**Effect of stock type characteristics and time of planting on field performance of aspen
(*Populus tremuloides* Michx.) seedlings on boreal reclamation sites**

4 **Abstract**
5

6 Aspen (*Populus tremuloides* Michx) has great potential as a reclamation species in mining
7 sites in the boreal forest, but planting stock has shown poor field performance after outplanting.
8
9 In this study we tested how different aspen seedling characteristics and planting times affect field
10 outplanting performance on reclamation sites. We produced three different types of aspen
11 planting stock, which varied significantly in seedling size, root-to-shoot ratio (RSR), and total
12 non-structural carbohydrate (TNC) reserves in roots, by artificially manipulating shoot growth
13 during seedling production. All three stock types were then field-planted either in late summer,
14 late fall, or early spring after frozen storage. Seedlings were outplanted onto two reclaimed
15 open-pit mining areas in the boreal forest region of central and east-central Alberta, Canada,
16 which varied significantly in latitude, reclamation history, and soil conditions. Overall, height
17 growth was better in aspen stock types with high RSR and TNC reserves. Differences in field
18 performance among aspen stock types appeared to be more strongly expressed when seedlings
19 were exposed to more stressful environmental site conditions, such as low soil nutrients and
20 moisture. Generally, aspen seedlings planted with leaves in the summer showed the poorest
21 performance, and summer- or fall-planted seedlings with no shoot growth manipulation had
22 much greater stem dieback after the first winter. This indicates that the dormancy and hardening
23 of the stem as a result of premature bud set treatments could improve the outplanting
24 performance of aspen seedlings particularly during summer and fall plants.

3
4 **Introduction**
5

6 Trembling aspen (*Populus tremuloides* Michx.) is a widely distributed tree species native to
7 North America. Its natural range extends from Alaska in the west, across Canada into north
8 eastern United States and in higher elevations in the western and south-western areas of the
9 United States and into northern Mexico (Little 1971; Perala 1990). This early successional, fast-
10 growing species grows over a wide range of climatic and soil conditions and is considered
11 relatively drought tolerant as compared to other boreal forest species (Lieffers et al. 2001). This
12 makes it an ideal species for reclamation of disturbed mine sites in the boreal region, where there
13 is a limited number of native tree species available for the reclamation and restoration of
14 disturbed sites (Macdonald et al. in press). Currently, most aspen reclamation programs in the
15 boreal forest region of Canada use nursery-grown seedlings. However, the outplanting success of
16 aspen seedlings has been limited on boreal sites, where aspen seedlings often suffer from
17 transplant shock and exhibit several years of slow growth after outplanting (Van den Driessche et
18 al. 2003; Martens et al. 2007).

36
37

38 There is a lack of knowledge in identifying seedling characteristics and planting techniques
39 that could be beneficial to improving aspen seedling establishment (Puttonen 1997). In the past,
40 aspen seedling quality was assessed similarly to conifer planting stock (Sutton 1979) based upon
41 height, root collar diameter (RCD), and terminal bud size (Chavasse 1980; Thompson 1985;
42 Navarro et al. 2006). The current choice of aspen seedling attributes might not be adequate for
43 assessing seedling quality and subsequent field performance since it has been recognized that
44 seedling height and RCD are not always associated with field performance of broadleaf seedlings
45 (Jacobs et al. 2005; Martens et al. 2007; del Campo et al. 2010). For example, there is a negative
46 correlation between seedling initial height and field performance in northern red oak seedlings
47

1
2
3
4 (*Quercus rubra* L.) (Thompson and Schultz 1995) as well as a negative relationship between
5
6 survival and initial height in sawtooth oak (*Quercus acutissima* Carruth.) seedlings (Hashizume
7
8 and Han 1993). Martens et al. (2007) observed that, after the first growing season, naturally-
9
10 regenerating aspen seedlings were short in stature but had very high root-to-shoot ratios (RSR)
11
12 and total non-structural carbohydrate (TNC) root reserves. However, these much shorter natural
13
14 seedlings outperformed the nursery-produced seedling stock in height and root growth in the
15
16 following growing season (Martens et al. 2007). The importance of TNC reserves in roots has
17
18 also been shown for conifers (Grossnickle 2005) and aspen root cuttings (Snedden et al. 2010),
19
20 which grew more new roots upon transplanting when higher reserves were present. TNC
21
22 reserves in seedlings are also important for maintaining respiration from the time of lifting until
23
24 restarting photosynthesis after outplanting (Marshall 1985). Since the balance between the water
25
26 absorbing roots and the transpiring leaf area of newly planted seedlings is important (Haase
27
28 2008), large seedling stock with proportionally lower RSR and TNC reserves might cause poor
29
30 outplanting success on reclamation sites, where a larger root system and greater root reserves
31
32 may become critical to seedling survival.

