SOMMAIRE

Des profils de vitesse et de la fluctuation des vitesses en régime turbulent ont été obtenus expérimentalement dans la couche limite et la région central de tuyaux circulaires à l'aide d'une méthode photographique utilisée pour mesurer les vitesses instantanées.

Les données expérimentales ont permis de déceler des erreurs d'interprétation des profils de vitesse pour des systèmes dans lesquels une réduction de perte de charge est observée, et ont offert un appui au phénomène d'éjections comme mécanisme responsable de la réduction de la perte de charge.

En particulier, il a été démontré que la corrélation empirique présentée par Bogue doit être incorporée au profil semi-logarithmique de vitesse de Seyer-Metzner pour que les données expérimentales soient représentées par des courbes parallèles à l'équation de Prandtl.

Il a aussi été démontré que la fonction B, définie par Seyer and Metzner et présentée à la figure II-12, peut être utilisée dans les limites de faible valeurs de e^+ , mais que la valeur asymptotique de 32 n'est pas unique.

Il est apparu évident que la fluctuation de vitesses des systèmes avec diminution de perte de charge peut être plus grand ou plus petite aux systèmes Newtoniens selon la base de comparaison choisie. Les données expérimentales ont démontré que le paramètre d'écheie, défini par Rudd, n'est pas aussi général que désiré.

ABSTRACT

An experimental study, based on streak photograph-determination of instantaneous velocities, was directed at determining the velocity and intensity profiles within the boundary layer and core regions of circular pipes.

The measurements resolve several discrepancies in interpretation of earlier velocity measurements in drag reducing systems by lending support to the ejection phenomena as the mechanism controlling drag reduction. In particular, it is shown that Bogue's empirical correction function must be incorporated in the semi-logarithmic velocity profiles to quantitatively represent the data of drag reducing systems. Failure to do so has led to confusion in determining the proper form of similarity law.

Study of the details of Seyer and Metzner velocity profile intercept function, defined in equation II-12, confirm the function for θ^+ up to approximately 12, but show the estimated maximum value of 32 is not unique.

Turbulence intensities may be viewed as being higher or lower than Newtonian intensities depending on the basis of comparison. The data show that Rudd's scaling factor, which superimposes his data for fixed U^* , does not account for changes in U^* and is therefore not as general as earlier anticipated.

ACKNOWLEDGEMENTS

I wish to express my gratitude and appreciation to:

- Dr. F. A. Seyer for his capable guidance during this research;
- all the technical staff of the Chemical and Petroleum Shop for its suggestions and assistance in the building of the equipment;
- Mr. Peter Smits for his assistance in building the equipment, and for his support during the photographic runs and analysing of the films;
- Mr. A. Chernick of the University of Alberta Photographic Department for his suggestions and assistance in the photographic field;
- the DACS Centre personnel of the Chemical and Petroleum Department for its assistance. Also to Ted Kizior for his helpful suggestions and assistance in computer programming;
- the National Research Council for the financial support which made this study possible;
- the Dow Chemical Company who donated the polymer;
- the personnel of the Department of Chemical and Petroleum Engineering, especially Mrs. Betty Boon and Lynda Masse for the typing.

A very special gratitude to my wife, Solange, and my daughters, Claudine and Martine; without whose understanding and support this work would not have been completed.

INTRODUCTION

Considerable numbers of theoretical and experimental studies, in the last 10 years, have been focused on the mechanism of turbulence in an attempt to reveal the character at the wall responsible for drag reduction observed in the presence of polymeric additives. In principle a detailed knowledge of the flow in the wall region would aid one in choosing the correct constitutive equation or variables to correlate drag reduction. Many mechanisms, as well as correlations of friction factor and velocity profiles, have been proposed. These correlations represent the available data, but none have been tested very severely over a wide range of variables. In particular the available velocity measurements in drag reducers do not provide a detailed verification of the semi-logarithmic velocity profile. Also great confusion is found from a survey of the measured relative intensities owing to the uncertainty in accuracy of the results and in how to scale or compare them for different systems.

I-1 MECHANISM OF TURBULENCE

Since Prandtl developed the 'Boundary Layer Hypothesis' in 1904, many studies of properties of Newtonian turbulence (19,21,14, 28,45,16,18,38) have indicated that the character of the flow in the wall region was responsible for most of the creation and dissipation of the turbulent energy.

It is only recently that a detailed physical picture of the mechanism was presented, mainly by the work of Bakewell and Lumley (3), Kline et al (20) and Corino and Brodkey (7). Bakewell and Lumley indicated that the dominant large scale structure of the flow in the boundary layer consists of randomly distributed counter-rotating longitudinal eddy pairs of elongated extent in the flow direction. The structure of these eddies was inferred from space-time correlation functions of the fluctuating velocities. The streamlines of these eddies were pictured as to push low momentum boundary layer fluid toward the core region, so that the renewal of fluid was by flow in the circumferential direction.

Qualitatively similar patterns of flow in the wall region were visualized by Kline et al using a dye ejection technique and in more detail from tracer photographs by Corino and Brodkey. Ejections of fluid, originating from a low velocity region adjacent to the viscous sub-layer, were responsible for extracting energy from lumps of fluid originating in the main flow and converting it into turbulent energy. They observed that these ejections were of large scale and moved through the boundary layer until broken down to small scale turbulence by mixing with the main flow.

The simple mechanism of turbulence then is that the turbulent shear stress is generated by the radial transport of low momentum fluid by the large eddies or 'bursts'. The magnitude of the stress is determined by the rate of fluid transported radially as well as its axial momentum. The rate of fluid transported in turn depends on the frequency of occurrence of the eddies as well as their size. The visual studies of wall turbulence provide a starting point for interpreting turbulence measurements in drag reduction.

Many mechanisms have been suggested in order to explain the drag reduction for flow of viscoelastic fluids in pipes (32,39). Generally it is agreed that elasticity of the fluid is responsible for the drag reduction. Furthermore, as emphasized by Wells and Spangler (42) who showed by injection of polymer in the boundary layer that drag reduction is controlled by the flow in the wall region, the elasticity must modify turbulence in the wall region.

From a continuum point of view, Seyer and Metzner (17) have shown that the drag reduction can result from the resistance to flow caused by stretching in the large eddies or 'bursts'. Although their arguments are based on a steady state analysis of eddies as pictured by Bakewell, Denn and Porteous (5) have shown identical ordering parameters appear if a transient analysis of the eddies is carried out. It is difficult to say what the effect of resistance to flow is on the structure of the eddy. For example, the eddies may be increased in size which would appear as a thickening of the boundary layer or they might be reduced in frequency. These points of view also have resulted in dimensionless groups which are the same as for

stretching arguments (24,17) but do not show conclusively what alterations in the structure have occurred.

II-2 SIMILARITY LAWS AND MEASUREMENT METHODS

For drag reducers, apart from completely empirical formulations, most studies have sought to modify the Newtonian similarity laws, so that they described drag reduction. For Newtonian fluids, Millikan (27), for example, has shown from a dimensional analysis that the velocity profile law is

$$U^+ = A \ln Y^+ + B \quad \text{I-1}$$

where

$$U^+ = \bar{u}_x / U^*$$

$$Y^+ = yU^* / \nu \quad \text{I-2}$$

$$U^{*2} = \tau_w / \rho$$

$$\tau_w = D\Delta P / 4L$$

The generally accepted values for A and B for Newtonian fluids are

$$(5) \quad A = 2.46 \text{ and } B = 5.6$$

Equation I-1 is an accurate representation of all consistent Newtonian data for Y^+ less than 400, but considerable deviation occurs for larger Y^+ . Correction factors have been empirically found (18, 5, 27). Bogue's correction factor represents the best fit of available data and is defined as

$$C_3(\xi, f) = 0.05 \sqrt{\frac{2}{f}} e^{-\frac{(\xi-0.8)^2}{0.15}} \quad \text{I-3}$$

where $\xi = y/R$

and the friction factor

$$f = \tau_w / \frac{1}{2} \rho \langle \bar{u}_x \rangle^2 \quad \text{I-4}$$

With Bogue's correction factor the form of the velocity profile for Newtonian fluids is then

$$U^+ = a \ln Y^+ + B + C_3(\xi, f) \quad \text{I-5}$$

From Equations I-4 and I-5, the friction factor relation for Newtonian fluids follows directly

$$\frac{1}{\sqrt{f}} = A \ln (N_{Re} \sqrt{f}) - 0.4 \quad \text{I-6}$$

For fluids represented by a power law model in which

$$\tau_w = K' \left(\frac{8 \langle \bar{u}_x \rangle}{D} \right)^{n'} \quad \text{I-7}$$

Dodge and Metzner (10) formulated the friction factor correlation based on the generalized Reynolds number

$$\frac{1}{\sqrt{f}} = \frac{4.0}{(n')^{0.75}} \log (N'_{Re} f^{1-\frac{n'}{2}}) - \frac{0.40}{(n')^{1/2}} \quad \text{I-8}$$

where the generalized Reynolds number

$$N'_{Re} = \frac{D^{n'} \langle \bar{u}_x \rangle^{2-n'} \rho}{K' 8^{n'-1}}$$

Notice Equation I-8 is simply a generalization of the Newtonian Equation I-6 to account for the non-Newtonian properties. Similarly,

Bogue (5) measured velocity profiles for pseudoplastic fluids and formulated the velocity profile equation such that

$$U^+ - C_3(\xi, f) = 5.57 \log (Y^+)^{1/n'} + I(n', N'_{Re}) \quad I-10$$

where I is a weak function of n' , N'_{Re} .

Equation I-10 when plotted gives a family of parallel curves to Newtonian fluid with slope $A = 2.46$ for the core region with intercept higher as n' decreases and N'_{Re} decreases. He also found that turbulent velocity profiles for purely viscous non-Newtonian fluids are essentially the same as those for Newtonian fluids when normalized to the mean velocity.

For drag reducing fluids it is obvious that one of the major effects appears as an increased intercept. Based on Pitot tube measurements, Elata et al (11) modified the law of the wall by incorporating an extra logarithmic term to interpret the higher intercept such that

$$U^+ = A \ln Y^+ + 5.5 + \alpha' \ln \left[\frac{U^+{}^2}{v_w} \right] \quad I-11$$

In this equation, A is assumed the same as for Newtonian fluids and the effect of the elasticity of a solution is expressed by the relaxation time θ which is assumed constant. The parameter α' is an empirical function of the polymer characteristics and the concentration.

The equation for the friction factor that follows is then

$$\frac{1}{\sqrt{f}} = \frac{(\alpha' + A)}{\sqrt{2}} \ln (N'_{Re} \sqrt{f}) - 0.4 + \frac{\alpha'}{\sqrt{2}} \ln \left(\frac{\theta v_w}{D^2} \right) \quad I-12$$

For a given flow rate and polymer, equation I-11 plots as a parallel line to the Newtonian curve. A detailed examination of the

data indicate however (especially for large amounts of drag reduction) that the parallel lines are only a crude representation of the data. Alternatively if the best fit straight line is drawn through a given velocity profile an increase of the slope A would be necessary.

A number of other studies, based on Pitot tube readings (49, 11, 26, 12) have subsequently shown velocity profiles which are qualitatively similar to Elata's.

In all these, owing to the large quantitative uncertainty in the Pitot readings, it is impossible to determine if the slope is actually different or if modified slope simply reflects errors in the Pitot readings. It has been shown for laminar flows (2) that the Pitot tube measurements in a viscoelastic fluid are made up not only of the kinetic contribution but also largely influenced by normal stresses. The magnitude of the normal stress contribution depends on the local shear rate or radial position and so the Pitot readings may not even determine the correct shape of velocity profile. In turbulent flows the flat velocity profile in the core region would tend to hide the effect of shear rate but would be serious near the wall.

Nicodemo et al (25) have presented velocity profiles using a probe calibrated in a tow tank. It was decided that the velocity profiles could not be interpreted according to Bogue's equation 1-5 by a simple increase in intercept. Although the check of integrated and measured flow rates is one of the few studies showing good agreement, this check is a very insensitive one for shape of profile. It should be noted their calibration does not indicate the magnitude of any contributions owing to turbulence.

Similar uncertainties occur in the case of heated probes (25,13,23,33,40). As well indicated by the recent study of Serth and Kiser (40) errors as large as 250% in determination of velocity can occur. Generally these studies indicate directly there is an undetermined quantitative uncertainty in all reported velocity and turbulence measurements utilizing either pitot or heated probes. Qualitatively there may even be errors in shape of profile owing to changes in probe response with radial position.

In 1969 Seyer and Metzner (43) presented experimental velocity profiles obtained from a photographic method which it is significant to note, are free from the uncertainties of Pitot or other probes. A theoretical analysis similar to the arguments of Millikan (27) and Dodge (10) was used to show that

$$U^+ = A \ln Y^+ + B(\theta^+)$$

where $\theta^+ = \theta U^{*2}/\nu$ I-13

and $\sqrt{\frac{2}{f}} = A(1-\xi)^2 \ln (N_{Re} \sqrt{f}) + (1-\xi_1)^2 [B(\theta^+) - A \ln 2\sqrt{2}] - G$ I-14

where ξ_1 is the boundary layer thickness (dimensionless) and G is assumed a constant equal to 3.0. Details of this analysis and some modifications will be presented in Chapter II.

In the limit for ξ^+ and θ_1 going to zero these equations reduce the usual equations for Newtonian fluids (I-1 and I-6).

For drag reducers the form of the equations is the same as Elata's with the exception of the intercept function.

