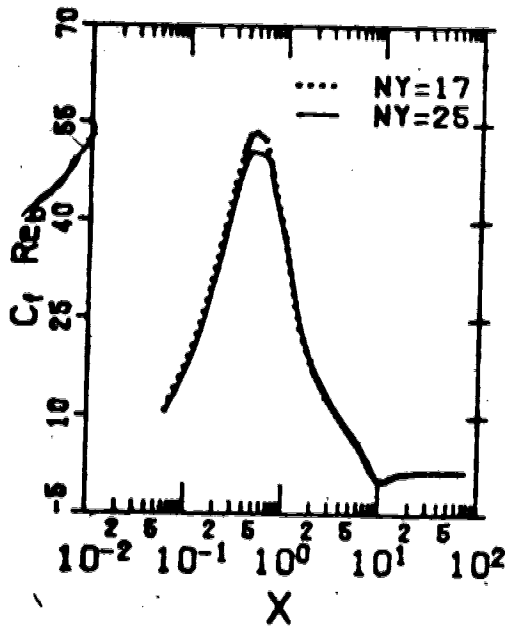

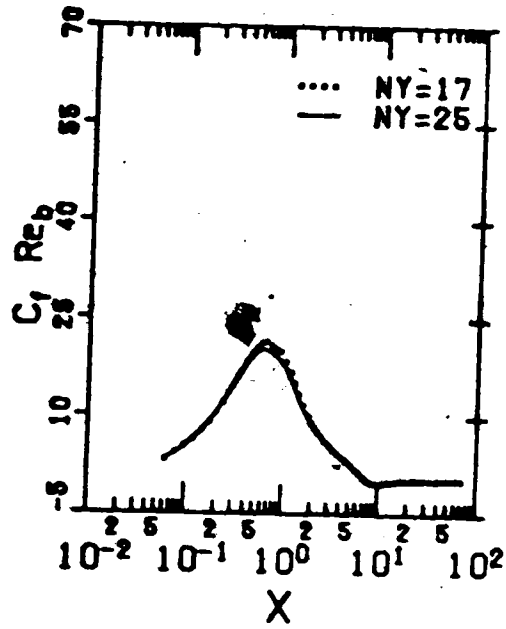

(a) $Re_b = 100$ (b) $Re_b = 200$ (c) $Re_b = 300$ (d) $Re_b = 400$

FIGURE 9.1.: INFLUENCE OF GRID NETWORK ON THE NUMERICAL SOLUTIONS FOR L=2 USING U.W.D.S.

approximately 5% only. Therefore, a conclusion can be made that both grid networks are suitable for the computation for the case of $L=2$. In all subsequent computations for the case of $L=2$, the network of 55×25 with the smaller grid size is used.

For $L=4$, numerical runs for different Reynolds number using two grid networks of 55×17 and 55×25 with $b_0=0.25$ are made. Again, the differencing scheme used is U.W.D.S.. The skin friction factors evaluated along the impingement plate from these two networks are plotted in Figure 9.2 for $Re_b=100, 200, 300$ and 400 with an initial parabolic velocity profile. There is little difference between the values of $C_f Re_b$ obtained from these two grid networks for $Re_b=100$. But for the $Re_b=200, 300$ and 400 , disagreement is found mainly in the stagnation flow region with the worst case occurred for $Re_b=400$. The maximum differences are 6%, 15% and 20% for $Re_b=200, 300$ and 400 , respectively. Therefore, the two grid network are only suitable when $Re_b \leq 200$. But the network of 55×17 with the coarser grid size is no longer suitable for high Reynolds numbers. In all subsequent computations for the case of $L=4$, the network of 55×25 with the finer grid size is used.

From the conclusion above, it is obvious that a grid network of 55×17 will be too coarse for the case of $L=12$ because of the large jet-to-plate spacing. For $L=12$, numerical runs for $Re_b=100, 200$ and 300 using two different grid networks of 67×25 and 67×33 , and for $Re_b=400$ using

(a) $Re_b = 100$

(b) $Re_b = 200$

(c) $Re_b = 300$

(d) $Re_b = 400$

FIGURE 9.2 : INFLUENCE OF GRID NETWORK ON THE NUMERICAL SOLUTIONS FOR $L=4$ USING U.W.D.S.

two grid networks of 69×25 and 69×33 are made. For all these grid networks, the value of b , is chosen to be 0.075. The differencing scheme used is U.W.D.S.. Unfortunately, for $Re_b=400$, no converged solution can be obtained using the grid network of 69×33 . The skin friction factors evaluated along the impingement plate from the two grid networks of 67×25 and 67×33 are plotted in Figure 9.3 for $Re_b=100$, 200 and 300 with an initial parabolic profile. There is again little difference between the values of $C_f Re_b$ obtained from these two grid networks for $Re_b=100$. For the cases of $Re_b=200$ and 300, disagreement is found mainly in the stagnation flow region. In all subsequent computations for the case of $L=12$, the network of 67×25 or 69×25 with the coarser grid size is used simply because a converged solution can be obtained from this network for all Reynolds numbers. It is noted that in order to obtain a converged solution for the case of $L=12$, a little sacrifice on the accuracy of the numerical solution in the stagnation flow region cannot be avoided.

For a particular numerical run in this work, only one grid network is used. These grid networks for different jet-to-plate spacing and Reynolds number are listed in Table 8.1.

The influence of grid arrangement on the numerical solution is not as obvious as that of the grid network. For $L=2$, numerical solutions of flow and concentration fields evaluated from grid network of 55×25 with $b=0.75$ and 1

(a) $Re_b = 100$ (b) $Re_b = 200$ (c) $Re_b = 300$

FIGURE 9.3 : INFLUENCE OF GRID NETWORK ON THE NUMERICAL SOLUTIONS FOR $L=12$ USING U.W.D.S.

are nearly the same for all Reynolds numbers. The variables such as local skin friction factor and local Sherwood number evaluated along the impingement plate from the two different grid arrangements are nearly the same for all Reynolds numbers. For $L=4$, numerical solutions of flow and concentration fields evaluated from grid network of 55×25 with $b_x=0.25$ and 0.75 are also nearly the same for all Reynolds numbers. Only in evaluating the local skin friction factor and the local Sherwood number along the impingement plate, this disagreement in these two arrangements is found near the stagnation flow region. In this work, the variables evaluated from the grid network of 55×25 with $b_x=0.75$ are used because these variables should be more accurate due to the finer grid spacings adjacent to the impingement plate. For $L=12$, only one grid arrangement with $b_x=0.075$ is used for both the grid network of 67×25 and the grid network of 69×25 .

9.2 INFLUENCE OF DIFFERENCING SCHEME

The influence of differencing scheme on the numerical solution is studied briefly for the case of $L=2$. To conserve on the computational costs, a grid network of 55×17 with $b_x=0.75$ is used. This grid network was found in Section 9.1 to be suitable for the computations for the case of $L=2$. Numerical runs with an initial parabolic velocity profile

are made using three different differencing schemes (C.D.S., U.D.S. and U.W.D.S.). Converged solutions are obtained for all runs using U.D.S. and U.W.D.S., while the converged solutions can only be obtained for $Re_b \leq 200$ using C.D.S..