33
34
35
36
37
38
39
40
41 The selection of a planting time for aspen on reclamation sites is generally based upon local
42
43 climatic conditions and/or operational constraints such as planter availability. In northern boreal
44
45 climates, fall-lifted and spring-planted aspen seedlings are generally stored frozen at -3°C for up
46
47 to seven months. In the spring, site conditions are generally moist (shortly after snowmelt), and
48
49 seedlings have a full growing season for growth and root system development before the
50
51 following winter. Summer planting uses aspen seedlings that have set a terminal bud and
52
53 stopped height growth and/or are top-pruned if too tall; however, these seedlings are not fully
54
55 dormant. These seedlings can be considered “hot”-planted because they still have green leaves
56
57
58
59
60
61
62
63
64
65

1
2
3
4 at the time of planting and can potentially re-flush if conditions are favorable. Summer planting
5
6 also allows for the expansion of the root system during the remainder of the growing season after
7
8 planting and results in a more intimate contact of the root system with the adjacent soils,
9
10 potentially providing an advantage to the seedling in the following spring (Taylor and Dumbroff
11
12 1975; Good and Corell 1982). Seedlings planted in the fall are generally considered to be fully
13
14 dormant, which eliminates the need for prolonged winter storage, but here seedlings do not have
15
16 time to develop much contact between the root system and the soil prior to winter. Different
17
18 planting times have been investigated for conifers (Barber 1989; Dierauf 1989; Adams et al.
19
20 1991) and temperate hardwoods (Seifert et al. 2006), but the effect of planting time for aspen in a
21
22 boreal climate has not been tested.
23
24
25
26
27

28 The objectives of this study were to determine the effect of planting time and different stock
29
30 type characteristics on the establishment and growth of regionally-sourced aspen seedlings. In
31
32 particular we were interested in the impact of seedling and root system size and the root reserves
33
34 on the early outplanting performance of aspen on reclamation sites.

43 **Materials and methods**

44 *Planting stock production*

45
46 The aspen seed used in this study was collected from two open-pollinated seed sources near
47
48 Edmonton, AB, Canada (53°34' N; 113°31' W; elevation 668 m asl) and near Fort McMurray,
49
50 AB, Canada (56°43' N; 111°22' W; 370 m asl). Government regulations required different seed
51
52 lots to be used for seedling stock production as the planting sites are in different seed zones.
53
54
55
56
57
58 Seeds were sown mid-May 2008 into 615A Styroblock™ (Beaver Plastics Ltd, Acheson, AB,
59
60
61
62
63
64
65

1
2
3
4 Canada) containers with a cavity volume of 340 cm³. Seedlings were grown in a mixture of peat
5
6 and vermiculite (9 to 1 by volume) and were germinated under greenhouse conditions at a
7
8 commercial tree nursery (Smoky Lake Forest Nursery, Smoky Lake, AB, Canada 54°6' N;
9
10 112°28' W; 598 m asl). During germination the greenhouse had a mean temperature of 21°C,
11
12 with a minimum of 18°C and maximum of 28°C; relative humidity was maintained at greater
13
14 than 70%. After seeding, styroblocks were irrigated using multiple automated mists per day for 4
15
16 weeks. Fertilization began 4 weeks after seeding using a standard nursery protocol used for
17
18 growing commercial aspen seedling stock. The fertilizer solution consisted of 83 ppm of N, 76
19
20 ppm of P, 160 ppm of K, and chelated micronutrients; fertilizer was applied with every watering.
21
22 Seedlings were moved to outside conditions after 8 or 11 weeks, depending on the stock type
23
24 produced. Once outside, the fertilization regime was changed to 54 ppm N and 95 ppm K, while
25
26 P remained at 76 ppm; this was done to limit height growth and the potential of re-flush in the
27
28 seedlings that had set bud (see below). Seedlings continued to be fertilized with every watering
29
30 cycle over the next 12 weeks.
31
32
33
34
35
36
37