Seyer's measurements as well as some later ones in a square tube by Rudd with a Laser Doppler Meter (36), are in excellent agreement with I-13. In each of these studies however a velocity profile was obtained at only one flow rate in a given tube for turbulent flow conditions. Therefore they do not provide a detailed verification of the form of equations I-13 and I-14 nor of the limits of applicability.

Seyer's measurements in a one-inch tube show that transitional flow occurs to Reynolds numbers in excess of 10^5 for what have been termed concentrated or maximum drag reducers. At high Reynolds numbers the function factors seem to approach an asymptote defined by a constant value of $B(e^+) = 32$. Virk et al (47) have published a number of papers which consider a different maximum drag reduction asymptote. Based on data from a number of sources of friction measurements it was found that

$$\frac{1}{\sqrt{f}} = 19 \log N_{Re} \sqrt{f} - 32.4 \quad \text{I-15}$$

Seyer's friction data in transitional flow follow closely to the friction factors defined by equation I-15. The corresponding "ultimate velocity profile" is

$$U^+ = 11.7 \ln Y^+ - 17 \quad \text{I-16}$$

Notice this is a much higher slope than for Newtonian fluids and has a negative intercept.

The transitional flow velocity profiles suggest the interpretation of I-16 is incorrect. In fact in the final limit the

profiles would be laminar over the entire tube cross section. Laminar (parabolic) profiles on U^+ - Y^+ coordinates are easily shown to be a family of parallel curves depending on the Reynolds number. For positions near the center, the curves can be approximated by equations like I-16 with large slope and negative intercept as determined by the Reynolds number. The transition profiles on these plots are qualitatively similar. Thus Virk's constants may simply reflect the transitional nature of the velocity profiles. In the absence of defined limits of transitional flow however, little more can be said about the correct interpretation of the velocity profiles for transitional flow. Clearly these questions are of prime importance in formulating the correct similarity laws and their limits of applicability.

I-3 PROPOSED WORK

In this work it is proposed to extend Seyer and Metzner's optical method of measurements in order to obtain instantaneous velocities, both axial and radial, which will provide a detailed test of the available similarity laws. The wall region as well as the core region will be investigated with different concentrations of polymeric solutions for different pipe sizes.

The statistical properties of the instantaneous velocities will be used to comment on the 'bursting phenomena', and any change in its structure, owing to the presence of polymers.

THEORY

II-1 PROBABLE MECHANISM

As previously mentioned, the recent physical interpretation of turbulence, presented by Corino and Brodkey and based on the observation of a 'bursting phenomena' present in the wall region can serve as a basis to analyse the data collected in this work. Figure II-1 shows schematically a lump of fluid originating in the main flow and entering at a small angle into the boundary layer with an axial velocity component corresponding to the average velocity of its origin. A second lump of fluid located in the boundary layer and possessing a lower velocity is then accelerated by the excursion and shear stresses start to build until one or more ejections occur. Because the origin of the ejections is assumed to be in a region of low momentum situated approximately at a Y^+ of 10, the axial velocity components of the ejections are expected to be smaller than those of the accelerating lumps. Corino and Brodkey observed that the ejected fluid, although accelerated in the axial direction, never reached the axial component of the main flow adjacent to the boundary layer.

ILLUSTRATION OF BURSTING PROCESS

FIGURE II-1

Denoting u_{x1} and u_{r1} as the velocity components of the lump of fluid entering the boundary layer and u_{x2} and u_{r2} for the ejection velocity components, one should expect to find

$$\bar{u}_{x1}(r) > \bar{u}_{x2}(r) \quad \text{II-1}$$

where

$$\bar{u}_x(r) = \frac{1}{n} \sum_{i=1}^n (u_x(r))_i$$

$\bar{u}_x(r)$ can represent the time average velocity at a fixed radial position if sufficient readings are taken (of instantaneous velocities) at random times. Thus a histogram of the axial instantaneous velocities, at a fixed radial position, should be composed of two distributions. Using a flash photolysis method, Popovich and Hummel (33,34) measured velocity profiles which showed a binodal distribution of the axial instantaneous velocities in the boundary layer with the peak of lower axial velocities becoming more pronounced at positions nearer the wall. This simply shows the influence of the velocities of fluid originating near the wall dominates the flow in that region.

The ejection phenomena approach taken in this work can explain, in more detail, the presence of dual distributions than the Popovich analysis, which is based on elements of fluid being directed toward the wall and others directed toward the center.

Each positive (directed toward the wall) radial velocity is associated with a u_{x1} while a negative radial velocity is associated with u_{x2} . The velocity histograms can then be split according to whether the instantaneous radial velocity is positive or negative.

According to the bursting analysis, instantaneous negative radial velocities should be larger than the positive components. Thus to obtain a zero time averaged radial velocity (the sum of all observed components) the positive components must be observed more often than the larger negative components. Defining

$$R_o = n^+/n^- \quad \text{II-2}$$

where

n^+ is the observed number of u_{r1}

n^- is the observed number of u_{r2}

then R_o is expected to be greater than unity in the boundary layer and approximately equal to unity in the core region. Also if the velocity of ejection is dependent on radial position, as Corino and Brodkey observed, an acceleration of the fluid during the trajectory from its origin to the radial position where it is broken up by the main flow, implies the presence of a peak in the plot of R_o versus dimensionless radial position. This peak should occur in the vicinity of the edge of the boundary layer.

In summary, an analysis of the histograms of axial and radial components of the instantaneous velocities at a radial position in the boundary layer should provide information about the mechanism of ejection. Also it should explain the presence of the binodal distributions in the boundary layer, if these distributions are split according to the direction of the radial component. In the case of drag reducers the available data, although in doubt quantitatively, show that the turbulence is similar to Newtonian turbulence. The

drag reduction, therefore, is probably a result of modifications to the ejection process. For example, if the boundary layer is thickened appreciably, then the peak in R_0 ought to appear at greater values of Y^+ than in the Newtonian case.

In the ejection process, earlier studies (37,43) suggest the increased resistance to stretching causes the radial fluctuations to decrease. Although in the work of Seyer and Metzner, where the ideal case of steady stretching was treated, the same conclusion, that is an increased resistance to stretching, follows from a consideration of the transient motion (8). In Figure II-1 the resistance to sudden deformations would

- (i) decrease u_{r_2} at a given point,
- (ii) not affect appreciably u_{r_1} and u_{x_1} , because the direction of these larger lumps of fluid are nearly parallel to the flow direction (no stretching in the axial direction),
- (iii) implies a lower radial variance from a combination of (i) and (ii) (u_{r_1} not affected, and u_{r_2} decreased).

One cannot predict the change in u_{x_2} but if a decrease results, as might be expected if the sublayer thickens appreciably, then higher axial intensity would result.

Similarly, however, the data of Meak and Baer (24) and Fortuna and Hanratty (15), show the frequency of occurrence of the ejection decreases in polymers. This would also decrease the radial intensity. Unfortunately, the method used in this work cannot distinguish directly which cause is effective in altering the intensity.

II-2 SIMILARITY LAWS

A) Velocity Profiles

Assuming the relaxation time as the characteristic time scale of viscoelastic solutions, Seyer and Metzner (43) introduced the relaxation time as an additional parameter in the wall region where the stretching is assumed to occur. They performed an analysis, similar to Millikan (27), to obtain the logarithmic velocity profile.

The velocity in the boundary layer can be expressed as

$$\bar{u}_x = \hat{f}_2 (\tau_w, y, \rho, \mu, \theta) \quad \text{II-3}$$

and in the core region as

$$\langle \bar{u}_x \rangle_m - \bar{u}_x = \hat{f}_3 (\tau_w, R, y, \rho) \quad \text{II-4}$$

so that for the entire section of the pipe

$$\bar{u}_x = \hat{F} (\tau_w, R, y, \rho, \mu, \theta) \quad \text{II-5}$$

Notice that the fluid parameters should be estimated at the wall shear stress value. Introducing the following dimensionless group

$$Z = RU^*/\nu \quad \text{II-6}$$

and using those already defined (in Chapter I), the following equations for the core and the wall regions can be found from a dimensional analysis

$$\frac{\langle \bar{u}_x \rangle_m - \bar{u}_x}{U^*} = -A \ln \xi + C_3 \quad \text{II-7}$$

and

$$\bar{u}_x / U^* = A \ln Z + B(\theta^+) \quad \text{II-8}$$

when combined, the expression for the overlapping region is obtained

$$U^+ = A \ln Y^+ + B(\theta^+) - C_3 \quad \text{II-9}$$

Extensive study was performed by Bogue (5) to find an expression for the C_3 factor. C_3 must be a function of ξ to permit equation II-7 to hold for the entire region. It must be zero at the centerline and contribute approximately 10% to values of the velocity defect for ξ smaller than 0.3 as shown by Bogue. In equation II-9 the correction function may be written in the form

$$C_3(\xi, f) = 0.05 \sqrt{\frac{2}{f}} e^{-\frac{(\xi-0.8)^2}{0.15}} \quad \text{II-10}$$

so that the corrected velocity profile becomes

$$U^+ = A \ln Y^+ + B(\theta^+) + C_3(\xi, f) \quad \text{II-11}$$

and where for Newtonian fluids $A = 2.46$ and $B(0) = 5.6$. Assuming, as an approximation, a linear profile in the boundary layer and neglecting $C_3(\xi, f)$ for small ξ , Equation II-11 becomes

$$Y_1^+ = A \ln Y_1^+ + B(\theta^+) \quad \text{II-12}$$

and serves to define the boundary layer thickness.

Figure II-2 shows the $C_3(\xi, f)$ function increasing with increasing wall distance, ξ . It can be observed that the function increases in value as the friction factor decreases, indicating that, if applicable, the correction becomes more important for drag reducers. Because of the passive role of the core region when drag reduction occurs, as shown experimentally by Wells and Spangler (48) and suggested by the bursting arguments, the same function may apply for viscoelastic fluids.

B) Friction Factor

In order to express the friction factor defined in Equation I-4, the bulk velocity is obtained from the integrated profile which can be divided into the boundary layer region and the core region

$$\langle \bar{u}_x \rangle = \frac{2}{R^2} \left[\int_0^{\delta} r u_{xL}(r) dr + \int_{\delta}^R r u_{xC}(r) dr \right] \quad \text{II-13}$$

In terms of the dimensionless radial position

$$\langle \bar{u}_x \rangle = 2 \int_0^{\xi_1} (1-\xi) u_{xL}(\xi) d\xi + 2 \int_{\xi_1}^1 (1-\xi) u_{xC}(\xi) d\xi \quad \text{II-14}$$

where

$$\xi_1 = \delta/R$$

Assuming a linear profile in the wall region and using the defect law for the core region, one can obtain

FIGURE II-2

BOGUE'S CORRECTION FUNCTION

$$\frac{\langle \bar{u}_x \rangle}{2} = \frac{RU^*}{v}^2 \left[\frac{\xi_1^2}{2} - \frac{\xi_1^3}{3} \right] + \frac{\langle \bar{u}_x \rangle}{2} m (1-\xi_1)^2 - U^* \int_{\xi_1}^1 (1-\xi) f_3(\xi) d\xi \quad \text{II-15}$$

Combining Equations I-4 and II-15 and grouping terms, the following expression is obtained

$$\sqrt{\frac{2}{f}} = A(1-\xi_1)^2 \ln(N_{Re} \sqrt{f}) + (1-\xi_1)^2 [B(\theta^+) - A \ln 2\sqrt{2}] - G(\xi_1, \frac{RU^*}{v}, f) \quad \text{II-16}$$

which is the same as Seyer's equation (41) except that G is now also a function of f. The function G can be expressed as

$$G = 2 \int_0^1 (1-\xi) f_3(\xi) d\xi - 2 \int_0^{\xi_1} (1-\xi) f_3(\xi) d\xi - \xi_1^2 \frac{RU^*}{v} \quad \text{II-17}$$

where

$$2 \int_0^1 (1-\xi) f_3(\xi) d\xi = -2A \left[\int_0^1 \ln \xi d\xi - \int_0^1 \xi \ln \xi d\xi \right] + 2 \int_0^1 C_3(\xi, f) d\xi - 2 \int_0^1 C_3(\xi, f) \xi d\xi \quad \text{II-18}$$

In Equation II-18 with A = 2.46

$$2A \left[\int_0^1 \ln \xi d\xi - \int_0^1 \xi \ln \xi d\xi \right] = -3.6 \quad \text{II-19}$$

The curves of Figure II-2 are used to graphically integrate the remaining terms of Equation II-18 involving $C_3(\xi, f)$ giving a value of 0.40 for the case of a very low friction factor of 0.003 where $C_3(\xi, f)$ is

largest. Because the correction factor, $C_3(\xi, f)$ is zero for small values of ξ , the remaining terms of Equation II-17 are not influenced by the correction factor. Therefore, since G is a minor term in Equation II-16, the dependence of G on f , as determined by $C_3(\xi, f)$, is negligible.

Figure II-3 shows the B function evaluated from friction factors and velocity profiles by Seyer (41) for solutions of Separan AP-30 for 1" and 2" pipes at three different concentrations. From Figure II-3 it can be observed that the function reaches an asymptotic value of approximately 32.2 for θ^+ greater than 20. If this function is unique for all viscoelastic fluids and pipe sizes, then maximum drag reduction will be reached whenever θ^+ is greater than 20. The only limitation on the use of Equation II-11 is the dividing point between turbulent and transitional flow.