The comparisons of the converged local skin friction factors obtained from the numerical runs using the three differencing schemes are shown in Figure 9.4 for $Re_b = 100, 200, 300$ and 400 . It is found that the differencing scheme has little effect on the solutions except in a small region near the stagnation flow region. In the range of disagreement, some of the observations by Raithby and Torrance (69) on comparison of differencing schemes are confirmed. According to their study, solutions from the C.D.S. are the most accurate solutions compared to the exact solutions as long as converged solutions can be found. Although U.D.S. gives converged solutions for all cases, in the range where C.D.S. can be used, U.D.S. is inferior. Furthermore, U.W.D.S. also gives converged solutions for all cases and the solutions obtained from U.W.D.S. are better than those from U.D.S.. These observations are confirmed as shown in Figures 9.4(a) and 9.4(b) by assuming the solutions from the C.D.S. are the most accurate solutions in this work. The disagreements between the solutions of C.D.S. and U.D.S. are the largest in both cases which indicate that the solutions of U.D.S. are worse than those of U.W.D.S..

Since the solutions of C.D.S. are the best, it is logical to use C.D.S. as long as it gives a converged

(a) $Re_b = 100$ (b) $Re_b = 200$ (c) $Re_b = 300$ (d) $Re_b = 400$

FIGURE 9.4 : INFLUENCE OF DIFFERENCING SCHEME ON THE NUMERICAL SOLUTIONS FOR $L=2$ USING A GRID NETWORK OF 55×17

solution. But unfortunately, the numerical solutions obtained by using C.D.S. for the chosen grid network of 55 x 25 did not give a converged solution. Therefore, in all subsequent numerical computations, only U.W.D.S. and U.D.S. are used while U.W.D.S. is expected to give a better solution for all cases.

10. RESULTS AND DISCUSSIONS

Experimental and numerical results for a confined air jet are both discussed in this chapter. Results are given for two different categories: flow characteristics and mass transfer characteristics. Flow characteristics can only be studied numerically in this work. While mass transfer characteristics are studied both experimentally and numerically. Experimental results in this case are used to verify the numerical predictions of the two-dimensional model.

10.1 FLOW CHARACTERISTICS

The flow behavior for different jet Reynolds numbers, jet-to-plate spacings and nozzle exit velocity profiles are studied numerically. A listing of the numerical runs is given in Appendix G. In this section, only the numerical results using the upstream-weighted differencing scheme (U.W.D.S.) are presented.

10.1.1 STREAMLINE CONTOURS

The flow field is studied qualitatively by observing the streamline contours from the numerical solution. The contours of the stream-function for $L=2$, 4 and 12 with an

initial parabolic velocity profile are shown in Figures 10.1, 10.2 and 10.3, respectively. The contours of the stream-function for $L=4$ with an initial flat velocity profile are shown in Figure 10.4. The jet nozzle exit is at the upper left hand corner with the main flow travelling from left to right. The upper horizontal streamline represents the confinement plate and the lower horizontal streamline represents the impingement plate.

For the case of an initial parabolic profile, in general, a primary vortex rotating in the counter-clockwise direction is found near the confinement plate with its size increasing with jet Reynolds number. With the exception of the case of low Reynolds numbers for $L=2$, a second vortex rotating in clockwise direction is found near the impingement plate. This secondary vortex is much smaller than the first one in size and it is also weaker in terms of rotational intensity. The variation of the location of the vortex centre with the jet Reynolds number is shown in Figure 10.5. It can be observed that the centers of both the primary and secondary vortices move downstream with increase in Reynolds number.

For the case of an initial flat profile, only the primary vortex is found near the confinement plate. This vortex behaves as the primary vortex for the case of an initial parabolic profile except it is smaller in size and also weaker in terms of rotational intensity. The variation of the location of the primary vortex centre with the jet

Reynolds number is shown in Figure 10.6. Again, the primary vortex move downstream with increase in Reynolds number.

A blow-up of the contours of stream-function for $L=2$, 4 and 12 with an initial parabolic profile are shown in Figures 10.7, 10.8 and 10.9, respectively, while that for $L=4$ with an initial flat profile is shown in Figure 10.10. The centre of the jet nozzle exit is at the upper left hand corner with the main flow travelling from left to right. The corresponding values of stream-function for each streamline numbered are listed as follows:

1. $\psi = 0$
2. $\psi = -0.09$
3. $\psi = -0.21$
4. $\psi = -0.33$
5. $\psi = -0.45$
6. $\psi = -0.5$
7. $\psi < -0.5$ (circulating flow)
8. $\psi < -0.5$ (circulating flow)

where streamline #1 represents the axis of symmetry and the impingement plate, and streamline #6 represents the confinement plate and the outermost free streamline of the submerged jet.

The spreading effect of the jet under the the influence of the confinement plate can be studied from the outermost free streamline (#6) in Figures 10.7, 10.8, 10.9 and 10.10.

FIGURE 10.10 : CONTOURS OF STREAM-FUNCTION FOR $L=4$ NEAR THE STAGNATION POINT WITH AN INITIAL FLAT VELOCITY PROFILE

The jet contracts slightly below the nozzle exit for an initial parabolic profile, while for an initial flat profile, the jet expands continuously. Similar spreading effects were observed by Van Heiningen et. al. (96) in their study of semi-confined air jet with different initial velocity profiles. The explanations of these spreading behaviors have already been given in Section 2.1.2.

From the outermost free streamlines in Figures 10.8 and 10.10, it is found that the free streamline is significantly closer to the impingement plate for an initial parabolic profile. This is due to the higher momentum of the initial parabolic profile jet. Same observation has also been made by Van Heiningen et. al. (96).

10.1.2 AXIAL VELOCITY PROFILE

Typical axial velocity profiles at various positions in Y-direction for different jet Reynolds numbers for a confined jet are shown in Figures 10.11, 10.12 and 10.13 for $L=2, 4$ and 12 with an initial parabolic profile, and for $L=4$ with an initial flat profile in Figure 10.14. In all cases the initial velocity at nozzle exit ($Y=0$) are plotted. The axial velocities are normalized by the centerline axial velocity at the nozzle exit, $(V_1)|_{x=0}$.

The spreading of the jet as it approaches the impingement plate ($Y=L$) is obvious for all cases. This spreading is more dramatic for the jet with an initial flat profile than that with an parabolic profile.

FIGURE 10.14 : AXIAL VELOCITY PROFILES FOR $L=4$ WITH AN INITIAL FLAT VELOCITY PROFILE

The decay of the centerline axial velocity, $V|_{x=0}$, originating from a parabolic velocity profile at nozzle exit for different jet Reynolds numbers is shown in Figures 10.15, 10.16 and 10.17 for $L=2, 4$ and 12 , respectively. The centerline axial velocity increases slightly with axial distance from the nozzle exit due to the contraction of the jet, and then decreases slightly due to the spreading of the jet. Not until the jet flow is about one slot width away from the impingement plate, does the centerline axial velocity decrease rapidly to zero at the stagnation point. In other words, the centerline axial velocity is affected by the presence of the impingement plate at a distance only one slot width from the plate.

The effect of Reynolds number on the decay of the centerline axial velocity for different jet-to-plate spacings can also be studied from Figures 10.15, 10.16 and 10.17. For all cases, the centerline axial velocity decays less rapidly at higher Reynolds numbers. This is mostly due to the more penetration of the jet with higher Reynolds number into the surrounding fluid.