38 Prior to moving seedlings to outside conditions, the styroblocks had been assigned to three
39
40 different shoot treatments to create stock types with different seedling characteristics. The three
41
42 stock types were labeled after the treatments used to terminate shoot growth: blackout, shoot
43
44 growth inhibitor, and control with no artificial shoot growth termination. Generally, nursery-
45
46 grown aspen seedlings for boreal forest climates are sown in early May, grown over the summer,
47
48 and lifted in late summer or fall, and stored frozen over the winter months to be planted the
49
50 following spring. Depending on the planting time, premature bud set can be artificially induced
51
52 in aspen by shortening day length by means of blackout cloths, or by using a chemical shoot
53
54 growth inhibitor (Rietveld 1988; Landhäusser and Lieffers 2009). Naturally, shoot growth
55
56
57
58
59
60
61
62
63
64
65

1
2
3
4 terminates in aspen seedlings in early fall as a result of shortened day length and cooler nights.
5
6 In an earlier study, the blackout and shoot growth inhibitor treatments had been found to be two
7
8 reliable methods to induce premature bud set in aspen (Landhäusser et al. in press). In the
9
10 blackout treatment, bud set was induced after 8 weeks of growth. These seedlings were moved
11
12 outside and subjected to an artificial shortening of day length for 7 consecutive days, by covering
13
14 them with a black plastic tarp for a portion of the day to shorten the photoperiod to 8 hours from
15
16 the ambient 17 hours. The same treatment was repeated again two weeks later. In the shoot
17
18 growth inhibitor treatment, premature bud set was induced after 8 weeks of growth by treating
19
20 seedlings with the plant growth regulator paclobutrazol (Bonzi®, Syngenta, North Carolina,
21
22 USA). Paclobutrazol is absorbed by roots and shoots and inhibits gibberellin biosynthesis
23
24 (Hedden and Graebet 1985) reducing internode expansion and apical dominance. This growth
25
26 regulator was applied to the roots by soaking the styroblocks in a water bath with a concentration
27
28 of 5 mL of Bonzi per L of water (0.02 g of paclobutrazol/L of water) as recommended by the
29
30 manufacturer. Seedlings in the untreated control were moved outside the greenhouse after 11
31
32 weeks, to continue to grow and harden off naturally in the fall.
33
34
35
36
37
38
39
40
41
42

43 *Planting time and planting sites*

44
45 For the summer outplanting treatment, a third of the seedlings were lifted after the third
46
47 week of August (14 weeks since seeding). The remaining seedlings stayed outside until another
48
49 third of the seedlings were lifted at the end of September for the fall outplanting (18 weeks after
50
51 seeding). The remaining third of the seedlings was lifted in November and stored frozen at -3 °C
52
53 until the following spring (May 2009).
54
55
56
57
58
59
60
61
62
63
64
65

1
2
3
4 Seedlings were outplanted in two different reclamation sites in central and east-central
5
6 Alberta. One site was located on a coal mine (Sherritt Coal) near Warburg, AB, Canada (53°10'
7
8 N, 114°19' W; 820 m asl) and the other site was on an oil sands mine (Suncor Energy) near Fort
9
10 McMurray, AB, Canada) (56°43' N, 111°22' W; 370 m asl). Generally, weather conditions
11
12 between 2008 and 2010 were not very different between the two sites except that winter
13
14 precipitation and winter mean air temperature was lower in Fort McMurray than at Warburg
15
16 (Table 1). However, the reclamation history and the soil conditions of the two reclamation areas
17
18 were very different. The Warburg area had been reclaimed in 1998 by placing 1 m of subsoil
19
20 over saline sodic overburden and capping it with 20 cm of salvaged topsoil. After placing the
21
22 cover, the area had been used as an agricultural reclamation area seeded with alfalfa (*Medicago*
23
24 *sativa* L.) for the last five years. A research site approximately 1000 m² in size was selected in
25
26 the area and, prior to planting, the alfalfa was killed using herbicide (Glyphosate, Roundup,
27
28 Monsanto, St Louis, MO, USA) and was incorporated into the soil using a rototiller. At Fort
29
30 McMurray, the area had been reclaimed in 2007 by placing 1 m of subsoil over a saline sodic
31
32 overburden and capped with a 30 cm layer of peat-mineral mix (70% organic – 30% mineral
33
34 component). No cover crop was seeded prior to planting. A similar sized research site (1000 m²)
35
36 was selected in the area.