The limits of transitional flow must be related to the thickening of the sublayer. The definition of sublayer thickness given by Equation II-12 shows how it depends directly on the elasticity of the system. Clearly the sublayer must be less than the tube radius for turbulent flow to occur, but the question of an exact value needs further investigation. In the case of Newtonian fluids the maximum sublayer thickness is approximately $\xi = 0.1$ (at N_{Re} of 2100).

FIGURE II-3

EXPERIMENTAL

An optical method of measurement was used to obtain streak photographs of small air bubbles in the water and polymeric solutions in order to measure instantaneous velocities in the boundary layer and core regions. As mentioned before, this method does not suffer from the uncertainties inherent in pitot tube and heated probe measurements.

III-1 FLOW SYSTEM

The flow system, as shown schematically on Figure III-1, consisted of a closed circuit in which the fluid could be pumped through a test section and returned to a 300 gal. stainless steel storage tank. A variable speed Lightnin mixer and a coil were attached to the tank to regulate the level of degradation and the operational temperature of the Separan AP-30 solutions. Two Moyno positive displacement pumps, each with a maximum delivery capacity of 200 gal/min permitted measurement of pressure drop over an extended range of flow rates. A 2" I.D. Foxboro magnetic flowmeter recorded the flow rate passing through the test section.

A variable pressure Desurger following the pump exit damped the flow fluctuations caused by the positive action of these pumps. Nominally the desurger pressure was set for the photographic runs at 75% of the pump discharge pressure. A calming section of 6" I.D. and 6' long containing a baffle plate was inserted before the test section in order to fulfill four requirements:

- i) injection point of the tiny air bubbles used as tracers,

- FLOW SYSTEM -

FIGURE III-1

- ii) trapping of the dirt particles in the system,
- iii) trapping of large air bubbles,
- iv) calmed the fluid and uniformly distributed the tracers in the fluid.

Air bubbles injected into the fluid flow were used as tracers. The injection point was situated in the calming section in front of the baffle plate (see Figure III-2). The number and size of the air bubbles were adjusted by a needle valve and a porous chamber located inside the calming section. This variable-position porous chamber allowed the bubbles to be mixed completely in the flow by locating it in the large eddies formed at the front of the plate. Additionally, since the velocity of the flow was very small in this 6" section, large air bubbles migrated to the top where they could be purged from the system. Simultaneously, dirt and rust particles, which caused a loss of contrast in photographs, could be collected at the bottom.

These variables were adjusted to obtain an average diameter of the bubbles of approximately 0.002". The maximum observed diameter of photographed bubbles was 0.0041" in diameter, which is smaller than the smallest turbulence scale. In all cases, however, readings of the large bubbles (0.004") were rejected.

The maximum percentage volume of air in the fluid was calculated using photographs obtained at an exposure time of 1/1000 second for run 14. On the average, 18 bubbles appeared per frame, between the wall and the center of the pipe. A percentage of air by volume, the maximum relative to the size of the bubbles and to the

- CALMING SECTION -

FIGURE III-2

estimated volume of fluid, was then calculated, using 0.004" as the diameter of the bubbles. Thus all bubbles are assumed to be of maximum size in the photographed volume of

$$V_{\text{fluid}} = 0.5" \times 0.752" \times 0.0592" = 0.0222 \text{ in}^3$$

The volume of air is

$$V_{\text{air}} = 18(0.524 \times 0.004^3) = 604 \times 10^{-9} \text{ in}^3$$

and therefore

$$\% \text{ volume of air} = (604 \times 10^{-9}) \times 100/0.0222 = 0.00272$$

which is considered negligible. It is interesting to note that, at the position where photographs were obtained, the air bubbles were found to be unevenly distributed in the illuminated cross section of the pipe. A maximum concentration occurred at a radial position $r/R = 0.890$ (see Appendix G for the experimental distribution curves of radial concentration).

Two different systems of test section were designed in order to study the diameter effect present with drag reduction. The first system consisted of precision bore pyrex tubes of 1" inside diameter and the second system consisted of standard plexiglass pipes of 2.75" inside diameter (dimensions of these systems can be found in Table III-1). It may be noted in Table III-1 that, in the case of the second system, part of the 1" tube was used and connected as a bypass, in order to measure pressure drops and determine the level of degradation of the solutions being used in the 2.75" pipe.

TABLE III-1

TEST SECTIONS

	System I	System II	
Nominal diameter (inch)	1	1	2.75
Material	pyrex bore	pyrex bore	plexiglass
Inside diameter (inch)	1.0 ± 0.0015	1.0 ± 0.0015	2.75 ± 0.005
Total length (ft)	28	21	36
Entry length to optical box L/D	187	--	114
Entry length to first pressure taps L/D	54	66	60
Pressure taps-hole diameter (inch)	0.025 ± 0.005	0.025 ± 0.005	0.020 ± 0.005
Length between pressure taps (in ft)			
(1)-(4)	22	--	23.60
(2)-(4)	16	12	17.50
(3)-(4)	11	6	11.69

Four sections of precision bore 1" tubes 7 feet in length were connected and clamped on a lathe bed in order to cut down vibrations originating mainly from the pump. Great care was taken to ensure that the upstream joints presented no discontinuity to disturb the flow. This was done by inserting a Teflon plug, 0.995" in diameter and 3" in length, inside the tubes at the joint before connecting two sections together. Four pressure taps were used and connected to two 60" manometers containing Mercury and O-Dichloro Benzene of density 1.305.

Similarly, in replacing the 1" system, the 2.75" sections were carefully jointed and clamped to the lathe bed. Three pressure taps were connected to the same manometers. The justification for the many pressure drop measurements along the pipe was to check the reproducibility of the measurements and also to verify that the large entry length (δ) had been exceeded at the optical section.

III-2 EXPERIMENTAL FLUIDS

The drag reducing fluid chosen for the entire work was a polyacrylamide product of Dow Chemical Co., named Separan AP-30. This granular white powder, of an estimated molecular weight between 2 and 3 million, possesses elastic properties when in solution with water. It was preferred to other polymers because of its known level of drag reduction which can be found in previous works (30,43).

Two different weight concentrations were used: the 0.01% (dilute) and the 0.10% (concentrated). Physical properties of these solutions are presented in Appendix A. The viscous properties of the 0.01% solutions showed that their behavior can be assumed to be Newtonian with a kinematic viscosity of 1.2×10^{-5} ft²/sec at room temperature.

To ensure the same degradation level for all of the final data, a new solution was prepared for each run and the following procedure was used. A mechanical degradation by shearing in the 1" pipe at a high flow rate was followed until the recorded pressure drop measurements reached the drag reduction level desired. The desired level was determined arbitrarily by a master curve of pressure drop versus flow rate in the 1" pipe which had been determined so that enough drag reduction could be obtained in the 2.75" pipe. Then the photographic run was started with a check of pressure drop before, in the middle, and at the end to assure that negligible degradation occurred. A slightly different procedure was followed for the determination of the level of degradation of the solutions used in the 2.75" pipe. Here the solutions were degraded in the 1"

pipe to the desired level, the flow was then diverted to the 2.75" pipe for readings of pressure drop and photographs taken. This ensured that drag reduction and velocity measurements in the 2.75" pipe would be at the same level of degradation as measurements in the 1" pipe. Friction measurements were also checked at the end of a photographic run in the 2.75" pipe by additional measurements in the 1" pipe.

III-3 OPTICAL SYSTEM

The main features of the optical system shown in Figure III-3 are

- i) a light source which illuminated a thin horizontal portion of the pipe cross section,
- ii) a chopping disk for the determination of the time scale,
- iii) an optical box,
- iv) a camera assembly.

The instantaneous velocities of the fluid in the pipe were determined by photographing the air bubbles sweeping through the narrow light beam located at the center of the pipe. A three phase 'Christie' transformer of D.C. maximum output of 3300 watts at 100 amps operated a 'Christie' Xenon arc-lamp. The converging mirrors in the lamp-housing, No. BSF 50, were positioned to direct the light beam through the view section of the pipe. An adjustable slit was placed immediately in front of the lamphousing lens to produce a narrow beam, and converging lenses used after to adjust the light beam to a thickness smaller than the slits on the chopping disk.

Aluminum disks of 15" in diameter and 1/8" thick were assembled on three phase motors to obtain constant rotational speed. In order to interrupt the light and provide streaks of known duration, each wheel was divided into an equal number of radial slits and spokes. The rotational speed of the motors and the number of slits on the wheels were determined in order to obtain time scales smaller than the reciprocal of the estimated frequencies of turbulence. Table III-2 represents the different combinations used for the various runs.

FIGURE III-3

- OPTICAL SYSTEM -

These time scales also provided convenient streak lengths on the films.

TABLE III-2

Motor rpm	Number of Divisions on the wheel	Time Scale sec.	Run Number
1790	40	0.001675	4,5,6,7
3577	40	0.000837	9,10
3575	60	0.00056	11,12,13,14
1790	60	0.001118	15,16,17

The chopping disks were placed perpendicular to the light beam in front of the view section with the axis of the motor in the plane of the light slit. Optical boxes placed around the test sections were slightly different in construction. For the 1" pipe, the view section consisted of a plexiglass box filled with a mineral oil of approximately the same index of refraction as glass. The second type consisted of a polished cylinder of 2.75" I.D. in a cubic piece of plexiglass which was inserted between two sections of pipe. The upstream joint was then polished to remove any discontinuity.

Figure III-4 shows a scheme of the optical box used for the 2.75" pipe. A slit of 0.0592" in height and 2" in width was placed on the view section to assure the illumination of a volume of fluid of nearly the same X-section. The outside of the optical box was painted black in order to cut down possible reflections.

A needle of 0.020" in diameter, inserted in the test section through a partially sealed hole, could be moved across the illuminated portion of the fluid. A cylindrical guide was attached to the rear portion of the view section to properly align the needle. This

- VIEW SECTION -

FIGURE III-4

needle served to obtain the radial calibration curves (see Appendix B)

A Miranda 35 mm camera, located perpendicular to the light beam, was attached to Setco Building Blocks equipped with micrometer handwheels graduated in 0.001" increments. Real magnifications of approximately 8X and 2X were obtained from different combination of extension tubes and lenses. A 1:1.9/50 mm lens with a depth of field of 0.077" was used for the runs in the 1" pipe while a 1:3.5/80 mm lens with a depth of field of 0.65" was used in the 2.75" pipe. Thirty-five mm Tri-X films with ASA speed of 400, were used in this study.

The best exposure times and shutter openings were determined by a trial and error procedure;

- a) obtaining a maximum number of streaks per frame (one streak per radial position if possible) to cut down the labor of analysing the films and to economize on film. This necessitated a long exposure time.
- b) alternatively, a long exposure time meant that the illuminated curvature of the wall would appear very dark and would mask the streaks near the wall. This necessitated closing the shutter opening.
- c) finally the air bubbles used as tracers had to appear very sharp on the films.

Experimentally, it was found that an exposure time of 1/15 of a second with a shutter opening of f:4 gave the best results.

III-4 OPERATIONAL PROCEDURE

After a solution was found to be at the desired level of degradation, it was pumped through the system at a very high flow rate for a few minutes to enable the air to escape from the apparatus. The light source was turned on and the optical system adjusted. Then the flow rate was adjusted to the desired value and the tracers were introduced into the system. When the flow rate and the other variables of the run were found to be steady (as indicated by the magnetic flow meter, the thermometer, etc.) photographs were taken. The photographic runs took 3 to 4 hours for the first few runs, but only between 1 and 1.5 hours for all other runs due to the amelioration of the procedure to obtain calibration curves (see section on Analysis of Streak Photographs).

III-5 STREAK PHOTOGRAPHS

Typical streak photographs are shown on Figures III-5 and III-6 for the case of four different runs at four different magnifications. Figure III-5a indicates an instant in time in which all of the streaks are parallel to the wall. This streak pattern is observed on a portion of the photographs during the photographic runs of the concentrated solutions and indicates a patch of laminar flow. Other photographs which show large radial components indicate a patch of turbulent fluid. Identical streak photographs can be found in Seyer's work (43). In contrast, Figure III-5b shows the presence of radial components and represents a fully turbulent flow. Those radial components as it is emphasized from an enlarged view, as shown on Figure III-6a for a water (run II), were observed on every photograph.

Figure III-6b shows three streak patterns located in an illuminated region (from illumination of the curved inside wall of 0.059' width), to indicate how close to the wall photographs of tracers could be obtained at high magnification. The closest streak pattern is located at radial position approximately 200 microns from the wall.

III-6 ANALYSIS OF STREAK PHOTOGRAPHS

All photographs were analysed using a 'digitizer' which determines the X-Y coordinates of a picture projected onto a glass screen. The projection provides an additional magnification of approximately 20X. The 'digitizer' automatically provided an IBM punched card containing the X-Y coordinates, in volts, of points relative to the 'digitizer' frame. The X-Y frame of the digitizer (22.9" x 21.7" in full scale) consisted of a cross hair device connected to two variable resistances. A power supply coupled to the variable resistances provided a reading of 10.000 ± 0.005 volts for the full trajectory of the axis. Six voltages were then punched on a card and two extra numbers were added in order to define the number of streaks-spokes read and the radial position.

Figure III-7 shows, schematically, a projected photograph containing a single streak pattern. The large arrows represent the interrupted streak and its direction for a period corresponding to the time taken by three spokes of the timing wheel to cut the light. The small lines represent the axial and radial components of the streak and spoke for one time period.