In the stagnation flow region, the centerline axial velocity is linearly proportional to the axial distance away from the stagnation point, $(L-Y)$, as can be noted from Figures 10.15, 10.16 and 10.17. A similar observation has been made by Schlichting (78) for unconfined submerged jet. Introducing the dimensionless variables in Equation 6.6 into Equation 2.5, yields

FIGURE 10.15 : DECAY OF CENTERLINE AXIAL VELOCITY FOR $L=2$ WITH AN INITIAL PARABOLIC VELOCITY PROFILE

FIGURE 10.16 : DECAY OF CENTERLINE AXIAL VELOCITY FOR $L=4$ WITH AN INITIAL PARABOLIC VELOCITY PROFILE

FIGURE 10.17 : DECAY OF CENTERLINE AXIAL VELOCITY FOR $L=12$ WITH AN INITIAL PARABOLIC VELOCITY PROFILE

$$(v/v_j)|_{x=0} = a_c [L / (v_j)|_{x=0}] [1 - (Y/L)] \quad (10.1)$$

The values of a_c can be easily evaluated from the slopes of all the curves of Figures 10.15, 10.16 and 10.17 for different Reynolds numbers and jet-to-plate spacings. The values of a_c are shown in Table 10.1. A plot of a_c versus L is shown in Figure 10.18. The least square fitted curves for different Reynolds numbers are:

$$\begin{aligned} a_c &= 2.56 L^{-0.111} && \text{for } Re_b = 100 \\ a_c &= 2.65 L^{-0.111} && \text{for } Re_b = 200 \\ a_c &= 2.65 L^{-0.111} && \text{for } Re_b = 300 \\ a_c &= 2.67 L^{-0.111} && \text{for } Re_b = 400 \end{aligned} \quad (10.2)$$

Equation 10.2 shows that the decay of centerline axial velocity in the stagnation flow region for a confined jet with initial parabolic profile depends not only on the Reynolds number but also on the jet-to-plate spacing.

The decay of the centerline axial velocity originating from a flat velocity profile at nozzle exit for different Reynolds numbers is shown in Figure 10.19 for $L=4$. The centerline axial velocity decreases rapidly near the nozzle exit. This is due to the large spreading effects in this region. The decrease of centerline axial velocity becomes more gentle when the jet flow is further away from the nozzle exit. Not until the presence of the impingement plate is sensed, the centerline axial velocity does decrease

rapidly to zero at the stagnation point. The decay of the centerline axial velocity for this case is nearly independent of the Reynolds number.

In the stagnation flow region, the centerline axial velocity is linearly proportional to the axial distance from the stagnation point, $(L-Y)$, as can be noted from Figure 10.19. The values of a , evaluated from the slopes of all curves of Figure 10.19 are approximately equal to 0.38 for all Reynolds numbers.

10.1.3 STREAMWISE VELOCITY PROFILE

The developments of typical streamwise velocity profiles with streamwise distance, X , for different Reynolds numbers and jet-to-plate spacings from a confined jet with initial parabolic velocity profile are shown in Figures 10.20-10.31. Those from a confined jet with initial flat velocity profile are shown in Figures 10.32-10.35. The dotted line in the plots represents the fully developed velocity profile for the particular case. The confinement plate is located at $(L-Y)/L=1$ and the impingement plate is located at $(L-Y)/L=0$.

For an individual streamwise velocity profile at a given streamwise distance, the streamwise velocity, U , increases from zero at the impingement plate to a maximum, U_{max} , within a thin layer. Such layer is referred to as the viscous boundary layer in the stagnation flow region. Outside the viscous boundary layer, the streamwise velocity

 VELOCITY PROFILE**

decreases as the axial distance from the impingement plate increases. In some streamwise locations, the streamwise velocity becomes negative near the confinement plate. These negative velocities are caused by the inflow of the primary vortex induced by the confinement plate.

The thickness of the viscous boundary layer in stagnation flow region, σ_s , is defined as the distance from the impingement plate where the streamwise velocity reaches 99% of U_{max} and can be determined from the streamwise velocity profile. The values of σ_s for $L=2$ and 4 are given in Table 10.2. It is found that for a given Reynolds number and jet-to-plate spacing, the value of σ_s remains quite constant in the stagnation flow region. The values of σ_s for $L=12$ cannot be accurately determined due to the coarser grid arrangement used near the impingement plate for this case.

The variation of the maximum value of the streamwise velocity at individual streamwise location, U_{max} , with streamwise distance, X , in the region of $X \leq 5$ is shown in Figures 10.36-10.38 for the case of parabolic profile and in Figure 10.39 for the case of flat profile. In the stagnation flow region, U_{max} is linearly proportional to the distance from the stagnation point due to the transformation of the axial momentum into the streamwise momentum. A similar observation has been made by Schlichting (78) for unconfined submerged jet. Introducing the dimensionless variables in Equation 6.6 into Equation 2.6 and choosing U_{max} instead of U , yields

FIGURE 10.39 : VARIATION OF U_{max} WITH STREAMWISE DISTANCE FOR $L=4$ WITH AN INITIAL FLAT VELOCITY PROFILE

$$U_{\max} = a, X \quad (10.3)$$

The values of $a,$ can be easily evaluated from the slopes of all the curves of Figures 10.36-10.39 for different Reynolds numbers and jet-to-plate spacings. The values of $a,$ for the case of parabolic profile are given in Table 10.3. Comparing the values of $a,$ in Table 10.3 to those in Table 10.1, agreement within 2.5% is obtained. The values of $a,$ for the case of flat profile are approximately equal to 0.4 for all Reynolds numbers. This value is within 5% agreement with that evaluated in Section 10.1.2.

The thickness of the viscous boundary layer in the stagnation flow region, $\sigma,$ can also be evaluated from $a,$ using Equation 2.9,

$$\sigma./b = 2.38 / (a, Re_b)^{0.5} \quad (10.4)$$

The values of $\sigma./b$ evaluated from Equation 10.4 are compared to those in Table 10.2 in Figure 10.40. The data points fall fairly closely on the zero error straight line with a slope of unity. It is noted that Equation 10.4 was obtained by Schlichting (78) in his study of unconfined submerged jet. Such a good agreement of the data points indicates that the presence of confinement plate has little effect on the flow in the stagnation flow region.

Due to the exchange of momentum with the circulating fluid in the primary vortex, U_{\max} which increases with X in

the stagnation flow region must eventually reaches a maximum and decreases in the wall jet region. The location of the maximum of U_{max} is a function of Reynolds number and jet-to-plate spacing as can be noted in Figures 10.36-10.39. In the wall jet region, flow separation is observed along the impingement plate for the case of parabolic profile with the exception of the cases of low Reynolds numbers for $L=2$. The locations where the flow starts to separate from the impingement plate are given in Table 10.4. For the case of flat profile, no flow separation along the impingement plate is observed.

The decay of U_{max} for different Reynolds numbers in the wall jet region are plotted as $\log(U_{max})$ versus $\log(X)$ in Figures 10.41-10.43 for a jet with an initial parabolic profile, and in Figure 10.44 for a jet with an initial flat profile. Obviously, the prediction by Glauert (25) using Equation 2.11 in his study of the decay of maximum streamwise velocity in the wall jet region originating from an unconfined submerged jet cannot be applied here. For a confined air jet, the flow which leaves the stagnation flow region is strongly influenced by the presence of the primary vortex as shown in Figures 10.1-10.4. U_{max} decreases more gently after it reaches its maximum value. As soon as the fluid flows pass the centre of the primary vortex, the flow expands and U_{max} decreases rapidly. Eventually, U_{max} approaches the value of that of the fully developed profile between two parallel plates. The lower the Reynolds number

and the smaller the jet-to-plate spacing, the shorter the streamwise distance needed to approach fully developed flow.