37
38 To characterize the soil conditions in both research sites, 12 random soil samples were
39
40 collected from the top 20 cm of the capping soil across each site and four samples were
41
42 randomly pooled and analyzed as a single sample (total of n=3 soil samples per site). Soil
43
44 texture was estimated using a graduated cylinder and hydrometer (Carter and Gregorich 2008).
45
46 Soils were analyzed for K⁺, Na⁺, Mg²⁺, and Ca²⁺ concentrations using the 1M NH₄OAc method
47
48 (Page 1982), for NO₃⁻ and NH₄⁺ using the 2N KCl method (Jones 2001), and for PO₄³⁻ with the
49

4 Kelowna method (Carter and Gregorich 2008). Total N and total P were analyzed with the
5
6 Kjeldahl digestion method (Carter and Gregorich 2008).
7
8

9 The soil conditions were very different between the two research sites due to differences in
10 soil properties and the reclamation and re-vegetation prescriptions. Soil at Warburg was a silty-
11 clay loam with 28% clay, 52.5% silt, and 19.5% sand while the soil at McMurray was a sandy-
12 clay loam with 25% clay, 27% silt, and 48% sand. Soil nutrient concentrations at Warburg were
13
14 higher than at Fort McMurray, particularly for N, P, and K (Table 2).
15
16
17
18
19
20

21 To conform to agricultural regulations pertaining to the spread of noxious weeds, plastic
22 mulch blankets commonly used in tree plantations to suppress competition (90 × 90 cm)
23 (Arbortec Industries Ltd, Mission, BC, Canada) were placed around the seedlings at the Warburg
24 site in May 2009 after the spring-planting treatment had been completed. Due to the dimensions
25 of the plastic mulch, seedlings had been planted at a slightly tighter spacing at Warburg (0.85 ×
26 0.85 m) than at Fort McMurray (1 × 1 m) where no plastic mulch was required. The use of
27 plastic mulch in Fort McMurray is not required and operational, as the spread of noxious
28 agronomic weed species is currently not considered a critical issue in this area. All seedlings
29 were planted by hand.

43 Prior to planting, each site was divided into 72 plots, which were randomly assigned to one
44 of 9 treatment combinations of three planting times (summer, fall, spring) and three stock types
45 (blackout, growth inhibitor, control) and replicated 8 times. Each plot contained 16 seedlings
46 (subsamples) of the same treatment combination; the plot was considered the experimental unit
47 in this study. In total 1152 seedlings were planted at each site. Both sites were surrounded by a
48 2 m buffer planted with aspen seedlings to ensure seedlings growing at the periphery of each site
49 experienced similar conditions to those growing in more central locations.

6
7 *Seedling measurements*
8

9 Prior to each planting time (summer, fall, spring), 10 seedlings of each stock type were
10 randomly selected to determine pre-planting seedling characteristics. After measuring height and
11 root collar diameter (RCD) of the seedlings, root systems were carefully washed to remove the
12 soil. Stems and roots were separated and dried to constant weight at 70°C for 2 to 3 days. To
13 determine water-soluble sugar and starch concentrations in root and stem tissues, samples were
14 ground to 40-mesh (0.4 mm) with a Wiley Mill (Thomas Scientific, Swedesboro, NJ, USA).
15
16

17 Water-soluble sugars were extracted using hot ethanol (80%) and concentrations were measured
18 colorimetrically using the phenolsulfuric acid method (Chow and Landhäusser 2004). Remaining
19 starch in residues were solubilized with sodium hydroxide and hydrolyzed using an enzyme
20 mixture of α -amylase (ICN 190151, from *Bacillus licheniformis*) and amyloglucosidase (Sigma
21 A3514, from *Aspergillus niger*) and then measured colorimetrically using peroxidase glucose-o-
22 dianisidine solution (Sigma Glucose Diagnostic Kit 510A) (Chow and Landhäusser 2004).
23

24 Initial measurements of the seedling characteristics are summarized in Table 3.
25
26

27 After planting, initial height (height at time of planting) was measured on all field-planted
28 seedlings. In the spring of 2009 prior to bud flush, two seedlings of each stock type planted in the
29 summer and fall of 2008 were excavated to determine whether root growth had occurred during
30 the previous partial growing season. Shoot dieback was determined on each seedling once bud
31 flush had occurred in the spring. At the end of the first and the second full growing seasons
32 (August 2009 and 2010), total height (from ground level to the highest terminal bud) was
33 measured. After the first and second growing season, seedling mortality was also assessed.