In order to determine the streak length in the axial and radial directions for a known time period, readings of four coordinates relative to the fixed frame of the digitizer were needed. Points 1 and 2 represent the beginning and end of a streak-spoke, respectively, and points 3 and 4 locate the line determining the pipe wall and consequently the axial direction in the pipe. With these readings and appropriate calibrations which convert the voltages to actual distances,

FIGURE III-7

INTERPRETATION OF STREAK PHOTOGRAPH

the resolution of a streak into a radial and an axial component follows directly.

The dashed lines represent the band defining a radial position where the streaks were classified as acceptable. The true radial position for each acceptable streak was taken to be the location of the center of the band. In the core region, where the velocity and intensity gradients are small, the width of the band is of little consequence. However, this is not true very near the wall. For the average velocity near the wall, since the profile is essentially linear over the width of the band, the average is not changed. However, the calculated intensity will be slightly higher than the actual intensity.

Generally, if two or more correlated streak patterns were observed in the band, only one reading of velocity was taken. This tends to eliminate the bias of too many readings of the same instantaneous velocity.

The reproducibility of readings and mechanical errors involved in the use of the 'digitizer' are presented in Appendix C. The instantaneous velocities were calculated on the IBM 1800 facilities in this department. Programs used in this work are presented in Appendix J which can be found in Book II.

To determine the axial magnification, pictures of a Keuffel and Esser ruler were taken outside the tube at identical camera focus (with respect to the photographic runs) and projected on the 'digitizer' screen where measurements of the scale were obtained. Trial runs have shown that identical magnifications were obtained with the ruler inside and outside of the pipe (see Table B-II).

The technique developed to find the radial magnification and the radial positions was complicated by the non-linearity of the curves due to wall curvature. A needle of 0.020" in diameter was positioned perpendicular to the camera and located at the center of the pipe or light beam (see Figure III-4). This needle was attached to a micrometer head with a smallest division of 2 microns and mounted on a sliding block. The needle was then moved to the wall of the pipe (where it could be photographed) and a sequence of pictures were taken as the needle was retrieved, one position at a time. The fine adjustment micrometer head provides accurate positions in the wall region and the handwheels, graduate in 0.001" increments, provided subsequent measurements to the center of the pipe. For most of the runs, this set of pictures was checked by a second set which was obtained with the needle moving from the center of the pipe toward the wall. Appendix B presents typical data for the calibration curves obtained and shows a typical example of the third order polynomial radial calibration curves. The knowledge of both axial and radial magnifications and the radial positions permitted the voltages to be transformed into instantaneous axial and radial distances, whereby Δx and Δr , could be calculated.

Knowing the time scale and length scale for each streak-spoke, the axial and radial instantaneous velocities could be found

$$u_x(r) = \Delta x/T$$

$$u_r(r) = \Delta r/T$$

where $T = 60/(M)(W)$ --- (sec)

M = number of slit-spoke on the chopping wheel

All the instantaneous velocities are presented in Appendix K, which can be found in Book II.

The mean velocities could then be calculated, at a radial position, from

$$\bar{u}_x = \frac{1}{n} \sum_1^n (u_x)_i$$

$$\bar{u}_r = \frac{1}{n} \sum_1^n (u_r)_i$$

and the Root Mean Square values calculated from

$$\sigma_x = \sqrt{\frac{\sum_1^n (\bar{u}_x - u_x)_i^2}{n-1}}$$

$$\sigma_n = \sqrt{\frac{\sum_1^n (\bar{u}_r - u_r)_i^2}{n-1}}$$

RESULTS AND DISCUSSION

IV-1 PRESSURE DROP MEASUREMENTS

Figure IV-1 represents the friction factor - generalized Reynolds number data obtained for both water and polymeric solutions in the 1" and 2.75" diameter pipes. These data are tabulated in Appendix I.

The experimental values of the friction factor for water were obtained in order to check the experimental equipment as well as the Newtonian form of the friction similarity law. All the Newtonian data representing the curve labelled water, in Figure IV-1, are obviously in close agreement with the accepted Newtonian curve.

In Figure IV-1 considering the 0.01% solution first, the data represent a certain level of degradation of the polymer. As shown by comparison of friction factors, the amount of degradation in this work is somewhat less than the amount of degradation in Seyer and Metzner's work with equivalent solutions. The somewhat 'fresher' solutions used were necessary in order to get significant drag reduction in the 2.75" tube. If the solutions were too fresh however, it was found that they would degrade significantly over the period of a photographic run. In Figure IV-1, runs were made from low to high flow rates and back, as a check, over which period little degradation occurred. Thus the set of data is not influenced by any changes in shape owing to degradation.

In the photographic work the data in the figure were used as a reference for obtaining a consistent amount of degradation. Data

FIGURE IV - 1

points obtained during the photographic runs are indicated by the large triangles. Table IV-1 summarizes the photographic runs. Except for run 10 and 12, it can be observed that no apparent large degradation occurred during the photographic runs from the reported range of friction velocities calculated from pressure drop measurements. However, the friction velocities of run 12 show a significant degradation occurred during the period of the run, and consequently run 12 was split into two separate entities: run 12a and run 12b. The degradation occurred simply because of the inordinate length of time necessary to complete the photographs for this particular run at high shear rate. For run 10 an average friction velocity was used.

As noted from the triangles, drag reduction of up to 60% could be obtained for the photographic runs in the 1" pipe and of 44% in the 2.75" pipe for the dilute solutions. The maximum of flow rate of the system prevented the photographic runs at higher N'_{Re} in the 2.75" pipe while degradation caused by high shear with vibration of the system limited readings in the 1" pipe.

The prediction of drag reduction in the 2.75" pipe from the 1" pipe data points, using Equation II-16 and the Seyer and Metzner B function, agreed well with the experimental friction data as shown on Figure IV-1. These predicted lines were obtained from an estimated relaxation time function $\epsilon = \frac{K}{w}$ obtained from the 1" pipe friction data (see Appendix A). At the highest Reynolds number (highest shear stress) there is a small disagreement between the data points and the curves, however, essentially exact agreement would have been found using point values of ϵ obtained from the 1" pipe friction data.

TABLE IV-1
SUMMARY OF ALL RUNS

Run No.	Fluid	Pipe I.D. in	$\langle \bar{u}_x \rangle$ ft/sec	U^* ft/sec	N_{Re}	f 10^5	% drag	n'	$\% \Delta \langle \bar{u}_x \rangle$ ft/sec	$\langle \bar{u}_x \rangle_{max}$ ft/sec

measurements.

These calculations quantitatively support the intercept function determined by Seyer and Metzner using solutions that are significantly more elastic and for a moderately larger tube than they used. In the calculations, however, the parameter θ^+ (see Appendix A) is limited to values less than 12 so that the calculations do not provide a test of the maximum drag reduction asymptote as noted in Chapter II ($B = 32$). For larger tubes at equivalent Reynolds number, however, θ^+ will generally be less than 12 so that predictions outside this range are of little consequence.

In Figure IV-1, the friction measurements of the concentrated solutions show the characteristic slow departure from the laminar curve relatively to Newtonian fluids. These solutions were prepared and degraded similarly to the dilute 0.01% solutions. The data serve to extend the previous measurements (41) for concentrated drag reducers which are known to exhibit transitional flow at surprisingly high Reynolds numbers. As with the 0.01%, these data show a bit more drag reduction than the same concentration studied by Seyer and Metzner. It is important to notice that the experimental curves for both the 1" and 2.75" pipes are reasonably close to the predicted maximum drag reduction asymptote of Virk et al (47) if plotted according to Re^* .

In order to check the asymptotic value of the B function, the 1" pipe data curve was extended, as indicated by the dashed line, to a Reynolds number of 10^6 , where, as shown later, fully turbulent

flow is estimated to exist (estimation based on the calculated intermittency factor presented in Figure IV-13). The calculated value of B at a N_{Re}' of 10^6 was calculated to be 43. This value is significantly larger than the asymptotic value of 32.2 obtained from Seyer and Metzner's work. It should be noted that the data do not prove the existence of an asymptote, but merely show that previous asymptotes are not unique.

IV-2 INSTANTANEOUS VELOCITIES AND ANALYSIS OF HISTOGRAMS

The data for all runs of the calculated values of velocity and turbulence intensity at a given point in the tube can be found in Appendix H. These runs correspond to those summarized in Table IV-1. The instantaneous velocities are available in tabulated form in Appendix K enclosed in book II.

In order to show that the number of instantaneous velocities used to estimate the mean velocities was adequate, the cumulative mean of axial and radial velocities were considered for each run. Figure IV-2 shows, as an example for different radial positions in the 1" pipe, the levelling of the axial velocities for run 6. Large fluctuations of the cumulative mean are observed when less than 10 velocities are used, but the curves level rapidly for 30 or more observations. It is apparent from the figure that with 30 observations or more, random fluctuations in velocity have negligible influence on the calculated mean. Similar results are predicted from simple statistical analysis.

Similarly, the typical cumulative axial and radial intensities (relative to the maximum velocity) are shown in Figure IV-3. For these calculations, particularly for the axial intensity, some of the curves tend to a stationary value rather slowly. This is shown best by the top curve in Figure IV-3, which does not become stationary until about 70 observations are used. Consideration of other runs with as many as 200 observations show that any change in intensity after 70 observations is insignificant. Again, simple statistics show that many more observations are necessary to estimate a variance than a mean. Uncertainty limits on the statistical quantities are considered

FIGURE IV-2

FIGURE IV 3
CUMULATIVE INTENSITIES
RUN 6 0.01% solution

in Appendix C. As illustrated by the figure, the axial intensity was found to be more sensitive than the radial intensity.

Histograms of instantaneous velocities for both water and 0.01% solution (run 9 and run 10), at approximately the same Reynolds number, are given in Figures IV-4 and IV-5 for axial and radial velocities respectively. The gross features of these histograms are in qualitative agreement with earlier independent studies and offer support for the bursting phenomena.

Except for the histograms of radial velocity for polymer, the presence of binodal instantaneous velocity distributions, similar to those presented by Popovich (33), can be observed on Figures IV-4 and IV-5 where the histograms consistently show a dip near the center of the plot. These are typical of all the histograms obtained in or near the boundary layer. As noted in Chapter 2, this suggests that the velocities, inside the boundary layer, are composed of two different distributions depending on the origin of the fluid. The lower peak can be identified with the mean axial velocity of lumps of ejected fluid, while the higher mean axial velocity or peak results from lumps of fluid originating from the flow outside the boundary layer. Double peaks in the core were not observed.

In Figure IV-5, the histograms of the radial velocities for the 0.01% are markedly different than the Newtonian ones and show no indication of two peaks. This is viewed as a consequence of the resistance to stretching in the radial direction destroying the large fluctuations or peak in the histograms. From the radial distributions it is clear that the magnitude of the largest fluctua-

FIGURE IV-4

HISTOGRAMS OF AXIAL INSTANTANEOUS VELOCITIES

FIGURE IV-5

HISTOGRAMS OF RADIAL INSTANTANEOUS VELOCITIES

FIGURE IV-6

AXIAL HISTOGRAMS

tions is reduced relatively to water. It is difficult to make a statement regarding the frequency of large fluctuations and whether they have been reduced or not, as noted by Meek and Baer for example (27), owing to the small number of large fluctuations observed.

In order to show in more detail the nature of the axial instantaneous velocity distributions, inside the boundary layer, the distributions of Figure IV-4 have been split according to the sign of the radial component and are presented in Figure IV-6 for run 10. The mean values of axial instantaneous velocity with positive radial component were found larger than the ones associated with negative radial components. This shows that the ejections must originate from a region of low momentum, and is in agreement with Kline et al (20), Corino and Brodkey (21), Klebanoff (19). Qualitatively the mean for each side of the distribution corresponds to each of the peaks in the binodal. Splitting of the histograms for flow in core did not show that a significant difference existed between means of axial velocity associated with plus and minus radial velocities. The splitting of distributions is tabulated in Appendix F.

Comparisons were also made at identical friction velocity, as suggested by previous work (15,36,44,5), and are presented later as intensity profiles. In any event, the radial fluctuations of the velocity were found to be identically lower than the Newtonian fluids in the boundary layer when normalized to the wall parameters, but the same outside the boundary layer.

Values of the correlation factor R_0 , defined in Equation II-2, are presented as Figure IV-7 for runs 6 and 10 of the dilute

polymer and run 9 for water. Data for the other runs, which have been omitted to clarify the figure, show similar behavior. Although there is considerable scatter in the data, there are distinct trends with radial position. As discussed earlier, the bursting arguments coupled with simple continuity considerations, imply R_0 should be greater than unity in the vicinity of the edge of the sub-layer. The data points for the water connected with the dashed line, although not extending deeply enough into the sublayer, suggest this trend. To map the trend completely, one would like measurements for $Y^+ < 10$ or to positions, as indicated previously (7), where the ejections originate. For example for water, the data point closest to the wall, at a $Y^+ = 14$, has R_0 of approximately 3. Equivalently, at this position positive radial fluctuations are observed three times as often as the larger negative fluctuations, while the mean of all the observed fluctuations is zero within the statistical uncertainty of the calculations.