10.1.4 IMPINGEMENT PLATE SKIN-FRICTION FACTOR

The study of local skin-friction factor along the impingement plate provides information of the local shear stress on the plate. The local skin-friction factor is defined by Equation 8.3. For fully developed flow between two parallel plates, the skin-friction factor can be evaluated by setting $Y=L$ in Equation 6.28 and substituting into Equation 8.5 to give

$$(C_f)_{fd} = 6 / (Re_b L^2) \quad (10.5)$$

A plot of $C_f Re_b$ versus X for a given jet-to-plate spacing leads to the collapse of all curves for different Reynolds numbers to a single curve in the region far away from the stagnation flow region where the influence of the impinging flow is not sensed. Individual curves for different jet-to-plate spacings approach the value of $6/L^2$ which is equal to 1.5, 0.375 and 0.0417 for $L=2, 4$ and 12 respectively. Variations of $C_f Re_b$ versus X are shown in Figures 10.45-10.47 for a jet with an initial parabolic velocity profile and for a jet with an initial flat velocity profile in Figure 10.48. The general variation pattern of the local skin-friction factor is that it increases sharply from zero at the stagnation point to a maximum value in a

FIGURE 10.45 : VARIATION OF LOCAL SKIN-FRICTION FACTORS FOR $L=2$ WITH AN INITIAL PARABOLIC VELOCITY PROFILE

FIGURE 10.46 : VARIATION OF LOCAL SKIN-FRICTION FACTORS FOR $L=4$ WITH AN INITIAL PARABOLIC VELOCITY PROFILE

FIGURE 10.47 : VARIATION OF LOCAL SKIN-FRICTION FACTORS FOR L=12 WITH AN INITIAL PARABOLIC VELOCITY PROFILE

FIGURE 10.48 : VARIATION OF LOCAL SKIN-FRICTION FACTORS FOR $L=4$ WITH AN INITIAL FLAT VELOCITY PROFILE

short distance and then decreases with the streamwise distance, X . The location of the maximum value is found at $X=0.625$ for both $L=2$ and 4 , and at $X=1.25$ for $L=12$ for a jet with an initial parabolic velocity profile. For a jet with an initial flat velocity profile, the maximum value of $C_f Re_b$ is located approximately at $X=1.25$ for $L=4$.

For impinging flow, the skin-friction factor is proportional to the Reynolds number to the power of -0.5 . A plot of $0.5C_f Re_b^{0.5}$ versus X for different Reynolds numbers is made so that all the curves will collapse into one general curve in the stagnation flow region. Such plots are shown in Figures 10.49-10.51 for the case of parabolic profile and in Figure 10.52 for the case of flat profile.

For the case of parabolic velocity profile, a general curve cannot be obtained in the range of Reynolds numbers studied. But there is a trend for $L=2$ and 4 that a general curve may be obtained if the Reynolds number becomes higher. For $L=12$, the value of $0.5C_f Re_b^{0.5}$ decreases as Reynolds number increases indicating that the normalization of the local skin-friction factor with $Re_b^{0.5}$ may be over-corrected the effect of Reynolds number. This is also probably due to the grid effects as mentioned in Chapter 9 for the case of $L=12$, resulting in the inaccuracy of the numerical results in the stagnation flow region. The numerical results computed by Van Heiningen et. al. (96) for a semi-confined two-dimensional jet are also included in Figure 10.50. Their results are at $Re_b=100$ and 450 for $L=4$. There is good

L = 2

agreement between their results and those of this work.

For the case of flat velocity profile, the collapse of the curves for different Reynolds numbers to nearly a single curve in the stagnation flow region can be noted in Figure 10.52. The curve for $Re_b=100$ deviates the most from the general curve probably because the Reynolds number in this case is simply not high enough as mentioned above. For $Re_b=100$, relatively significant retardation of the submerged jet is found on the way from the nozzle exit to the impingement plate. Also included in Figure 10.52 are the theoretical results of Miyazaki and Silberman (58) for an unconfined two-dimensional jet. Their results which are totally independent of Reynolds number and jet-to-plate spacing ($L \geq 1.5$), are consistently higher than those of this work. The disagreement is mainly due to the error introduced by their assumption of potential flow outside the viscous boundary layer.

10.2 MASS TRANSFER CHARACTERISTICS

A measure of local mass transfer is represented by the evaluation of local Sherwood number along the impingement plate. Local Sherwood numbers along the impingement plate are evaluated both experimentally and numerically. Experimental and numerical results of local Sherwood number are first discussed separately, and finally a comparison of

these results is made.

10.2.1 EXPERIMENTAL RESULTS

For a confined two-dimensional jet, experimental runs for various experimental variables such as the Reynolds number, jet-to-plate spacing and duration of the mass transfer experiment are made. The range of these experimental variables are listed below

1. Jet-to-plate spacing: $L=2, 4, 12$
2. Reynolds number: $Re_b=100, 200, 306, 400$
3. Duration of mass transfer experiment: $T=120, 180, 240, 360, 480s$
4. Type of velocity profile at nozzle exit: parabolic

A listing of the experimental runs together with the experimental variables and operating conditions are given in Appendix E.

The "frozen fringe" pattern for run no. J021-3B for $L=2$, $Re_b=100$ and $T=180s$ is shown in Plate 10.1a. The "frozen fringe" pattern for run no. J021-6A for $L=2$, $Re_b=100$ and $T=360s$ is shown in Plate 10.1b. These fringes are interpreted as contours of equal mass transfer rate. The local mass transfer rate can be observed in Plate 10.1 to decrease monotonically from the stagnation flow region. It will be shown later that only for this case of $L=2$ and $Re_b=100$, a local minimum and a local maximum in local mass transfer rate is not observed.

(a) $T = 180s$ (b) $T = 360s$

PLATE 10.1 : CONTOURS OF EQUAL MASS TRANSFER RATE FOR
A CONFINED TWO-DIMENSIONAL JET
($Re_b=100$, $L=2$)

The "frozen fringe" pattern for run no. J023-2B for $L=2$, $Re_b=306$ and $T=120s$ is shown in Plate 10.2a. The "frozen fringe" pattern for run no. J023-4B for $L=2$, $Re_b=306$ and $T=240s$ is shown in Plate 10.2b. By observing the contours of equal mass transfer rate, the presence of a local minimum and a local maximum in the mass transfer rate can easily be observed in the outer region. The presence of local extrema in the mass transfer rate is observed for all the experimental runs in this work except for the case of $Re_b=100$ and $L=2$ mentioned above.

In Plate 10.2, it is of interest to note that the fringes exhibit spanwise fluctuations at the two ends and the outer region. The intensity of these fluctuations increases with Reynolds number and the fluctuation patterns are very much the same for $Re_b=306$ and 400. This phenomenon was explained by Masliyah and Nguyen (53). The fluctuations are attributed to the presence of very slight roughness at the edge of the aluminum slot tube.

For $L=12$, a typical "frozen fringe" pattern is shown in Plate 10.3 for run no. J123-2B with $Re_b=306$ and $T=120s$. The presence of local extrema in the mass transfer rate is again observed. But in this case the fringes are too wide for analysis. In other words, the local mass transfer rates in this outer region are too small to measure. Therefore, no quantitative study in the outer region for all the experimental runs of $L=12$ is made.