21 *Experimental design and data analysis*

22
23 Initial planting stock characteristics were combined for Warburg and Fort McMurray, as
24 seedling stock type characteristics were not different between the two seed sources. Initial
25 characteristics were analyzed using a two-way ANOVA with three stock types and three lifting
26 times as the fixed factors. The field study was designed as a completely randomized 3×3
27 factorial design, with the three stock types (blackout, GI, control) and three planting times
28 (spring, summer, fall) as the fixed factors. Each treatment combination was replicated 8 times at
29 each planting site (Warburg and Fort McMurray). Planting sites were analyzed separately as seed
30 source, reclamation operations, and planting procedures were very different between sites (see
31 above) and a comparison of these geographically distant locations was not an objective of this
32 study; however, qualitative comparisons were made between the two sites when reasonable. The
33 effect of stock type and planting time on shoot dieback, RCD increment, and root growth was
34 tested with a two-way ANOVA. Because height growth was measured in 2009 and 2010, height
35 growth was analyzed as a three-way ANOVA with planting time, stock type, and measurement
36 year as main factors. Prior to analyses, the variables were examined for normality (Shapiro-Wilk
37 test) and homogeneity of variances (Levene test). Variables not conforming to normality or

26 The control stock type was twice as tall as seedlings of the blackout and growth inhibitor
27
28 stock types regardless of planting time ($P<0.01$) (Table 3). However, the control stock type also
29
30 tended to have the lowest root volume (Table 3) and root mass (data not shown) particularly
31
32 when lifted in the summer. The control stock type had a root volume similar to seedlings treated
33
34 with growth inhibitor only in the spring, which resulted in a significant planting time by stock
35
36 type interaction term ($P<0.001$) (Table 3). Generally, summer-planted stock types had lower
37
38 root volumes, root dry mass, and root-to-shoot ratio (RSR) compared to fall- and spring-planted
39
40 seedlings; however, differences in RSR among stock types became larger in the fall- and spring-
41
42 lifted seedlings resulting in a significant interaction term ($p<0.001$) (Table 3). Overall, the
43
44 seedlings treated with the growth inhibitor had the highest RSR, followed by the blackout stock
45
46 type and the control stock type ($P<0.001$). Root TNC in fall- and spring-planted seedlings was
47
48 high among all stock types, while summer-planted stock types had the lowest root TNC,
49
50 particularly in the control stock type. This also resulted in a significant interaction between
51
52
53
54
55
56
57
58
59
60
61
62
63
64
65

1
2
3
4 planting time and stock type ($P<0.001$) (Table 3). Generally, the TNC concentration in stems
5
6 was about half of those in the roots, and stem TNC concentrations showed little difference
7
8 among stock types (data not shown).
9

10 11 12 13 14 *Field performance at Warburg*

15
16 After two growing seasons, overall seedling mortality at Warburg was 4% and was not
17
18 significantly different among stock types or planting times (data now shown). After the first
19
20 growing season, there was a significant difference in height growth among stock types
21
22 ($P<0.001$), while planting time had no effect on height growth ($P= 0.737$) (Fig. 1). The growth
23
24 inhibitor and blackout stock types grew an average of 39 cm, which was almost double the
25
26 height growth of the control stock type (21 cm). After the second growing season all three stock
27
28 types had grown a similar amount resulting in a significant year by stock type interaction term
29
30 ($P<0.001$). There were no differences in RCD and root growth among the three stock types and
31
32 the three planting times after the first growing season (data not shown). Shoot dieback after the
33
34 first winter was about 10 times greater in the summer- and fall-planted control stock type
35
36 compared with the other two stock types; however, the control stock type had similar dieback
37
38 than the other two stock types when planted in the spring (Fig. 2). This resulted in a significant
39
40 interaction term between planting time and stock type ($P<0.001$).
41
42
43
44
45
46
47
48
49

50 51 *Field performance at Fort McMurray*

52
53 At Fort McMurray, seedling mortality after two growing seasons was not significantly
54
55 different among stock types or planting times and was less than 4.5% of all seedlings planted
56
57 (data now shown). The selection of stock type had a significant influence on height growth in
58
59
60
61
62
63
64
65