For the polymer solutions, runs 6 and 10, there is a distinct peak in values of R_0 at ξ of about 0.05. The values become constant at about $\xi = 0.1$. Consideration of the dimensionless velocity profiles shown later in Figure IV-16, indicates, as expected, this peak is within the sublayer and the end of the peak ($\xi=0.1$) coincides with the outer edge of the sublayer which has been shifted to about $Y^+ = 100$ for the polymer. Qualitatively the bursting arguments suggest that R_0 , in addition to being greater than unity, should show a peak owing to the acceleration from small to large radial velocity as the element of fluid moves through the sublayer. The values should decrease to

FIGURE IV-7

R_o - R_o CORRELATION FACTOR -

unity at the edge of the sublayer as the fluid mixes with the core fluid.

For the remainder of the cross section, for all the runs, R_0 scatters around unity, except over a narrow range of radial positions near to $\xi = 0.65$ where it is consistently less than unity. Seyer's earlier data (4') show exactly the same trends, however, no explanation can be offered for this behavior.

IV-3 VELOCITY PROFILES

Figures IV-8 to IV-10 represent actual time average velocity profiles for all the runs in the 1" and 2.75" pipes. The mean or bulk velocities obtained by integrating these profiles (using actual data points and not smoothing the profiles) agreed within 2% of the recorded bulk velocities, except for run 12 which was 4% in error (see Table IV-1). Owing to the small amount of scatter, these data show the usefulness of the streak photograph method over a wide range of conditions. It should be noted that no discontinuity appears in the curves owing to different magnifications used during a run.

More information about the nature of the profiles is found in Figure IV-11 where dimensionless velocity profiles are compared to predictions using Bogue's equation for turbulent flow and the Newtonian laminar equation. The water data are in excellent agreement with the predicted curve while the 0.01% profile which is at the highest Reynolds number for the dilute solutions is markedly flatter in the core. For the other runs at lower Reynolds number where less drag reduction is occurring, the flattening is not so large and the curves approach Newtonian behavior.

FIGURE IV-8

FIGURE IV-9

FIGURE IV-10

FIGURE IV-11

IV-4 TRANSITIONAL FLOW

Figure IV-12 is a plot of the velocity data for the 0.10% solutions which serve to extend Seyer's earlier data (41) for transitional flow. The fact that these profiles reflect transitional flow has been documented in detail before. Briefly, the transitional flow consists of alternating patches of turbulent and laminar fluid. The relative number of each is described by the intermittency factor, γ , defined as the fraction of the time the flow is turbulent. Thus γ equal unity is fully turbulent while γ of zero reflects laminar flow. Furthermore, it has been shown (35) that the intermittency, at the center of the pipe, is given simply by the position of the velocity profile relative to the fully turbulent and fully laminar profiles.

Figure IV-13 represents the intermittency factors calculated from the velocity profiles at the center line of both 1" and 2.75" pipes and are compared with Rotta's data points for water (35). The 1" pipe intermittency factor curve indicates how slowly γ increases with the Reynolds number for the concentrated drag reducer as compared to the Newtonian curve (see Rotta (35) and Patel and Head (31)). This curve indicates also that the fully turbulent flow will be reached at a $N'_{Re} = 10^6$. Although there is some uncertainty in locating the point of zero intermittency, it is clear that the Reynolds number where turbulence first appears is not significantly different from 2100. From the frictional data curve on Figure IV-1, it was not so evident that the transitional flow existed at that N'_{Re} .

The velocity measurements indicated that the intermittency factor depends strongly on the tube diameter where a 39% increase

FIGURE IV-12

FIGURE IV-13

relative to the 1" pipe curve was recorded for the 2.75" pipe at a N_{Re} of 2×10^4 . Similarly the intermittency factors determined from Seyer's profiles in a 1" pipe are significantly larger than the ones in this work and suggest a Reynolds number of about 10^5 is necessary for fully turbulent flow. Thus the intermittency, at high Reynolds number is very sensitive to the level of degradation of the polymer.

Figures IV-14 to IV-16 give the corresponding intensities for the transitional flow. These simply confirm Seyer's earlier data (41) which shows a very small radial intensity but an apparently large axial intensity. The radial fluctuations decrease rapidly to zero, because they can only occur γ of the time; however, large axial fluctuations still occur because of the profile alternating between fully laminar and fully turbulent profiles.

These measurements make it apparent that the limits of transitional flow should be investigated in order to determine the range of applicability of the similarity laws for drag reducers. The limits must be related to the thickening of the boundary layer as defined by Equation II-12 for example, and clearly must be less than the tube radius. Currently the true upper limit of stable boundary layer thickness is unknown; however, for Newtonian fluids at Reynolds number of 2100 the thickness is approximately $\xi = 0.1$.

5

IV-5 SEMILOGARITHMIC VELOCITY PROFILES

Velocity profiles for the dilute drag reducer and water, plotted on U^+ - Y^+ coordinates are given by Figure IV-17. For the polymer solution the solid lines represent eyeball estimates of the best curve through the data. The curve through the water data has been determined using Equation II-11. At Reynolds number of 80354 in the 1" tube there is a considerable shift in the data points for $30 < Y^+ < 100$. The upper points which form a continuous curve to Y^+ about 90 were obtained at high magnification while the remaining points were obtained with a lower magnification. As noted before and in Table IV-1 with runs designated 12a and 12b this run suffered from a significant amount of degradation. Thus the shift simply reflects the increase in U^* that occurred between the high and low magnification portions of the run. In the other runs where a change in U^* was noted the average was used in Figure IV-17 and one cannot distinguish between data obtained at high and low magnifications.

In all cases the data correspond roughly to Equation I-1 but not in detail. In particular the Newtonian data have a constant intercept B and slope A up to Y^+ about 400 but deviate considerably at higher Y^+ . This behavior is quantitatively equivalent to that observed in the number of other studies reporting turbulent velocity profiles of Newtonian fluids (18).

The velocity profiles for the 0.01% polymer solutions show a marked similarity to the Newtonian data at high Y^+ suggesting the same correction $C_3(\xi, f)$, may be applicable. From the figure it is evident that the velocity profiles could be interpreted in a number of

FIGURE IV-17

LOGARITHMIC VELOCITY PROFILES

ways:

- (i) using Equation I-1 the best fit line through the data would clearly have a slope somewhat higher than the value 2.46 for Newtonian fluids.
- (ii) using Equation I-1 with $A = 2.46$ would fit the data poorly, at least at the higher Reynolds numbers, and would result in a large uncertainty in vertical location of the line.
- (iii) using Equation II-11 and assuming Bogue's correction function, at least as a first approximation, is applicable to the drag reducers.

It is emphasized that each of the above yield different values of the intercept function B . In the extreme case the data in Figure IV-17 shows that the discrepancy between (i) and (iii) above could be as large as 20%. In the case of predictions for small amounts of drag reduction in large tubes an error of 20% in B can be shown to cause significant discrepancies in predicted pressure drops.

For drag reducers apparently only one study has applied Bogue's correction function to velocity profiles. As mentioned earlier Nicodemo et al (29) have measured velocity profiles in typical drag reducers using a Pitot probe calibrated in a circular tow tank filled with the polymer solution under consideration. Based on the observation that the data on a semilog plot are linear over only a small portion of the tube near the center, they conclude the profiles cannot be interpreted according to Equation II-11 without major modification. In contrast the velocity profile obtained by Seyer (41)

from streak photographs is in good agreement with Equation II-11. A detailed examination of the profile however, indicates the data are really inconclusive and could be just as well interpreted with or without the function $C_3(\xi, f)$. This being mostly because $C_3(\xi, f)$ is negligible for Seyer's data.

In Figure IV-17 Bogue's correction function has been applied to the smoothing curves drawn through the polymer data. The resulting corrected velocity profiles are given by the lines located below the data points of the various runs. For all of the runs the correction applied to the smoothed curve yields a line that is parallel (within the uncertainty of locating the smoothed curve) to the corrected Newtonian curve showing that (a) Bogue's correction function is adequate for the drag reducers, and (b) the constant A is the same as for Newtonian fluids.

Examination of the resulting velocity profiles shows that the difficulty in interpreting the uncorrected profiles results from the greatly thickened transition portion of the profile merging with the high Y^+ data approximately where the correction function becomes significant. For Newtonian fluids there is a large range of Y^+ ($30 < Y^+ < 400$) separating these two regions.

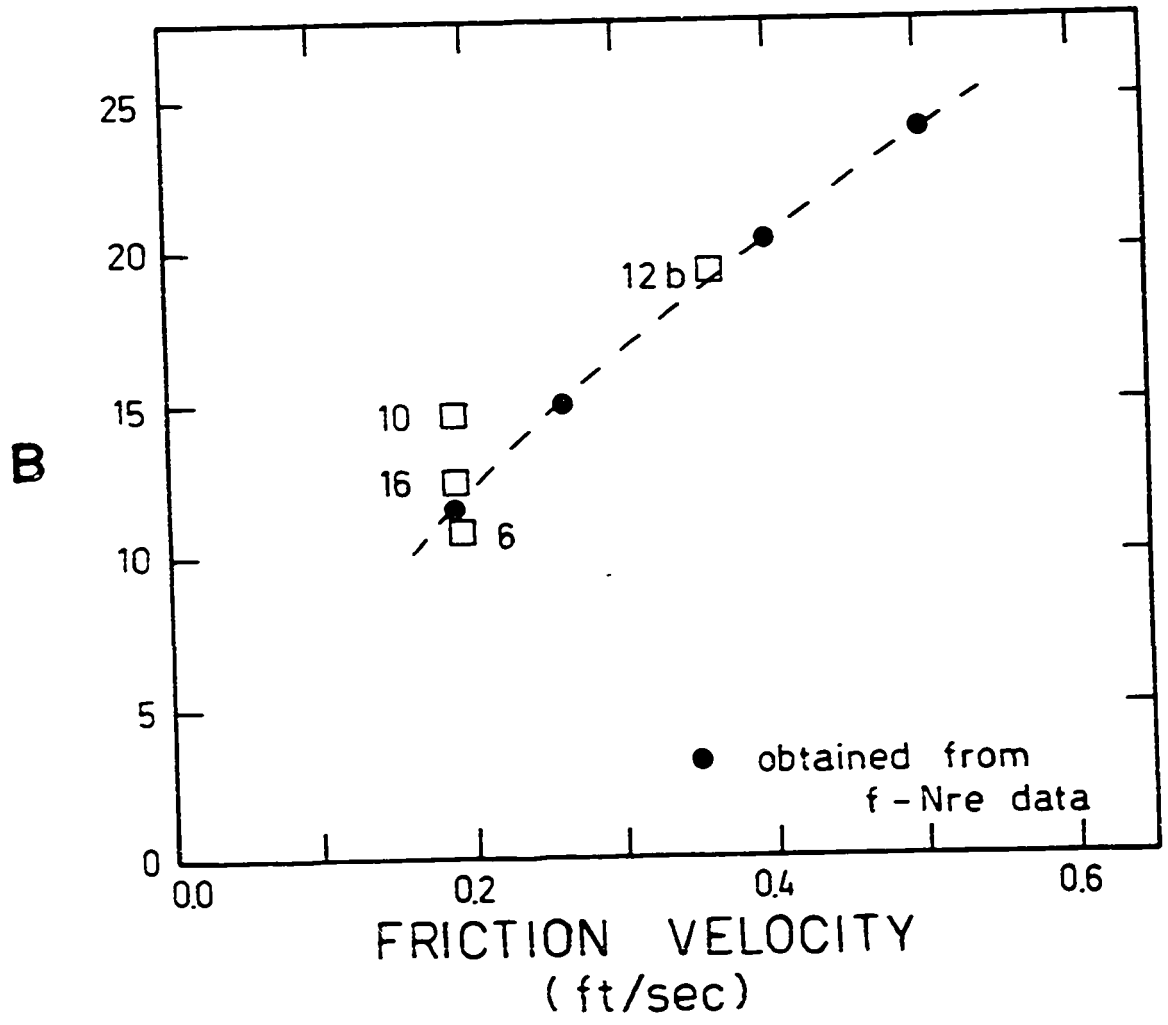

Figure IV-17 shows quantitatively the marked thickening of the sublayer region. For the highest Reynolds number the influence of the wall extends to $Y^+ = 200$ whereas for Newtonian fluids $Y^+ = 30$ is about the upper limit of the wall region. It is interesting to note that the buffer region is somewhat larger in the 2.75" than that in the 1" tube.

If the correction factor is ignored significant errors may result in the determination of the intercept $B(\theta^+)$ and uncertainty in the intercept function may be serious in prediction of drag reduction particularly in large pipes.

Since no elasticity measurements were made in this work it is not possible to determine B as a function of the parameter θ^+ as is suggested by Seyer (43). However, for a given polymer and concentration θ^+ depends on U^* and therefore it is equivalent to plot B as a function of U^* .

The function B as determined from friction measurements and corrected velocity profiles is given by Figure IV-18. The agreement from the velocity profiles of the two tubes as well as that from friction measurements supports in some detail, and over a significant range of variables, the velocity profile and attendant analysis given by Equations II-1 to II-11. The largest disagreement occurs for the point designated as run 10. As indicated by the somewhat lower friction factor for this point in Figure IV-1, the polymer had not been degraded sufficiently and so the higher value of B is expected. Alternatively, if the function were plotted against the relaxation time parameter the higher elasticity of the material at conditions of run 10 would cause this point to shift to the right relative to points 6 and 16, and would fall much nearer to the curve.