(a) $T = 120s$ (b) $T = 240s$

PLATE 10.2 : CONTOURS OF EQUAL MASS TRANSFER RATE FOR
A CONFINED TWO-DIMENSIONAL JET
($Re_D=306$, $L=2$)

**PLATE 10.3 : CONTOURS OF EQUAL MASS TRANSFER RATE FOR
A CONFINED TWO-DIMENSIONAL JET
($Re_D=306$, $L=12$)**

Due to the presence of local extrema in mass transfer rate, more complicated "frozen fringe" pattern for a confined two-dimensional jet is observed. In such a case, in order to determine the local fringe order, the method of zero fringe identification used by Masliyah and Nguyen (51) is no longer applicable. Therefore, real time holographic interferometry is used. In order to determine the fringe order of the "frozen fringe" pattern, a duplicate experimental run is made using real time holography interferometric technique.

As soon as the local fringe order is known, local Sherwood number, Sh_b , defined by Equation 5.1 can be easily determined by using Equation 5.9. In this work, only the local Sherwood numbers on the centerline along the streamwise direction are measured. For each experimental run, the variation of local Sherwood number, Sh_b , with dimensionless streamwise distance, x/b or X , are determined. Experimental results of local Sherwood number, Sh_b , and dimensionless streamwise distance, x/b , are given in Appendix E.

Variation of local Sherwood number with X are shown in Figures 10.53-10.55 for $L=2, 4$ and 12 . In general, the variation pattern of the local Sherwood number can be divided into two regions. The first region is where $\log(Sh_b)$ versus $\log(X)$ is linear. The range of such a region is depended on the Reynolds number as can be observed in Figures 10.53-10.55. Regression analysis is made to obtain a

FIGURE 10.53 : VARIATION OF LOCAL SHERWOOD NUMBER WITH DIMENSIONLESS STREAMWISE DISTANCE FOR $L = 2$

FIGURE 10.54 : VARIATION OF LOCAL SHERWOOD NUMBER WITH DIMENSIONLESS STREAMWISE DISTANCE FOR $L = 4$

FIGURE 10.55 : VARIATION OF LOCAL SHERWOOD NUMBER WITH DIMENSIONLESS STREAMWISE DISTANCE OF $L = 12$

correlation for local Sherwood number with the Reynolds number and streamwise distance in this region. The second region is where the local extrema in Sherwood number occurred. For $L=12$, no local Sherwood numbers are measured in this region because the local mass transfer rates are too small to measure. For $L=2$ and 4 , although local Sherwood numbers are measured in this region, no regression analysis is attempted due to the unusual behavior of the local Sherwood number with the Reynolds number and streamwise distance in this region. While the location of the local maximum in Sherwood number shifts further away from the stagnation point when the Reynolds number increases, the value of the local maximum Sherwood number also increases with the Reynolds number.

Two regression equations are obtained from the experimental data for $L=2$ and 4 and for $L=12$. The range of data points used is within the region where $\log(\text{Sh}_D)$ versus $\log(X)$ is linear and is shown in Table 10.5. The regression analysis is made in such a way that each data point has approximately the same weighting.

The regression equation for $L=2$ and 4 is given by:

$$\text{Sh}_D = 0.34 \text{Re}_D^{0.4} X^{-0.1} \quad (10.6)$$

for $100 \leq \text{Re}_D \leq 400$, with an average error of 6.8%. A total of 685 data points are used. A plot to test the applicability of Equation 10.6 is shown in Figure 10.56. For a perfect fit

TABLE 10.5 : RANGE OF DATA POINTS USED FOR REGRESSIONS EQUATIONS

	306	X≤12	52
	400	X≤13	60

FIGURE 10.56 : TEST OF GOODNESS FIT FOR L = 2 AND 4

with zero experimental error, all data points should lie on a straight line having a slope of unity. In addition, the results obtained by Masliyah and Nguyen (53) presented by Equation 5.14 for unconfined two-dimensional jets with $L=4$ and 8 are also plotted on Figure 10.56, as a dashed line. Their data are well within the range of the experimental accuracy of this work, indicating that there is little effect of a confinement plate in the wall jet region. However, the effect of confinement plate is obvious in the outer region where the local extrema of the local Sherwood number occur.

The exponent of X , -0.78 , in Equation 10.6 is in fair agreement with the experimental findings by Masliyah and Nguyen (53) of -0.73 , and the analytical solutions by Schwarz and Caswell (82) of -0.75 . Although the exponent of Reynolds number, 0.66 , in Equation 10.6 does not agree with either study, it is within the range of their values of 0.55 and 0.75 .

The regression equation for $L=12$ is given by:

$$Sh_b = 1.34 Re_b^{0.66} X^{-0.78} \quad (10.7)$$

for $100 \leq Re_b \leq 400$, with an average error of 3.8%. A total of 195 data points are used. A plot to test the applicability of Equation 10.7 is shown in Figure 10.57. The exponent of X , -0.72 , in Equation 10.7 is approximately the same as that of $L=2$ and 4 . However, the exponent of Reynolds number,

FIGURE 10.57 : TEST OF GOODNESS FIT FOR L = 12

0.33, is less than that for $L=2$ and 4. This indicates that for $L=12$, local Sherwood number is a weaker function of Reynolds number than that for $L=2$ and 4.

10.2.2 NUMERICAL RESULTS

Local Sherwood number, Sh'_p , along the impingement plate defined by Equation 5.2 are computed numerically using Equation 8.12 for various Reynolds number, jet-to-plate spacing and type of velocity profile at the nozzle exit. The listings of all the numerical runs for $L=2, 4$ and 12 are given in Appendix G. In this section, only the numerical results using the upstream-weighted differencing scheme (U.W.D.S.) are presented.

Thermal entrance solutions with a fully developed laminar velocity profile for flow between parallel plates were obtained by McCuen (46,62) for arbitrarily prescribed wall temperature or heat flux. Due to the analogy between heat and mass transfer, entrance solutions of mass transfer with fully developed laminar flow between parallel plates can be obtained. The boundary conditions used in this work are similar to those of the fundamental solution of the third kind. The solution of the third kind corresponding to the coordinate system used in this work is listed in Table 10.6.

Therefore, a plot of $2L Sh'_p$ versus $(X/2L)/(Re_p Sc)$ for a given jet-to-plate spacing leads to a collapse of curves for the different Reynolds numbers to a general curve in the

**TABLE 10.6 : ENTRANCE SOLUTION OF THE THIRD KIND FOR

0.1	4.861
0.15	4.861
0.25	4.861
INFINITY	4.861

outflow region. The general curve approaches the fully developed value of $2L Sh'_b = 4.861$ in a manner similar to the solution curve obtained from Table 10.6. Such plots are shown in Figures 10.58-10.60 for a jet with an initial parabolic profile and in Figure 10.61 for a jet with an initial flat profile.

It is noted that in Figures 10.58-10.61, the group $(X/2L)/(Re_b Sc)$ fails to correlate the local Sherwood number for the different Reynolds numbers in the region influenced by the impinging jet. It is only good in the outflow region where the flow behavior is similar to those between two parallel plates. Furthermore, from Figures 10.58-10.61, the values of $2L Sh'_b$ approach 4.861 in a similar manner regardless of the jet Reynolds number, jet-to-plate spacing and the initial velocity profile at the nozzle exit.

The effect of Reynolds number on the local Sherwood number for different jet-to-plate spacings are shown in Figures 10.62-10.64 for the case of parabolic profile and in Figure 10.65 for the case of flat profile. The maximum local Sherwood number is found to occur at the stagnation point for all cases. The local Sherwood number remains quite constant in the stagnation flow region directly below the jet nozzle ($X \leq 0.5$), and it then decreases with distance away from the stagnation point.