1
2
3
4 the first growing season ($P<0.001$); the growth inhibitor-treated stock types grew the most with
5
6 16 cm, followed by blackout stock (11 cm) and then control stock (6 cm) (Fig. 3). However, in
7
8 the second growing season the differences seen in height growth in 2009 were reduced among
9
10 stock types, which resulted in a significant stock type by year interaction ($P<0.001$). In addition,
11
12 shoot dieback was different for the stock types after the first growing season ($P=0.04$) with the
13
14 control stock type experiencing three times more shoot dieback than the other two stock types
15
16
17
18
19 (Fig. 3).
20

21 The spring- and fall-planted stock types had 44% greater height growth than the summer-
22
23 planted stock types ($P=0.001$) (Fig. 4). Spring- and fall-planted seedlings grew on average 13
24
25 cm in height while the summer-planted seedlings grew only 9 cm over both growing seasons.
26
27
28 Overall, seedlings grew more in the second growing season than in the first growing season
29
30
31 ($P=0.043$) (Fig. 4).
32
33

34 *Impact of initial seedling characteristics on field performance*

35
36
37 When exploring which seedling characteristics explained most of the subsequent growth in
38
39 the field we found that initial root TNC concentrations and RSR played a significant role in
40
41 height but not in root growth performance. There was a significant positive relationship between
42
43 the first season's height growth and initial root TNC concentrations at the Fort McMurray site,
44
45 but this relationship was not detectable at the Warburg site (Fig. 5a). However, initial RSR of
46
47 the seedlings had a significant positive influence on first-growing-season height growth at both
48
49
50
51 planting sites (Fig. 5b).

3
4 **Discussion**
5

6
7 Differences in the growth performance of aspen seedlings in response to the different
8
9 planting times and stock types can be related to initial seedling characteristics, particularly root
10
11 TNC concentration and RSR (Fig. 5), but they were also likely influenced by planting site
12
13 conditions, such as fertility, soil texture, and climatic conditions. Seedlings with high TNC
14
15 reserves and RSR (e.g., fall- and winter-planted and blackout and growth inhibitor-treated stock
16
17 types) grew the best, indicating that RSR and TNC reserves are important characteristics to
18
19 consider for describing aspen seedling quality. This might become more important for seedlings
20
21 planted on sites with potentially limiting resources such as Fort McMurray, where both TNC
22
23 reserves and RSR showed stronger relationships with height growth than at Warburg (Fig. 5). At
24
25 Warburg, the above seedling characteristics might not have played such a prominent role due to
26
27 the potentially higher resource availability. Apart from the initial transplant check (stem
28
29 dieback, see below), seedlings at Warburg were exposed to more suitable soil moisture and
30
31 nutrient conditions over the first growing season, which resulted in much better aspen growth
32
33 than at Fort McMurray. These improved growing conditions were likely in part due to the use of
34
35 the plastic mulch, but also due to the higher soil nutrient conditions (Table 2). The high nutrient
36
37 content was likely a result of the alfalfa crop, which had occupied the site prior to becoming a
38
39 research site, and had been incorporated into the soil. Secondly, in addition to reducing
40
41 competition, the plastic mulch also reduced water evaporation (Allen et al. 1998; Mamkagh
42
43 2009) and increased soil temperature, which might have amplified N mineralization (Truax and
44
45 Gagnon 1992). The greater percentage of sand in the soil at Fort McMurray may also have
46
47 negatively influenced growth due to reduced water holding capacity and faster drainage.

1
2
3
4 Carbohydrate reserves have been found to be important in newly establishing seedlings
5
6 (Farmer 1978; Wilson and Jacobs 2006) as an energy source between planting and the restart of
7
8 photosynthesis (Marshall 1985; Carlson and Miller 1990; Landhäusser and Lieffers 2002). The
9
10 lifting and planting of seedlings during the summer coincides with a phenological stage of low
11
12 carbohydrate reserves (Kozłowski and Pallardy 2002). During summer planting, seedlings had
13
14 green leaves and in general their TNC reserves were low as compared to fall- and spring-planted
15
16 seedlings. This could have exposed them to greater water stress after outplanting, reducing their
17
18 ability to photosynthesis and accumulate additional reserves for the winter and the following
19
20 growing season (Rietveld 1989; Carlson and Miller 1990; Kozłowski 1991; Martens et al. 2007).
21
22
23
24
25