FIGURE IV-18

Rudd (37) indicated that if Schubert and Corcos theory of the wall turbulence is considered and modified for the case of viscoelastic fluid, then the similarity laws can be rescaled to take account of the viscoelastic terms so that the parameters for drag reducers can be predicted from the Newtonian values. From his development and experimental determination of the scale factor, he obtained the following expression for the B function

$$B = 12 D - 2.44 \ln D - 6.5 \quad \text{IV-1}$$

where

$$D^2 = 1 + K e^+ \quad \text{IV-2}$$

is the scale factor with $K = 0.5$ as found from Rudd's data. This scale factor should, if calculated for each run, rescale all turbulence parameters (velocity and distance) to bring them on a single curve, the Newtonian case. From his work the predicted values of B with e^+ were compared to the experimental results of Seyer and Metzner. The B functions are in agreement for e^+ lower than 17 but Rudd's estimated asymptote is higher with value of 40 for e^+ of 37. This is in reasonable agreement with the extrapolation of the friction data in this work.

It is interesting to use his correlation to estimate the boundary layer thickness and the value of B for run 12b of this work. The estimated relaxation time obtained from the friction data of run 12b and using Equation II-16 was used in Equation IV-2 to evaluate the scale factor D. It was found that $e = 8.8 \times 10^{-4}$ sec and $D = 2.4$. The estimated dimensionless thickness of the boundary was $Y^+ = 84$

$(Y_{1\text{water}}^+ \times D)$ and the value of B was found to be 20.61. From Figure IV-17 the intercept is 19.1 for this run and the boundary layer extends to something in the order of 100. This is surprisingly good agreement.

IV-6 TURBULENCE INTENSITIES

The RMS values obtained for each set of the axial and radial instantaneous velocities are used to estimate the relative turbulence intensities. As indicated in Chapter I, great confusion is found from a survey of the measured relative intensities in the drag reducers owing to the uncertainty in accuracy of the results and in how to scale or compare them for different systems.

The sample histograms for polymer in Figure IV-5 when compared to water have already indicated a significant lowering of radial fluctuations or intensity occurs for the dilute drag reducer at a given Y^+ .

Figures IV-19 to IV-23 show all of the Newtonian intensity data obtained in this work. The curves on the figures represent Sandborn's data for air at the indicated Reynolds numbers. Runs 4 and 5 on Figures IV-19 and IV-20 do not extend over an appreciable portion of the tube but are considered to be in excellent agreement with the curves at the smallest radial positions. Reference to Appendix H shows these data are based on a small number of instantaneous readings relative to the other runs in this work.

In Figure IV-21 for run 9 the circled points form a group of data which are consistently lower than the curves. These data which have been circled are from a separate set of photographs (the high magnification portion of the run) than the remaining points and apparently reflect some mistake in determining calibration constants. If they are ignored the data show excellent agreement with Sandborn's curves over the entire section.

The data in Figures IV-22 and IV-23 for the remaining runs which are at the highest Reynolds numbers are again in excellent agreement with the curves over most of the section. Near the centerline the data are somewhat higher than the curves, however, it is not clear what the origin of this discrepancy is. As shown in Appendix E, calculations of the Reynolds stress by forming the product $\overline{U_x'U_r'}$ and the kinetic energy $\overline{U_x'U_x'}$ for run 11 are in excellent agreement with the measured Reynolds stress and Laufer's (21) kinetic energy. Thus it is not clear that the intensities are seriously in error.

The .01% intensities relative to maximum velocity for runs 6, 10 and 12 in the 1" tube and run 16 in the 2.75" tube are compared to the air curves in Figures IV-24 to IV-27. These figures provide a comparison of the intensity calculated relative to maximum velocity at approximately equal Reynolds number. Since the water and polymer viscosities are about the same the comparison could also be viewed as one at the same flow rate or bulk average velocity.

In each run the radial intensities are markedly lower at all radial positions than the intensities for Newtonian fluids. The amount of lowering of the intensities is ordered according to the amount of drag reduction; thus the radial intensities for the 2.75" pipe are somewhat higher than those in the 1" pipe at an equivalent Reynolds number.

Axial intensities for the low Reynolds number runs, run 6 and run 10 are not altered significantly from the Newtonian values. At high Reynolds number however, they are significantly lower in the core. Notice that the Newtonian curves of axial intensity in Figures IV-26 and IV-27 are for Reynolds number of 170000 and that a curve for Reynolds number coinciding with the data points would be above this curve.

In all cases the rapid increase in intensity, usually associated with the edge of the boundary layer, is shifted toward larger radial positions. This suggests, as do the velocity profiles, a thickening of the boundary layer occurs.

The intensity data made dimensionless with friction velocity U^* are plotted as a function of Y^+ in Figure IV-28. The effect of dividing by U^* is to shift the intensities of the drag reducers upward relative to the water curves. In the lower portion of the figure the radial intensities still tend to be lower than the Newtonian intensities, particularly in the wall region. The general trend is that the polymer intensities are increasing more slowly with radial position, in accord with the thickening of the sublayers. Ultimately, they attain about the same value as for Newtonian fluids. In terms of the bursting arguments the radial intensities indicate that the large wall eddies are simply rescaled in size. It is apparent, however, since the frequency of occurrence can be reduced, as shown in studies by Fortuna and Hanratty (15) as well as Meek and Baer (24), that the process of lowering the radial intensities is more complicated than scaling just the size.

In contrast to the radial intensities the axial intensities in Figure IV-28 relative to U^* are all significantly larger than the Newtonian values in the wall region and approach a single curve in the core region. The shape of these curves is identical to Rudd's (26) for a similar amount of drag reduction. However, these data are not ordered with respect to amount of drag reduction on this type of plot. Reference to Table IV-2 shows that runs 5, 6, 10 in the 1" tube and 16 in the 2.75" tube are all at approximately the same U^* (the value of U^* for run 12 is two times larger).

In Figures IV-17 and IV-18, it is seen that these runs have increasing intercepts owing to different levels of elasticity

FIGURE IV-28

of the fluid. The increased intensities are in the order of increasing elasticity or equivalently increase in the velocity profile intercept, B , at fixed U^* . It is obvious that the level of intensity, at a fixed U^* , is very sensitive to the elasticity of the system.

Consideration of the velocity intercept for run 12, which has the highest intercept of all the runs, would indicate the intensities for this run should be extremely high. This is not the case, however, as these intensities are lower than for runs 10 and 16 and about the same as those of run 6. In the core these data are consistent with the other runs.

Dimensional considerations suggest (see Chapter II) that the increase in intensities in the wall region should be ordered with respect to the parameter $\theta^+ = \frac{\theta U^{*2}}{\nu}$. Rudd (37) as indicated earlier has formulated an explicit expression for the dependence of the flow parameters on θ^+ . Figure IV-29 is a plot of the rescaled intensities and distances as suggested by Rudd. The parameter D , defined in Equation IV-1, has been determined directly by substituting values of B from the velocity profiles. Notice if equation IV-2 were used to find relaxation times, the times so determined would be slightly different than those shown in Appendix A. The axial intensities for the runs with equal U^* are collapsed to single curve which coincides with the curve for water. Rudd has based his conclusions on a similar plot for only one intensity profile. The intensities for run 12, which is at different U^* , are not scaled properly. In fact the spread of intensities between run 12 and the master curve is about the same as the maximum spread in the previous

FIGURE IV-29

- RELATIVE INTENSITIES -

figure.

The radial intensities do not superimpose on the water curve, but are much lower at all radial positions. The polymer intensities follow a single curve but there is no obvious improvement over the plot of the same data in Figure IV-28.

CONCLUSION AND RECOMMENDATIONS

An extensive series of measurements of instantaneous velocity streak photographs have been obtained in Newtonian and drag reducing fluids. Based on a comparison with available Newtonian data of velocity profiles and axial and radial intensities, the quantitative usefulness of the technique is verified. Since the streak photograph technique does not suffer from the serious limitations of probe devices in drag reducers it is implicit that the measurements in the drag reducing fluids are also quantitatively correct.

Histograms of instantaneous axial velocity confirm the presence of binodal distributions in the boundary layer. Histograms of radial velocity are binodal for water but there is no evidence of two peaks for the polymer solutions. By ordering the set of instantaneous velocities according to the sign of radial component it is found that on the average the fluctuating velocities toward the center of tube are large than those toward the wall. This observation agrees with the visual observations of "bursting" described by Brodkey amongst others. For a given radial position the largest fluctuations in radial histograms for polymer solutions are less than those for Newtonian fluids at similar conditions.

For drag reducing fluids Bogue's correction function must be applied to the data in order to obtain a consistent representation of velocity profiles. Failure to use the correction function can result in large uncertainties in determining the intercept $B(\theta^+)$ of the velocity profiles.

The correct form of the function $B(\theta^+)$ determined by Seyer and Metzner is correct for θ^+ less than approximately 12. At large θ^+ , where a drag reduction asymptote is predicted the function is not unique. The data in this work show that lower friction factors can be observed than Seyer and Metzner's.

Turbulence intermittency factors, determined from velocity profiles for a 0.1% solution in a one-inch pipe show the first turbulence appears at a generalized Reynolds number of 2100. Extrapolation of the data show that the flow is not fully turbulent until Reynolds numbers in the vicinity of 10^6 are attained. Consideration of earlier data and data obtained in a 2.75" pipe show the intermittency is highly sensitive to level of elasticity as well as the diameter. These measurements show the need for further consideration of the so-called asymptote as well as the limits of transition.

If the root mean square of the axial and radial velocity fluctuations of the polymeric solutions are made dimensionless with the maximum velocity, both are found to be lower than those for water at all radial positions; the amount of lowering being larger as the level of elasticity of the solutions increases. On the other hand when compared to friction velocity the axial fluctuations are larger while the radial remain smaller than those for Newtonian fluids. Scaling of the intensities according to Rudd does not superimpose the curves unless only data obtained at the same friction velocity are considered.

Further work is needed to determine the proper scaling factors for turbulence in these systems.

APPENDIX A

RHEOLOGICAL BEHAVIOR OF THE SOLUTIONSi) 0.01% Solution

A sample of solution was drawn from the experimental apparatus when pressure drop measurements, recorded in the 1" and 2.75" pipes, corresponded to the predetermined curves for 0.01% solution as presented in Figure IV-1. Viscometric measurements were done with a Weissenberg Rheogoniometer precalibrated with a standard oil. Curves for the standard oil and polymer solutions are presented in Figure A-1. The straight line obtained for the standard oil is representative of Newtonian behavior with a slope of unity and a viscosity of 8.62 cps. The specified viscosity at the same temperature is 8.63 cps.

The curve of the 0.01% solution indicated a slightly pseudo-plastic behavior in the range of shear rates obtained with the Rheogoniometer. The flow behavior index varied from 0.922 to 0.930 and the apparent viscosity from 1.25 cps to 1.50 cps at the lowest shear rate. Although the Rheogoniometer data are at much lower shear rates than those in the pipe experiments, they join smoothly with Seyer's data (41) at the shear stresses of interest. Thus the kinematic viscosity is assumed to be 1.2×10^{-5} ft²/sec for τ_w ranging from 0.06 to 0.25 lb/ft², which is the value used by Seyer. Table A-1 represents the viscometric data and the results obtained from the Rheogoniometer for the standard oil and 0.01% solution.

RHEOGONIOMETER PARAMETERS

α - angle of the cone	0.952°
d - diameter of the cone	10.00 cm
K_t - torsion bar constant	8.916 dynes-cm/microns
Δt - displacement	volts
β - transducer calibration	1.009 micron/volt
W - rotational speed	rpm

FORMULAE

$$\text{SHEAR STRESS } \tau = (3.82 \beta \Delta_t K_t) / d^3 = 0.0343 \Delta_t \text{ dynes/cm}^2$$

$$\text{SHEAR RATE } 8\langle \bar{u}_x \rangle / D = (360 W) / (60 \alpha) = 3.61 W \text{ sec}^{-1}$$

ii) 0.10% Solution

The experimental points, calculated from the laminar friction data, are compared to Seyer's (41) viscometric data for the 0.10% solutions on Figure A-1. Calculated values are tabulated in Table A-II. The procedural similarity in the preparation of the solutions and the excellent agreement obtained with Seyer's data for the same concentration show the shear rate-shear stress behavior of the 0.10% solution is the same. Therefore for calculational purposes the same relation assumed by Seyer will be used for $6 \times 10^2 < \frac{8\bar{u}_x}{D} < 1.2 \times 10^4$.

$$\ln \tau_w = -6.540 + 0.598 \ln \frac{8\bar{u}_x}{D} + 0.00599 \left(\ln \frac{8\bar{u}_x}{D} \right)^2$$

where τ_w is in psf

$$\frac{8\bar{u}_x}{D} \text{ is in } \text{sec}^{-1}.$$

TABLE A-II

Shear Rate $(8\bar{u}_x/D)(\text{sec}^{-1})$	9.32	20.56	49.36	51.43

iii) Estimate of the Elasticity Level and Calculations for Prediction of 2.75" Friction Factor from 1" Data

Using Equations II-16, II-12 and I-4, four of the experimental friction points tabulated in Appendix I for the 0.01% solution were used to estimate (by a trial and error solution of Equation II-16) values of B and consequently relaxation time in the range of the experimental photographic runs. These calculations are tabulated in Table A-III. Figure A-2 shows the relaxation time as a function of τ_w along with Seyer's (41) and Oliver's (30) data for their respective 0.01% Separan solutions. As suggested, from the lower friction measurements, the level of elasticity of the present solutions is higher than Seyer's solutions. The dashed line is taken to represent the relaxation time of the 0.01% solution in this work and for purposes of calculation, can be represented empirically by

$$\ln \theta = 0.000388 - 0.4930 \ln \tau_w$$

where τ_w is expressed in psf and θ in sec^{-1} .