For all cases with an initial parabolic profile, except the case of $L=2$ and $Re_b=100$, the local Sherwood number is found to exhibit a local minimum and a local maximum in the

FIGURE 10.64 : VARIATION OF LOCAL SHERWOOD NUMBER FOR L=12 WITH AN INITIAL PARABOLIC PROFILE

FIGURE 10.65 : VARIATION OF LOCAL SHERWOOD NUMBER FOR $L=4$ WITH AN INITIAL FLAT PROFILE

region further downstream. The locations of the extrema points are a function of Reynolds number and jet-to-plate spacing. Contours of the stream-function, shown in Figures 10.1-10.3, indicate that the presence of these extrema is attributed to flow recirculation in the region between the confinement plate and the impingement plate. In particular, Figure 10.66 compares the streamwise location of the secondary vortex centre and the streamwise location of the minimum of Sherwood number. The data points fall fairly closely on a straight line with a slope of unity. This indicates that there is a strong correlation between the streamwise location of the secondary vortex and the local minimum of the Sherwood number.

Local extrema in Sherwood number are also found for all cases with an initial flat profile. Only this time, the extrema are not as obvious as those for the case of parabolic profile.

The effect of initial jet velocity profile on local Sherwood number can be studied from Figures 10.63 and 10.65. The local Sherwood number for the case of parabolic profile is consistently higher than that for the case of flat profile at a given Reynolds number except in the region where the local minimum of Sherwood number occurs. Significant difference is found in the stagnation flow region where the stagnation point Sherwood number for the case of parabolic profile is between 1.8 and 2.5 times that for the case of flat profile. Such an effect of initial

FIGURE 10.66 : STREAMWISE LOCATIONS OF SECONDARY VORTEX CENTRE AND LOCAL MINIMUM SHERWOOD NUMBER

velocity profile was also observed by numerous investigators (77,81,90,96) in their studies of both unconfined and semi-confined jets.

The effect of jet-to-plate spacing on the local Sherwood number for different Reynolds numbers is shown in Figure 10.67 for the case of parabolic profile. Comparing the cases of $L=2$ and 4, there is no significant difference in the local Sherwood number in the wall jet region before the minimum in Sherwood number occurs. While in the stagnation flow region, only slight difference in Sherwood number is found for the case of low Reynolds numbers. This observation is similar to those by various investigators (19,53,79) studying heat and mass transfer due to an unconfined impinging jet for a small jet-to-plate spacing. But for the case of $L=12$, local Sherwood numbers in the stagnation flow and the wall jet regions are consistently lower than those for $L=2$ and 4. This can be explained in that the impingement plate is no longer located inside the potential core of the submerged jet, therefore the decayed centerline approaching velocity results in a lower mass transfer rate in the stagnation flow region.

10.2.2.1 STAGNATION POINT SHERWOOD NUMBER

Since the stagnation point Sherwood number, Sh_0 , is very difficult to measure in the experimental set-up of this work, the stagnation point Sherwood numbers computed numerically are compared with the results in the literature.

(a) $Re_b = 100$ (b) $Re_b = 200$ (c) $Re_b = 300$ (d) $Re_b = 400$

FIGURE 10.67 ; EFFECT OF JET-TO-PLATE SPACING ON LOCAL SHERWOOD NUMBER FOR THE CASE OF PARABOLIC VELOCITY PROFILE

Comparison of stagnation point Sherwood numbers evaluated in this work for $L=2$ and 4 with those in the literature for the case of parabolic profile is shown in Figure 10.68. It is noted that the difference between the stagnation point Sherwood number of this work for two different jet-to-plate spacings of $L=2$ and 4 is higher at low Reynolds numbers. As Reynolds number increases, this difference diminishes. Also included in Figure 10.68 are the experimental results for an unconfined jet given by Sparrow and Wong (90), the theoretical results for an unconfined jet given by Sparrow and Lee (90) in Equation 2.24 and the numerical results for a semi-confined jet computed by Van Heiningen et. al. (96). Comparing the stagnation point Sherwood number for $L=4$ of this work with that computed by Van Heiningen et. al., the stagnation point Sherwood number of this work is consistently higher. This is probably due to the assumption of fully developed flow at the outflow region of $X=16.4$ and 42 for $Re_b=100$ and 450 , respectively by Van Heiningen et. al.. Such streamwise locations of $X=16.4$ and 42 for $Re_b=100$ and 450 , respectively are very close to the locations where the local extrema in Sherwood number occur as can be noted in Figure 10.63.

Comparison of stagnation point Sherwood numbers evaluated in this work for $L=4$ with those in the literature for the case of flat profile is shown in Figure 10.69. Included in Figure 10.69 are the theoretical results for an unconfined jet given by Miyazaki and Silberman (58) in

FIGURE 10.68 : COMPARISON OF STAGNATION POINT SHERWOOD NUMBER WITH LITERATURE FOR THE CASE OF PARABOLIC VELOCITY PROFILE ($Sc=2.74$)

FIGURE 10.69 : COMPARISON OF STAGNATION POINT SHERWOOD NUMBER WITH LITERATURE FOR THE CASE OF FLAT VELOCITY PROFILE ($Sc=2.74$)

Equation 2.23 and the numerical result for a semi-confined jet computed by Van Heiningen et. al. (96). The stagnation point Sherwood number predicted by Miyazaki and Silberman is consistently higher than that of this work. The disagreement is mainly due to the error introduced by their assumption of potential flow outside the viscous boundary layer. On the other hand, the disagreement between the results computed by Van Heiningen et. al. and that of this work is less obvious.

10.2.3 COMPARISON OF EXPERIMENTAL AND NUMERICAL RESULTS

Comparison of experimental and numerical results can only be made in the region where $X > 1$. As mentioned above, local mass transfer within the stagnation flow region ($X \leq 1$) is difficult to measure in the experimental set-up of this work. Comparison of experimental and numerical results are shown in Figures 10.70-10.81 for $L=2, 4$ and 12 , with local Sherwood number defined by Equation 5.1.

For $L=2$ and 4 , excellent agreement is obtained between the experimental and numerical results. Furthermore, the numerical results confirm the presence of local extrema in the Sherwood number. The numerical results from the upstream-weighted differencing scheme (U.W.D.S.) gave a better prediction as would be expected (69).

For $L=12$, disagreements between experimental and numerical results are found in the stagnation flow and the wall jet regions for the cases of $Re_p \geq 300$. This is probably due to the inaccuracy of the numerical results for $L=12$ in

FIGURE 10.70 : COMPARISON OF EXPERIMENTAL AND NUMERICAL RESULTS OF SHERWOOD NUMBER FOR L=2 AND $Re_b=100$

FIGURE 10.60 : COMPARISON OF EXPERIMENTAL AND NUMERICAL RESULTS OF SHERWOOD NUMBER FOR L=12 AND $Re_b=300$

FIGURE 10.81 : COMPARISON OF EXPERIMENTAL AND NUMERICAL RESULTS OF SHERWOOD NUMBER FOR $L=12$ AND $Re_b=400$

the stagnation flow region as mentioned in Chapter 9. On the other hand, this may be also due to the large jet-to-plate spacing of the experimental set-up in this case. Since the aspect ratio of the channel is 0.1295 for $L=12$ comparing to those of 0.0216 and 0.043 for $L=2$ and 4, respectively, the end effect is important and the geometry of the experimental set-up is no longer two-dimensional. The higher the Reynolds number, the more severe the end effect. This could also be the reason why the two-dimensional model fails to predict the experimental results for $L=12$ at high Reynolds numbers which are measured along the centerline of a three-dimensional channel. To clarify the failure of the two-dimensional numerical model in this case, a three-dimensional numerical model is recommended to study the mass transfer characteristic due to a confined impinging two-dimensional jet when the jet-to-plate spacing is large. Although no experimental data for $L=12$ are obtained in the region where the local extrema in Sherwood number occur, the presence of such extrema is confirmed by the qualitative study of the contours of equal mass transfer rate shown in Plate 10.3.