26 Interestingly, root TNC reserves, particularly in the spring-planted seedlings, did not differ
27
28 much between the control and growth-inhibitor stock type; however, the growth-inhibitor stock
29
30 type still had twice the height growth at the Fort McMurray site. This response appears
31
32 somewhat puzzling and might indicate that either the paclobutrazol affects other physiological
33
34 mechanisms related to stress tolerance, or that the size of shoot tissue relative to the root system
35
36 (RSR) could have an effect on root performance (Wan et al. 2006; Percival and AlBalushi 2007).
37
38
39
40

41 There was a very strong indication that the RSR played a significant role in the ability of
42
43 aspen seedlings to establish and grow in the following year. The stock types that had a much
44
45 smaller shoot relative to its root mass (high RSR) at the time of planting showed consistently
46
47 better height growth regardless of planting time and location. A larger root system relative to the
48
49 shoot should increase the capacity to supply more water to the shoot, which initially carries
50
51 fewer leaves, and, in combination with high TNC reserves, this could result in greater growth
52
53 over the growing season (Galvez et al. 2011; Landhäusser et al. in press). Further, the smaller
54
55 shoots of the growth inhibitor and blackout seedlings could potentially be beneficial in coping
56
57
58
59
60
61
62
63
64
65

1
2
3
4 with the greater transpirational demands imposed on the root system when outplanted on harsh
5
6 sites (Ritchie 1984).
7

8
9 Shoot dieback regardless of stock type and planting time was much more severe at Warburg
10
11 than at Fort McMurray. However, only the summer- and fall-planted control seedlings at
12
13 Warburg were severely affected. This could have been the result of seed source selection or site
14
15 conditions. Seedlings planted at the Warburg site were produced from a more southern seed
16
17 source; therefore, seedlings might require stronger cues for stem hardening to occur during
18
19 seedling production than seedlings grown from a more northern seed source. Bud dormancy and
20
21 cold hardening in plant populations are known to be influenced by latitude and altitude, where
22
23 longer night lengths are required to induce dormancy in more southern populations (Dormling et
24
25 al. 1968; Heide 1974; Ledgard and Norton 1988). During the early stages of stem hardening,
26
27 and after bud set, seedlings are able to withstand air temperatures close to 0°C and can withstand
28
29 stem cavitation (Levitt 1980). During that time, seedlings still maintain cambial activity
30
31 (Timmis and Worrall 1974), root growth (Day and Butson 1989), and reserve accumulation
32
33 (Landhäuser and Lieffers 2003). However, if stems are not woody enough, drought or frost
34
35 might affect the planted seedlings more severely. At Warburg the summer and fall stock types
36
37 were planted into a recently rototilled field and the freshly disturbed soil likely provided poor
38
39 root contact, which increased the risk of drought. At Fort McMurray, these stock types were
40
41 planted into soil that had last been disturbed a year prior to planting, which allowed it to settle. In
42
43 addition, shortly after planting in the fall, a night killing frost event occurred at Warburg (-6°C)
44
45 which was less severe at Fort McMurray (-2°C). Regardless, this shoot dieback appeared not to
46
47 be a significant impediment for future seedling growth, as seedlings grew well in the following
48
49 growing seasons, likely as a result of the high resource availability at the Warburg site.

1
2
3
4 The results of this study suggest that aspen seedling planting stock with high initial RSR and
5
6 TNC reserves will perform much better on reclamation sites. This effect appears to become
7
8 more prominent under resource-limiting site conditions. Summer seedling stock, which had the
9
10 lowest TNC and RSR, performed the poorest, particularly on the harsher reclamation site at Fort
11
12 McMurray. Artificially inducing bud dormancy increases TNC reserves and RSR in seedlings
13
14 and these are linked to improved seedlings outplanting performance. When artificially inducing
15
16 bud and shoot dormancy during seedling production, seed provenance locations should also be
17
18 considered, where seedlings grown from a more northern seed source appear to achieve a higher
19
20 state of shoot dormancy earlier than seedlings grown from a more southern seed source.