TABLE A-III

LEVEL OF ELASTICITY FOR 0.01% SOLUTIONS

Reynolds number	132980	93369	50000	30000
Friction factor	0.00140	0.00177	0.00270	0.00382

iv) B Function Obtained from Velocity Profiles

Table A-V represents the intercept values of the corrected semi-logarithmic velocity profiles in Figure IV-17. These values of B for the 0.01% solutions are plotted versus the friction velocity in Figure IV-18.

TABLE A-V

VALUES OF B FUNCTION

Run Number	U^* friction velocity (ft/sec)	$B(\theta^+)$
6	0.1890	11.0
16	0.1832	12.5
10	0.1830	14.7
12b	0.3606	19.2
12a	0.3462	≈ 21.0

APPENDIX B

CALIBRATIONi) Calibration of the Magnetic Flowmeter

The bulk flow rate was measured by a 2" Foxboro, Model 696, magnetic flowmeter connected to a Hewlett Packard strip chart recorder. From a previous study (6), calibration curves for water were obtained from a weighing procedure for two sensitivities in order to cover a range of flow rates from 0-32 and 0-210 USgal/min. Figure B-1 shows the high and low sensitivity curves of flow rate versus voltage obtained from the previous study. The data points presented on the figure serve as check points. These data were taken during the course of this work and verify the calibration curves.

ii) Check of Velocity Profiles

For every photographic run, a check of the velocity profile against the flowmeter reading was obtained by integrating the velocity profile. The percent difference between the bulk velocities obtained from the integrated profiles and the recorded bulk velocities are shown on Table B-I. A $\pm 2\%$ average difference can be found (except for run 12 which was -4%) confirming good agreement for the measured profiles.

FIGURE B - 1
FLOWMETER CALIBRATION

TABLE B-I

COMPARISON OF RECORDED BULK VELOCITY
WITH INTEGRATED BULK VELOCITY

RUN NUMBER	BULK VELOCITY (ft/sec)		PERCENT DIFFERENCE
	Recorded	Integrated	
4	4.825	4.802	+0.48
6	4.428	4.428	-1.76
9	4.975	5.084	-2.15
10	4.980	5.080	-1.97
11	13.26	13.672	-2.49
12	11.62	12.128	-4.18
13	22.02	21.616	+1.87
14	33.40	33.64	+0.72
15	4.996	5.142	+2.79
16	5.068	5.09	+0.43
17	8.77	8.668	+1.08

iii) Axis of the Digitizer

As already mentioned, the full scale movement of the digitizer cross hair for both axes of the digitizer was 10 volts. In order to transform the digitizer readings (in mvolts) into length scales, calibration functions for both axes were obtained, mainly in the limits of the projected frames by taking readings of a 10 cm ruler.

Figure B-2 shows the voltage corresponding to 10 cm movement in both the X and Y directions for positions spanning the digitizer screen. Calibration points in the X-direction have been determined for various Y positions and similarly Y-direction readings have been taken for various X-positions. The data show the response is constant over the entire surface of the screen. Before analyzing a series of photographs these data were used as a check to ascertain that the digitizer electronics were stable and operating properly.

iv) Projected Axial Magnification

As mentioned in Chapter III, several pictures of a ruler divided into 1/10 cm increments were taken and projected on the digitizer screen where the projected length was measured. Because difficulties were encountered in disconnecting the optical box for every run, in order to take a picture of the ruler inside the pipe, the pictures were taken with the ruler outside the pipe. To assure the validity of this procedure, the projected axial magnification was obtained from two different rulers, one inside the pipe, the other outside. As shown in Table B-II for run 15 as an example, the percentage difference in magnification for the photographs of rulers inside and outside the pipe demonstrates the correctness of the procedure.

FIGURE B-2

Very careful attention was given to the focus of the ruler, particularly with the 1.9 lens assembly which had a relatively large depth of focus. Table B-III shows results for run 15 where magnifications were obtained for different focal distances (the ruler still in focus). For a maximum deviation of 30 microns from the apparent point of focus, the magnification could be off by 1%. This indicates little variability in magnification owing to focus of the camera.

TABLE B-II

AXIAL MAGNIFICATION DATA FOR RUN 15Projected axial magnification

ruler inside	ruler outside
31.2	31.0
31.7	31.5
31.3	31.5
31.5	31.7
31.5	31.7
31.2	31.5
31.7	31.5
31.9	31.7
31.8	31.8
31.1	--
<hr/>	<hr/>
31.49 cm/ cm	31.54 cm/ cm

Percent difference is 0.159%

TABLE B-III

AXIAL MAGNIFICATION WITH CHANGE OF FOCUS

For the camera raised higher than the focal point for run 15.

focal point	10 microns	20 microns	30 microns
31.50	31.30	31.50	31.12
31.50	31.54	31.30	31.34
31.50		31.46	31.24

v) Radial Magnification

As in the case of defining the axial magnification, projected radial lengths were measured to determine the radial magnification. As explained in Chapter III, Section III-6, photographs of the tip of a needle were taken at known radial positions. Figures B-3 and B-4 show, as an example for run 6, the curves obtained for high and low magnification of actual distance from the wall versus the distance measured on the digitizer screen. It can be noted that the curve for high magnification crosses the origin and that pipe curvature makes the magnification vary. A third order Lagrangian interpolating polynomial was used in the computer program to represent these curves.

Data obtained for calibrations for each of these runs in this work have been omitted from this thesis because they are of no significance once the projecting apparatus has been moved. The axial and radial magnifications can be determined directly from the photographs which have been filed.

FIGURE B - 3

FIGURE B-4
RADIAL CALIBRATION CURVE
low magnification

APPENDIX C

ANALYSIS OF ERRORSi) Confidence Interval for Time Average Velocities and Variances

The mean values and variances of the axial and radial velocities were obtained from measurements of instantaneous velocities. Because the population from which the sample was drawn has unknown mean (μ) and unknown variance (σ^2), the 100(1 - α)% confidence interval for the mean value in which μ is contained, if 30 or more observations are taken, is

$$\bar{u} \pm Z_{\frac{\alpha}{2}} \left(\frac{S_m}{\sqrt{n}} \right) \quad \text{C-1}$$

and the 100(1 - α)% confidence interval for σ^2 is

$$\frac{(n-1)S_m^2}{\chi_{n-1, \alpha/2}^2} \leq \sigma^2 \leq \frac{(n-1)S_m^2}{\chi_{n-1, 1-\alpha/2}^2} \quad \text{C-2}$$

where S_m is the variance of a sample of n observations from a normal distribution $N(\mu, \sigma^2)^*$.

As already mentioned and tabulated in Appendix H most of the mean velocities and variances were obtained from a large sample (larger than 80). In order to show the confidence limit associated with the data of this work an example is done for the case where the number of observations was small. This gives the largest confidence interval.

* "Introductory Engineering Statistics", by Guttman, I. and Wilks, S.S., John Wiley, N.Y., 1965.

For run 6 at a radial position near the wall 27 observations were recorded and the sample mean velocity and variance (in the axial direction) obtained were

$$\bar{u}_x = 1.958 \text{ ft/sec}$$

$$S_m = 0.568 \text{ ft/sec}$$

Thus the 95% confidence interval for the mean velocity is

$$\pm 0.318 S_m$$

and for the variance

$$0.818 S_m \leq \sigma \leq 1.373 S_m$$

Thus the time averaged velocities are generally estimated to within less than 5% at 95% confidence. The confidence interval for variance is somewhat larger.

ii) Experimental Errors in Reading the Streaks

The mechanical errors, e , involved in reading the streaks from the digitizer table can be expressed as

$$X_m = X_t + e \quad \text{C-3}$$

where X_m is the measured length of a streak

X_t is the true length of a streak.

If no intrinsic error is assumed and the mechanical errors are normally distributed, then the net effect on the measured mean value is zero and

$$\bar{X}_t = \bar{X}_m \quad \text{C-4}$$

In the case of the sample variance, the mechanical errors are additive. The measured sample variance can be expressed as

$$S_m^2 = \frac{1}{n-1} \sum_1^n (x_m - \bar{x})_i^2 \quad C-5$$

Substituting Equation C-3 in the last equation and manipulating the terms the following expression is obtained

$$S_m^2 = \frac{1}{n-1} \sum_1^n e_i^2 + \frac{1}{n-1} \sum_1^n (x_t - \bar{x})_i^2 + \frac{1}{n-1} \sum_1^n 2e_i(x_t - \bar{x})_i \quad C-6$$

The first term in this equation can be estimated from repeated readings of a known length with digitizer apparatus. The last term of Equation C-6 represents the covariance between the error and $(x_t - \bar{x})$ and is zero because random mechanical errors cannot be correlated with turbulent fluctuation $(x_t - \bar{x})$.

Thus Equation C-6 can be expressed as

$$S_m^2 = S_e^2 + S_T^2 \quad C-7$$

or rearranging the equation

$$\frac{S_T}{S_m} = \sqrt{1 - \frac{S_e^2}{S_m^2}} \quad C-8$$

To estimate S_e , Figure C-1 gives the variance obtained from reading a given streak many times with the digitizer as a function of the length of the streak. These readings show scatter or variance because of the digitizer electronics error involved, because of the blurry ends of the streaks, and human error in positioning the cross hair. The error

FIGURE C-1

increases slightly with length because the longer streaks have a larger tail or blurred region and it is therefore more difficult to locate the beginning or end of the streak.

As an example, run 14 was chosen because of the measured low intensities. The calculated sample variances obtained at $y = 0.0119$ are

$$S_{mx} = 2.76 \text{ ft/sec}$$

$$S_{mr} = 0.239 \text{ ft/sec} \quad \text{for } n = 87$$

as found in Appendix H.

At this position the corresponding average actual lengths measured were

$$\Delta x = 0.100'' \quad \text{and} \quad \Delta r = 0.000''$$

Taking the axial magnification (31.4) and using the radial calibration curve both lengths can be transferred into projected lengths on the digitizer screen

$$\Delta x = 3.05'' \quad \text{and} \quad \Delta r = 0.00''$$

Using Figure C-1, S_e can be found as

$$S_{ex} = 0.0084'' \quad \text{and} \quad S_{er} = 0.010''$$

Or in terms of velocities, using the time scales in Table C-I

$$S_{ex} = 0.0398 \text{ ft/sec}, \quad S_{er} = 0.1485 \text{ ft/sec}$$

Plugging into Equation C-8

$$S_{tx} = S_{mx}$$

$$S_{tr} = 0.785 S_{mr}$$

This calculation shows that errors in the calculated axial intensity owing to measuring errors are entirely negligible. For the radial intensity however, the calculated value can be as much as 21.5% higher than the true value owing to the mechanical error. This is the extreme case and generally for other runs or other radial positions the percent error will be much smaller.

iii) Location of Wall and Tracers

From Figure III-6b it can be observed that the wall location is masked by a shadow region. Along with uncertainty because of wall curvature it was estimated from a projected photograph that the wall could be located to within ± 0.0010 ". The smallest reading recorded for the radial position near the wall is for run 6 and is 0.0040". This radial position can then be 25% in error, but represents the worst case encountered. Furthermore the error of ± 0.001 " in the locating the wall is of the same order as the length corresponding to non-zero average radial velocities reported in Appendix H.

iv) Error in Intensity

a) air bubbles

As already discussed in Seyer's thesis (41), the influence of the air bubbles on the intensity measurements will be negligible if their size is smaller than the scale of the energy containing eddies (approximately 0.006"). Because in this work the average diameter of the bubbles was found to be 0.002", no influence is expected.

b) uncertainty in radial position

The fact that velocities were taken over a band of positions

rather than at a single radial position causes the calculated intensities to be too high. This occurs because of the mean velocity gradient and so velocities of streaks at the bottom of the band (nearest to wall) are on the average slightly smaller than velocities of streaks near the top. Thus there is a fluctuation in velocity owing to variations in the radial position of the streaks. The magnitude of the error depends on the velocity gradient as well as the width of the band.

In reading the photographs the radial positions of interest were determined by lines drawn on a clear plastic sheet which was placed on the digitizer screen. The situation is illustrated by Figure III-7 where the limits of the band correspond to lines on the plastic sheet. For positions near the wall the spacing of the lines on the sheet was approximately .25" and was about 1" for positions near the centre. For the high magnification portion of run 6 the .25" band on the plastic sheet corresponds to a band .0024 inches wide in the one inch pipe.

A conservative estimate of the error in the calculated intensity can be obtained by assuming the streaks are located either at the center or top or bottom of the band. In fact there will be a distribution of positions which peaks sharply at the center of the band. In the following sketch the positions $y + \Delta y$ and $y - \Delta y$ represent the limits of the band for a radial position y . Suppose that

n streaks are observed in the band. Roughly $n/2$ streaks will have a velocity characteristic of position y , while $n/4$ streaks will have

velocities reflecting the top position and $n/4$ reflecting bottom.

Thus the variance owing to velocity gradient will be

$$\begin{aligned}
 S_u^2 &= \frac{1}{n-1} \left\{ \sum_i^n (\bar{u} - u)_i^2 \right\} \\
 &= \frac{1}{n-1} \left\{ \sum_{i=1}^{n/2} (\bar{u} - \bar{u})^2 + \sum_{i=1}^{3/4n} (\bar{u} - (\bar{u} + \Delta\bar{u}))_i^2 \right. \\
 &\quad \left. + \sum_{i=3/4n}^n (\bar{u} + (\bar{u} - \Delta\bar{u}))_i^2 \right\} \\
 &= \frac{1}{2} (\Delta\bar{u})^2
 \end{aligned}$$

C-9

If S_m and S_t are the measured and true variances then

$$S_m^2 = S_t^2 + S_u^2$$

or

$$\frac{S_t}{S_m} = \sqrt{1 - \left(\frac{S_u}{S_m}\right)^2}$$

C-10

This equation shows the influence of the velocity gradient on the true intensity.