11. CONCLUSIONS

1. Local Sherwood number along the impingement plate is found to exhibit a local minimum and a local maximum in the region far away from the stagnation flow region. The locations of these extrema are a function of Reynolds number and jet-to-plate spacing.
2. Regression equations correlating local Sherwood number in terms of Reynolds number and streamwise distance for different jet-to-plate spacings are presented in the wall jet region up to the region where the local extremum of Sherwood number occurs.
3. In the wall jet region, for the cases of $L=2$ and 4 , no effects of jet-to-plate spacing are found.
4. Effect of initial nozzle exit velocity profile on the stagnation point mass transfer rate is important. The stagnation point mass transfer rate for an initial parabolic velocity profile is between 1.8 and 2.5 times the value for an initial flat velocity profile.
5. Mass transfer due to a confined laminar impinging two-dimensional jet can be successfully predicted by using a two-dimensional numerical model with upstream-weighted differencing scheme (U.W.D.S.).

12. RECOMMENDATIONS

1. A more advanced interferometric technique can be used instead of the holographic interferometry employed in the present experimental study. A technique, so called "speckle interferometry", can be employed by replacing the hologram in the holographic interferometry by an electronic system. This technique deals with ordinary images rather than holographic reconstructions, therefore the intermediate production, processing and reconstruction of a hologram is avoided. An image of the object illuminated by a coherent light, is formed by conventional optical methods at a photo-sensitive surface of a vidicon tube and can be stored and handled electronically. In this way, the development of fringes can then be studied quantitatively in real time in front of the video monitor.
2. A three-dimensional numerical model should be developed for the study of mass transfer due to a confined impinging two-dimensional jet with large jet-to-plate spacing. This model can then be used to predict the experimental results for $L=12$.
3. The two-dimensional numerical model, developed in this work, can be improved by using a high order differencing scheme derived from local solutions of the differential equation. This numerical technique, so called "single

cell high order differencing scheme" (SCHOS) is
understudy by Manohar and Masliyah at the University of
Alberta.

13. NOMENCLATURE

a	dimensionless parameter defined in Equation 7.1
a ₁ , a ₂	proportional constants in Equations 2.5 and 2.7
A	calibration constant, kg/m ³
b	slot width, m
b ₁	arbitrary stretch constant used to adjust the grid transformation in Y-direction
B	geometric constant of optical set-up
c	concentration of swelling agent, kmole/m ³
c ₁ , c ₂ , c ₃ , c ₄	coefficients in Equations 2.15, 2.16, 2.21 and 2.22
C	dimensionless concentration of swelling agent, $(c-c_j)/(c_s-c_j)$
C _f	skin-friction factor, $\tau_s/(0.5 \rho \bar{v}_j^2)$
d	nozzle diameter, m
d ₁ , d ₂	proportional constants in Equations 2.1 and 2.3
D	diffusion coefficient, m/s ²
e ₁ , e ₂	proportional constants in Equation 2.2 and 2.4
E _j	eigenconstants in Equation 6.29
f	coefficient in Equation 7.50
f ₁ , f ₂	proportional constants in Equations 2.11 and

2.13

F	exterior flux of momentum flux, m^2/s^2
g	coefficient in Equation 7.50
g_1, g_2	proportional constants in Equations 2.12 and 2.14
$-g'(0)$	dimensionless gradient of concentration at impingement plate
G	constant value defined in Equation 5.9, m
h	jet-to-plate spacing, m
k	local mass transfer coefficient defined in Equation 5.1, m/s
k'	local mass transfer coefficient defined in Equation 5.2, m/s
k_c	constant value equals to $\cos\beta$
K	parameter in Equation 7.50
L	dimensionless jet-to-plate spacing, h/b
m_1, m_2, m_3, m_4, m_5	coefficients defined in Equation 7.16
M_v	molecular weight of swelling agent, $kg/kmole$
n	fringe order
n_1, n_2, n_3, n_4, n_5	coefficients defined in Equation 7.21
n_p	refractive index of glass prism
n_s	refractive index of swollen polymer coating
n_j	number of nodes in X-direction which covers half of the slot width
n_x	total number of nodes in X-direction
n_y	total number of nodes in Y-direction
N	mass flux, kg/m^2s

Nu_b	Nussult number for two-dimensional jet
p_b	partial vapor pressure of swelling agent in bulk flow, kPa
p_j	partial vapor pressure of swelling at jet nozzle exit, kPa
p_s	partial vapor pressure of swelling at polymer surface, kPa
P	total pressure, kPa
P^*	vapor pressure of swelling agent, kPa
Pr	Prandlt number
Q	volumetric flow rate of air, m ³ /s
r	radial distance measured from the jet centre, m
r'	displacement or recession of polymer coating, m
R	molar rate of production of swelling agent per unit volume, kmole/m ³ s
Re_b	Reynolds number for two-dimensional jet, $\bar{v}_j b / \nu$
Re_d	Reynolds number for axisymmetric jet, $\bar{v}_j d / \nu$
Rs	local Reynolds number based on the local velocity and distance between adjacent nodes in Y-direction defined in Equation 7.46
Rx	local Reynolds number based on the local velocity and distance between adjacent nodes in X-direction defined in Equation 7.44
S	parameter in Equation 8.2

Sc	Schmidt number, D/ν
Sh_b	Sherwood number, kb/D
Sh_d	Sherwood number, kd/D
Sh'_b	Sherwood number, $k'b/D$
Sh^*_b	stagnation point Sherwood number
t	temperature, °C or K
T	duration of mass transfer experiment, s
u	streamwise velocity in X-direction, m/s
u_{max}	maximum value of streamwise velocity in X-direction for an individual streamwise velocity profile, m/s
\bar{u}	mean velocity in X-direction in outflow region, m/s
\hat{u}	dimensionless streamwise velocity in X-direction, u/\bar{v}_j
U_{max}	maximum value of dimensionless streamwise velocity in X-direction for an individual streamwise velocity profile, u_{max}/\bar{v}_j
v	axial velocity in Y-direction, m/s
\bar{v}_j	mean velocity of jet at nozzle exit, m/s
V	dimensionless axial velocity in Y-direction, v/\bar{v}_j
w	constant relaxation factor
x	streamwise distance measured from the jet centre, m
X	dimensionless streamwise coordinate, x/b
y	axial distance measured from the jet nozzle

	exit, m
Y	dimensionless axial coordinate, y/b
Y_i	eigenfunctions in Equation 6.29
Z_1, Z_2	coefficients defined in Equations 7.38 and 7.40