4 List of Figures:
5

6
7 Figure 1. Height growth of growth inhibitor, blackout, and control aspen seedling stock types in
8
9 2009 and 2010 at the Warburg planting site. Bars with the same letter are not considered
10 significantly different (n=24).
11
12
13

14
15
16 Figure 2. Shoot dieback after the first winter at the Warburg planting site for growth inhibitor,
17
18 blackout, and control aspen stock types planted in the summer and fall of 2008 and spring of
19
20 2009. Shoot dieback was measured after leaf flush during the first growing season. Bars with the
21
22 same letter are not considered significantly different (n=8).
23
24
25

26
27
28 Figure 3. Height growth in 2009 and 2010 and shoot dieback after the first winter of the growth
29
30 inhibitor, blackout, and control aspen seedling stock types at the Fort McMurray planting site.
31
32 Shoot dieback was analyzed separately from height growth. Bars with the same letter are not
33
34 considered significantly different (n=24).
35
36
37

38
39
40 Figure 4. Height growth after the 2009 and 2010 growing season of aspen seedlings planted in
41
42 the summer and fall of 2008 and the spring of 2009 at the Fort McMurray planting site. Different
43
44 letters for the 2009 and 2010 growing season combined indicate that there was a significant
45
46 planting time effect in both years, but not a significant year by season interaction (n=48).
47
48
49

Table 1. Winter (September [previous year] to April) / summer (May to August) precipitation and mean air temperatures for 2008, 2009, and 2010 at Warburg and Fort McMurray planting sites (AgroClimatic Information Service).

Planting site	2008		2009		2010	
	Precipitation	Air Temp.	Precipitation	Air Temp.	Precipitation	Air Temp.
	(mm)	(°C)	(mm)	(°C)	(mm)	(°C)
Warburg	87.6/262.2	-1.4/15.1	102.3/217.5	-3.4/14.3	306.9/288.9	-0.3/13.8
Fort McMurray	26.2/305	-9.7/16.2	131.8/229	-5.8/14.4	24.4/219	-2.6/15.4

Table 2. Average nutrient concentrations (standard deviation) of capping soil collected at Warburg and Fort McMurray planting sites. Numbers in a column followed by the same letter are not significantly different (n=3).

Planting site	Na ⁺ ^a	K ⁺ ^a	Mg ²⁺ ^a	Ca ²⁺ ^a	NH ₄ ⁺ ^a	NO ₃ ⁻ ^a	PO ₄ ³⁻ ^a	Total N ^b	Total P ^b
Warburg	31 a	194 a	475 a	2779 b	14.2 a	79 a	32.1 a	4.1 a	1.8 a
	(13)	(26)	(68)	(119)	(2.1)	(30)	(5.8)	(0.8)	(0.7)
Fort McMurray	58 a	68 b	544 a	5357 a	12.8 a	1.8 b	18.3 b	2.9 b	1.1 a
	(31)	(24)	(35)	(682)	(1.5)	(0.7)	(6.4)	(1.1)	(0.9)

^a Values of Na⁺, K⁺, Mg²⁺, Ca²⁺, NH₄⁺, NO₃⁻, and PO₄³⁻ are expressed in mg Kg⁻¹ of oven dried soil.

^b Values of Total N and Total P are expressed in mg L⁻¹ of soil.

Table 3. Average (standard deviation) of pre-planting characteristics of aspen seedling stock grown from Edmonton and Fort McMurray seed sources combined. Numbers in a column followed by different letters indicate significant difference among treatment means (Fisher LSD test; n=20). Initial seedling height was only significant for the stock type which is indicated by an asterix.

Planting time	Stock type	Height (cm)	Root volume (ml)	Root-to- shoot ratio	Root TNC (%)
Summer	Blackout	22.80 (4.27)	3.02 c (0.79)	1.98 d (0.78)	24.88 d (5.36)
	Growth Inhibitor	21.31 (3.84)	4.50 b (1.76)	2.64 c (1.24)	26.97 d (3.18)
	Control	46.91 * (3.80)	2.52 c (0.56)	0.57 f (0.11)	14.52 e (2.45)
Fall	Blackout	22.05 (2.34)	4.43 b (0.94)	2.79 bc (0.57)	37.15 bc (2.83)
	Growth Inhibitor	21.63 (2.56)	6.00 a (1.32)	4.22 a (0.83)	39.92 a (3.22)
	Control	42.73 * (4.78)	4.64 b (1.14)	1.14 e (0.17)	37.06 bc (2.63)
Spring	Blackout	22.63 (6.12)	4.46 b (0.88)	3.12 b (1.02)	35.34 c (4.13)
	Growth Inhibitor	22.78 (2.74)	6.15 a (1.62)	4.03 a (0.84)	38.82 ab (2.77)
	Control	45.43 * (3.28)	5.82 a (1.04)	1.26 e (0.27)	35.00 c (4.70)