As an example we will consider the first 3 data points in Table H-I-3 for Run 6. Consideration of the velocity profiles shows this case will have the largest error owing to the above considerations. In the following table the appropriate data for use of equation C-10 is tabulated. The $\Delta\bar{u}$

No.	y <u>inch</u>	$\Delta \bar{u}$ <u>ft/sec</u>	S_m <u>ft/sec</u>	S_t/S_m <u> </u>
1	.0040	.18	.567	.95
2	.0073	.13	.508	.97
3	.0102	.04	.535	.97

for a band width of .0024 inches have been determined directly from the slopes of a plot of the velocity profile at the indicated radial positions. The measured intensity is obtained directly from Table H-I-3 by multiplying I_x by the maximum velocity.

It is evident from the tabulated values of S_t/S_m there is little difference between the measured and true intensities. For the radial position nearest to the wall, where the velocity gradient is largest, the error would be approximately 5%. In view of the conservative nature of this calculation it is concluded that for all runs in this work error in intensity because of velocity gradient is negligible.

v) Time Scale Relative to the Dissipative Frequencies

Table C-I compares the time scales used for each photographic run and the estimated frequency of maximum energy dissipation for organic solvents as found by Patterson and Zakin (32) for 1 and 2" pipes. It can be observed that for all the runs, except run 14, the time scale used are lower than the dissipative frequencies. A true indication of the turbulence intensity, (containing the contribution from all significant frequencies) was therefore obtained.

TABLE C-1

TIME SCALE VERSUS DISSIPATIVE FREQUENCIES

RUN NUMBER	BULK VELOCITY ft/sec	$N_{\max-1}$ sec ⁻¹	TIME SCALE sec ⁻¹
4	4.8	250	596.6
5	3.1	130	596.6
6	4.4	220	596.6
7	5.0	260	596.6
9	5.0	260	1194
10	5.0	260	1197
11	13.2	1000	1787.5
12	11.6	800	1787.5
13	22.0	1900	1787.5
14	33.4	=4000	1787.5
15	5.0	260	895
16	5.0	260	895
17	8.8	600	895

APPENDIX D

SAMPLE CALCULATIONSi) Velocities

The sample calculation will be made for water run 11 at a radial position $y = 0.0906$ inch from data tabulated in Appendix H.

Conditions of Operation

Temperature	70°F
Flow	32.4 gal/min
Manometer Reading	6.1 in of Hg
Length between taps	11.0 ft
Diameter of tube	1.0 in
Rotation of disk	3575 rpm
Number of slits	60 slit-spoke/rev

Readings from the Digitizer of Streak Relative to Pipe Wall

Referring to Figure III-7 the following points correspond to the reading of the streak and spoke and the wall. The points are in volts and relative to the digitizer axis as zero.

$Y_1 = 6.287$ volts	$X_1 = 5.401$ volts
$Y_2 = 6.221$ volts	$X_2 = 3.363$ volts
$Y_3 = 8.077$ volts	$X_3 = 7.552$ volts
$Y_4 = 8.052$ volts	$X_4 = 4.972$ volts

With calibration constants as shown in Figure B-2

$$k_x = 0.1718 \text{ volt/cm} \quad k_y = 0.1811 \text{ volt/cm}$$

these readings can be transformed into lengths on the projection screen.

$$\begin{array}{ll}
 Y_1 = 13.668 \text{ inches} & X_1 = 12.377 \text{ inches} \\
 Y_2 = 13.524 \text{ inches} & X_2 = 7.707 \text{ inches} \\
 Y_3 = 17.559 \text{ inches} & X_3 = 17.306 \text{ inches} \\
 Y_4 = 17.505 \text{ inches} & X_4 = 11.394 \text{ inches}
 \end{array}$$

With these numbers, from the geometry of the figure the axial component of the streak, Δx , parallel to the wall is found to be

$$\Delta x = 4.72 \text{ inches}$$

The measured axial magnification is 53.18 and therefore the true length of the streak is $4.72/53.18 = .0887$ inch.

From the rotational speed of the chopping wheel and number of slit-spoke of the wheel the time scale can be found

$$T = (60 \text{ sec/min}) / (30 \text{ division/rev})(3575 \text{ rpm}) = 0.00056 \text{ sec}$$

and the instantaneous velocity is

$$u_x = \Delta x / T(53.18) = 13.184 \text{ ft/sec}$$

Similarly, the radial instantaneous velocity was found to be (using the radial calibration curve, as shown for run 6 as an example, in Figures B-III, B-IV)

$$u_r = -0.330 \text{ ft/sec}$$

From the computer the average of all these readings gives for the mean velocities

$$\bar{u}_x = 13.400 \text{ ft/sec} \quad \text{and} \quad \bar{u}_r = +0.219 \text{ ft/sec}$$

and the variances $S_x = 1.022 \text{ ft/sec}$ and $S_r = 0.47 \text{ ft/sec}$.

ii) Flow Calculations for Water

The pressure drop between two pressure taps can be calculated from the manometer reading

$$\Delta P = \frac{(6.1)(62.3)(12.55)}{(12)(32.2)} = 397.5 \text{ psf}$$

The Reynolds number

$$N_{Re} = \langle \bar{u}_x \rangle D / \nu$$

$$N_{Re} = Q D (8.337) / (\rho A \nu) = 104299$$

The shear stress at the wall

$$\tau_w = D \Delta P / 4L = 0.753 \text{ psf}$$

The friction factor

$$f = 2\tau_w / (\rho \langle \bar{u}_x \rangle^2) = 0.00442$$

The friction velocity

$$U^* = \sqrt{\tau_w g_c / \rho} = 0.624 \text{ ft/sec}$$

The dimensionless distance from the wall

$$Y^+ = y U^* / \nu = 444.5$$

The dimensionless velocity

$$U^+ = \bar{u}_x / U^* = 2.148$$

iii) Calculations of K' , n' and N'_{Re}

A sample calculation is made for run 13 as an example for Separan AP-30 0.10% and these data can be found in Appendix H.

Flow	54.00 USgal/min
Manometer reading	7.95 inches of Hg
Length between taps	22.00 ft

From these

$$\Delta P = 519.38 \text{ psf}$$

$$\tau_w = 0.491 \text{ psf}$$

The constants of viscometric equation are (see Appendix A)

$$A = -6.540 \quad B = 0.5989 \quad C = 0.00599$$

so that

$$\ln 8\langle \bar{u}_x \rangle / D = \frac{-0.5989 + \sqrt{(0.5989)^2 - 4(0.0060)(-6.540 - \ln 0.491)}}{2(0.00599)}$$

$$\ln 8\langle \bar{u}_x \rangle / D = 8.95$$

$$8\langle \bar{u}_x \rangle / D = 7.71 \times 10^3 \text{ sec}^{-1}$$

$$n' = 0.5989 + 2(0.00599)(8.95) = 0.705$$

$$K' = 0.491 / (7.71 \times 10^3)^{0.705} = 8.93 \times 10^{-4}$$

iv) Determination of θ from Friction Data

The relaxation time found from friction data in the 1" pipe is tabulated in Table A-3. From Appendix I the friction factor is

$$f = 0.00177$$

and $N_{Re} = 93369$

Putting the constants in Equation III-16 the following expression is obtained

$$\frac{1}{\sqrt{f}} = 1.74(1 - \epsilon_1)^2 \ln(N_{Re} \sqrt{f}) + 0.707(1 - \epsilon_1)^2 [B(\theta^+) - 2.56] - \frac{3.0}{\sqrt{f}}$$

From the data

$$\sqrt{f} = 0.0421$$

$$1/\sqrt{f} = 23.753$$

$$N_{Re} \sqrt{f} = 3931$$

$$\ln(N_{Re} \sqrt{f}) = 8.2764$$

For the first trial assuming $\epsilon_1 = 0$, we have, solving the above equation for B,

$$B(\theta^+) = (23.753 - 14.401 + 1.810 + 2.121)/0.707 = 18.79$$

Thus using Equation II-12, the first estimate of ϵ_1 is

$$Y_1^+ - 2.46 \ln Y_1^+ = 18.79$$

and $Y_1^+ = 26.9$ and $\epsilon_1 = 0.0194$

For the second trial $\xi_1 = 0.0194$ is used as an approximation and

$$B(\theta^+) = 20.25$$

$$Y_1^+ = 28$$

$$\xi_1 = 0.0202$$

The final $B(\theta^+)$ which satisfies the above equation is $B(\theta^+) = 20.30$. From the Seyer's B function (see Figure II-3) $\theta^+ = 9.25$ and from the experimental values of

$$U^* = 0.4002 \text{ ft/sec}$$

$$\tau_w = 0.3096 \text{ psf}$$

$$\theta = \theta^+ \nu / U^{*2} = 6.93 \times 10^{-4} \text{ sec}$$

APPENDIX E

TURBULENT SHEAR STRESS AND KINETIC ENERGY DATA

In order to provide additional support for the turbulence measurements, it is possible to estimate the covariance of the instantaneous velocities as well as the axial kinetic energy of the turbulence

$$S_{xr} = \frac{1}{n-1} \sum_1^n [(u_x - \bar{u}_x)(u_r - \bar{u}_r)]_i \quad \text{E-1}$$

which is proportional to the Reynolds shearing stress. Similarly for the kinetic energy in axial direction

$$S_{xx} = \frac{1}{n-1} \sum_1^n [(u_x - \bar{u}_x)^2]_i \quad \text{E-2}$$

Sample calculations were done for two radial positions for water run 11 in the 1" pipe because of the large number of observations available. From Appendix K in Book II the instantaneous velocities can be found for positions $y = 0.462$ inch and $y = 0.387$, and the mean velocities can be found in Appendix H.

Table E-I represents the calculated Reynold stress and the kinetic energy. These terms are plotted on Figure E-1 and compared to Laufer's data.

TABLE E-1

TURBULENCE PROPERTIES

Radial position -y (inch)	0.462	0.387
Number of observations	210	192
$\overline{u_x u_r}$	-0.0483	0.0098
$\overline{u_x u_x}$	0.6859	0.7075
$\overline{u_x u_r / U}^2$	-0.1242	0.0252
$\overline{u_x u_x / U}^2$	1.763	1.819

Three of the four points are in excellent agreement with the expected values. The low point for shear stress is in fact in reasonable agreement in view of the extreme difficulty in estimating a covariance. Reference to statistical tables shows that with these points the 95% confidence interval about the lower point includes the known curve of shear stress.

FIGURE E-1

REYNOLDS STRESS AND KINETIC ENERGY

APPENDIX F

R₀ CORRELATION FACTOR

The R₀ correlation factor given in Table F-I and defined in Equation II-2 was calculated for all the radial positions of all the runs in this work and also for some of Seyer's data (41). R₀ is simply the ratio of number of positive radial velocities to the number of negative radial velocities. To calculate R₀ raw data, that is each instantaneous radial velocity in Appendix L, has been adjusted slightly by requiring that the mean radial velocity be exactly zero. Alternatively the non-zero mean radial velocity has been subtracted from each instantaneous velocity. This effectively removes bias in the data owing to small error in locating the wall. This has the effect of changing the relative number of negative and positive fluctuations; but only insignificantly.

APPENDIX G

MIGRATION OF AIR BUBBLES

As already indicated in Chapter III, Section III-1, the tiny air bubbles (average diameter of 0.002") used as tracers were uniformly distributed in the calming section. On the other hand it was noticed (as suggested crudely by Figure III-5a, for example) that most bubbles were at a radial position of $\xi = 0.11$. Figure G-1 presents for photographic runs (4,9,16,12,13) the number of observed air bubbles as a function of their radial position. It can be noticed that for most of the runs a peak is located at the radial position already mentioned. For water runs (4.9) the peak is sharp and represent approximately 25% of all bubbles observed during the photographic run. For the case of the photographic runs with Separan AP-30 solutions, the air bubble distribution is more uniform in the core region of the pipe.

Even though there is an apparent migration of bubbles to the radial position of 0.1, the concentration in volume % is still extremely small and no influence on the turbulence is expected. The curves show one of the limitations of the technique for velocities near the wall is the small number of bubbles that occur there and therefore a large number of photographs is needed to get a reasonable number of instantaneous velocities.

FIGURE G-1
DISTRIBUTION OF AIR BUBBLES IN PIPE

APPENDIX H

SUMMARY OF ALL RUNS

In this appendix all of the data have been tabulated in Table H-I in a format to summarize the velocity and intensity profiles at all the radial positions for each photographic run. The primary data concerning the velocity measurements can be found in Appendix L (in Book II) and the flow conditions are tabulated in Table IV-I. The axial and radial turbulent intensities tabulated are made dimensionless to the maximum velocity.

APPENDIX I

PRESSURE DROP MEASUREMENTS

Pressure drops over a range of flow rates were obtained for each of the experimental fluids and are tabulated in Tables I-I. For the Newtonian fluids the data serve to validate the apparatus while for the drag reducing solutions the data characterize the drag reduction over a range of flow rates of interest. The tables representing pressure drop measurements during a photographic run are specified so that degradation effects may be following.