GREEK SYMBOLS

α	weighting factor for convective term in X-direction
α_i	eigenvalues in Equation 6.25
β	weighting factor for convective term in Y-direction
β_1	incident angle of light path travelling from glass prism to polymer coating
β_2	refractive angle of light path travelling from glass prism to polymer coating
γ	weighting factor for diffusion term in X-direction
δ	weighting factor for diffusion term in Y-direction
ΔX	grid increment in X-direction measured between adjacent boundaries of control volume
ΔY	grid increment in Y-direction measured between adjacent boundaries of control volume

ΔX	grid increment in X-direction measured between adjacent nodes
ΔY	grid increment in Y-direction measured between adjacent nodes
ϵ	maximum absolute different of parameter S between two consecutive iterations defined in Equation 8.13
δ	spread of jet, m
η	coefficient defined in Equation 7.17
λ	wavelength of light, m
λ_i	eigenvalues in Equation 6.29
μ	viscosity of air, kg/m s
ν	kinematic viscosity of air, m ² /s
ξ	coefficient defined in Equation 7.17
ρ	density of air, kg/m ³
ρ_s	density of swollen polymer coating, kg/m ³
ρ^o	molar density of gas mixture, kmole/m ³
σ	viscous boundary layer thickness in wall jet region, m
σ_o	viscous boundary layer thickness in stagnation flow region, m
τ_s	shear stress at impingement plate, N/m ²
Φ	dimensionless variable in Equation 7.1
ψ	stream-function, m ² /s
Ψ	dimensionless stream-function, $\psi/(b \bar{v}_j)$
ω	vorticity, s ⁻¹
Ω	dimensionless vorticity, $\omega(b/\bar{v}_j)$

SUBSCRIPTS

b	slot width as characteristic length
B	bulk flow
d	nozzle diameter as characteristic length
e, w, n, s	east, west, north and south side boundaries of control volume
fd	fully developed flow
i	element number
j	at jet nozzle exit
max	maximum value
o	in outflow region
s	at coating surface or impingement plate

15. APPENDIX A : PHYSICAL PROPERTIES

The physical properties used in this work in determination of local Sherwood number are given by Masliyah and Nguyen (51,52,53). The physical data which are independent of the operating conditions are given as follows:

density of swollen polymer, $\rho_s = 1.01 \times 10^3 \text{ kg/m}^3$
molecular weight of ethylsalicylate, $M_w = 166.17 \text{ kg/kmol}$
wave length of laser light, $\lambda = 632.8 \times 10^{-9} \text{ m}$

Other physical properties such as vapor pressure of ethylsalicylate, viscosity of air, molar density of the gas mixture and diffusion coefficient for ethylsalicylate and air are functions of the operating conditions. The correlations for evaluating these properties at given operating temperature and pressure are given as follows:

1. The vapor pressure of ethylsalicylate, P^o , is a strong function of operating temperature, t , and can be evaluated from the following equation (36),

$$\log_{10} P^o = 7.897 - (2931.6 / t) \quad (15.1)$$

where t is in K.

i.e. $P^* \text{ (at } 21^\circ\text{C and } 93.9\text{kPa)} = 0.00843 \text{ kPa}$

2. The molar density of gas mixture, ρ^* , can be approximated by using the molar density of air at the operating conditions. Applying ideal gas law, the molar density of gas mixture can be evaluated from the following equation,

$$\rho^* = P / (8.31 t) \quad (15.2)$$

where P and t are operating pressure and temperature, respectively.

i.e. $\rho^* \text{ (at } 21^\circ\text{C and } 93.9\text{kPa)} = 0.0385 \text{ kmol/m}^3$

3. The viscosity of air, μ , is used in the evaluation of the Reynolds number for an air jet. This property is almost independent of pressure at low pressure, but increases with increasing temperature (51).

i.e. $\mu \text{ (at } 21^\circ\text{C and } 93.9\text{kPa)} = 1.817 \times 10^{-3} \text{ kg/m s}$

4. The diffusion coefficient, D, is evaluated by using the Lennard-Jones expression for gas pairs of non-polar molecules.

i.e. $D \text{ (at } 21^\circ\text{C and } 93.9\text{kPa)} = 5.95 \times 10^{-6} \text{ m}^2/\text{s}$

16. APPENDIX B : CALIBRATION OF FLOWMETERS

Two rotameters are used in this work. Rotameter A, a Fischer & Porter Rotameter (Tube no. FP-0.25-09-G-6.75/61) is used for volumetric air flow rate less than $1.1798 \times 10^{-4} \text{ m}^3/\text{s}$. Rotameter B, a Brook Rotameter, is used for volumetric air flow rate greater than $1.1798 \times 10^{-4} \text{ m}^3/\text{s}$ up to $8.6 \times 10^{-4} \text{ m}^3/\text{s}$.

Rotameter A was calibrated at 22.2°C and 93.45 kPa . The calibration curve of volumetric air flow rate is shown in Figure 16.1 with rotameter reading at the top of the float. The calibration curve of volumetric air flow rate of Rotameter B was supplied by Masliyah and Nguyen (51) with calibration conditions at 22°C and 95.73 kPa . This curve is shown in Figure 16.2. The rotameter reading is at the bottom of the float.

The value of volumetric flow rate from the calibration curve, Q' , must be corrected for the actual experimental operating conditions using the following expression

$$Q = Q' (t/t')^{1.4} (P'/P)^{0.7} \quad (16.1)$$

where Q is actual experimental volumetric flow rate, Q' is volumetric flow rate from calibration curve, t is operating temperature, t' is calibration temperature, P is operating pressure and P' is calibration pressure. All temperatures

FIGURE 16.1 : CALIBRATION LINE FOR ROTAMETER A

FIGURE 16.2 : CALIBRATION LINE FOR ROTAMETER B

and pressures in Equation 16.1 are in K and kPa, respectively.

The Reynolds number for an air jet issuing from a circle tube with diameter d or a slot tube with width b can then be evaluated from the volumetric flow rate, Q , as follows:

$$Re_b = \bar{v}_j d / \nu = 4 Q / M \nu \quad (16.2)$$

or $Re_b = \bar{v}_j b / \nu = 2 Q / M \nu \quad (16.3)$

where M is the wetted perimeter of the tube.

**17. APPENDIX C : LISTINGS OF EXPERIMENTAL RESULTS FOR
UNCONFINED AXISYMMETRIC JET**

A listing of the experimental runs together with the mass transfer duration, operating pressure and operating temperature for unconfined axisymmetric jet are given in Table 17.1. Local fringe orders of different experimental runs are given in Table 17.2.

20. APPENDIX F : COMPUTER PROGRAM

The main program, PROGRAM, together with four subroutines, ITER1, CALC1, ITER2 and CALC2 are listed in this appendix.

A typical output for numerical run no. 2B100 for $L=2$ and $Re_D=100$ with an initial parabolic velocity profile are also listed. The differencing scheme used in this numerical run is the upstream-weighted differencing scheme (U.W.D.S.).

21. APPENDIX G : LISTINGS OF NUMERICAL RUNS

The listings of all numerical runs of which the results are used for studying the flow and mass transfer characteristics due to a confined laminar impinging two-dimensional jet are given in Tables 21.1, 21.2 and 21.3 for $L=2$, 4 and 12, respectively. Numerical runs with an initial parabolic velocity profile at the nozzle exit are studied for all three different jet-to-plate spacings. Numerical runs with an initial flat velocity profile at the nozzle exit are studied for the case of $L=4$ only.

TABLE 21.1 : NUMERICAL RUNS FOR L=2

 $b_1 = 0.75$

Re_b	RUN NO.	n_x	n_y	DIFFERENCING SCHEME	NOZZLE EXIT PROFILE
