ABSTRACT

The excretion of gold in urine and feces of Sprague Dawley rats has been examined after administration of radioactive ^{198}Au-labelled sodium aurothiomalate (ATM). Single doses of ^{198}Au-ATM (0.5 mg and 1.0 mg Au/kg,im) were injected into rats and the urine and feces collected at 24 ± 4 hr intervals for 7 days. The 412 KeV gamma emission of the labelled gold specimens was then counted and the average amount of gold excreted in the urine and feces calculated. Using the urinary and fecal excretion rates, pharmacokinetic indices were calculated for the single-dose studies. For each 24 hr interval, approximately twice as much gold was excreted in urine and feces of rats given the 1.0 mg as compared to the 0.5 mg Au/kg dose, but pharmacokinetic indices were similar in both groups.

The effect of chronic administration of gold on its excretion in urine and feces was also examined. A dose of 1.0 mg "cold" Au/kg was administered for 13 consecutive weeks, the 14th dose being ^{198}Au-ATM. Urine and fecal specimens were again collected at 24 ± 4 hr intervals and the amount of gold in the urine and feces, and the pharmacokinetic indices calculated as before. Urine and fecal excretion of gold after repeated administration of ATM (1.0 mg Au/kg,im) was not significantly different from excretion after a single dose of ATM (1.0 mg Au/kg,im). However, repeated administration increased the overall elimination rate constant and reduced T½ Au.

To try and explain the relatively high and consistent excretion of gold in the feces, we examined the effect of the cholestatic agent alpha-naphthylisothiocyanate (ANIT), on fecal excretion. ANIT causes

reversible intrahepatic cholestasis within 24 hrs with normalization occurring within 3-6 days depending on the dose administered. Rats were gavaged with ANIT in doses of 300 and 150 mg/kg, 24 hrs before injection of ^{198}Au-ATM (1.0 mg Au/kg,im) and urine and feces collected as before. Significantly less ^{198}Au was recovered in feces within the first 72 hrs however a compensatory increase in urine gold concentration was observed. After 72 hrs, ANIT-treated rats and controls excreted similar amounts of gold in the urine and feces. Pharmacokinetic indices were similar for both ANIT-treated and control rats.

Lastly, we examined the effects of single and repeated administration of ATM on metallothionein (MT) levels in rat kidney and liver. Sprague Dawley rats were given either a single or 14 weekly injections of ATM (1.0 mg Au/kg,im). 24 hrs after the last injection, the rats were killed and the kidneys and livers removed, washed in chilled isotonic saline and either fractionated immediately using the method of Shaikh and Smith (1976) or quick-frozen (-40°C) and analyzed later. Detectable levels of a low molecular weight protein resembling MT were observed in kidney and liver cytosol of the rats examined. This material contained low concentrations of gold (detected using neutron activation analysis). No differences were found between MT levels of kidney and liver supernatants of rats receiving single or repeated injections of ATM, but gold concentrations were greater in kidney tissue.

URINARY AND FECAL EXCRETION OF GOLD

BY RATS GIVEN SODIUM AUROTHIOMALATE

1

INTRODUCTION

2

This thesis reports the investigations of the excretion kinetics of gold and the involvement of a low molecular weight metal-binding protein (metallothionein) in gold excretion.

The introduction will review the following topics:

A. Chrysotherapy in the treatment of rheumatoid arthritis

B. Toxicity from gold therapy and its treatment, and

C. Gold pharmacodynamics.

A. CHRYSOTHERAPY IN THE TREATMENT OF RHEUMATOID ARTHRITIS (RA)

Gold has been used in medicine for many centuries. At one time or another it was considered a "cure-all" for every known disease. In the thirteenth century, Roger Bacon recommended gold compounds for the treatment of leprosy (Dyson, 1929), and in 1500 Paracelsus stated that a mixture of gold and mercury was an "elixir of life" and could be used to treat syphilis and tuberculosis (Slot & Deville, 1934). No scientific evidence has been found to substantiate any of these claims.

No scientific basis was provided for the use of gold in specific medical disorders until 1890. At this time, Robert Koch demonstrated that gold cyanide inhibited the growth of tubercle bacilli in vitro, but was less effective when administered to animals infected with tuberculosis. This discovery led to the development of gold compounds which were used in experimental tuberculosis and later in the treatment of humans.

In 1927 Landé first reported the use of aurothioglucose (Solganol®) in the treatment of diseases other than tuberculosis. Believing that gold had a nonspecific antiseptic effect, he treated 14 patients who

had poorly defined diseases of a "rheumatic" origin with aurothioglucose. He observed improvement in the patients' general appearance and significant relief from the joint pain that accompanied the disorders. A year later Forestier treated patients suffering from rheumatoid arthritis (RA) with gold thiopropanol sodium sulfonate (Allochrysine®). The treatment was based mistakenly upon the belief that RA resulted from an infection similar to tuberculosis. Because gold was effective in the treatment of tuberculosis, he thought that it would help in the management of RA (Forestier, 1932).

Forestier began treatment with 50 to 100 mg of Allochrysine® im injected weekly until a total of 1.5 to 2.0 g of gold compound had been administered. After a rest period of 6 to 8 weeks, a second similar series of injections was administered provided there were no serious toxic reactions. Gold therapy was continued in this manner for 1 to 2 years. In 70% of his 48 patients, marked reduction in joint inflammation and pain was observed. By 1935 Forestier had treated over 550 patients suffering from RA with a variety of gold compounds including Allochrysine®, sodium aurothiomalate (Myochrysine®), aurothioglucose (Solganol®) and calcium aurothioglycolate (Myoral®). In 70-80% of patients, gold effectively reduced joint inflammation and pain.

Numerous European investigators (Pemberton, 1935; Crosby, 1936; Copeman & Tegner, 1937) confirmed Forestier's observations — generally in patients refractory to other forms of treatment. The clinical trial by Hartfall, Garland & Goldie (1937a) was particularly impressive. Eighty percent of 690 patients with RA were "cured", or greatly improved, following chrysotherapy however treatment

resulted in a higher incidence of toxicity (42%) and death (1%) than had been observed by Forestier.

In the United States at this time, chrysotherapy was viewed with extreme scepticism and was not considered an initial treatment for RA because of the high incidence of serious, often fatal, toxic reactions. It was customary to begin treatment with more conservative measures (Cecil, 1934; Holbrook & Hill, 1936) which included rest (both emotional and physical), a high caloric high vitamin diet, blood transfusions for existing anemia, analgesics, physical therapy, and orthopedic procedures for the prevention or correction of any deformities. Therapy with vaccines and removal of the foci of infections were popular, but no studies provided evidence of the benefit to be derived from these treatments. Only patients with unremitting progressive disease and those refractory to the conventional forms of treatment were candidates for gold therapy (Sashin, Spanbock & Kling, 1939; Snyder, Traeger & Kelly, 1939; Key, Rosenfeld & Tjoflat, 1939).

By 1940 in both Europe and the United States, gold was recognized as one of the most valuable agents for the treatment of RA. A controlled clinical study by Ellman, Lawrence & Thorold (1940) provided definitive evidence of the beneficial effects of gold on the course of the disease. RA was considered inactive in 74% of 60 patients treated for 9 months with Solganol[R]. By contrast, the disease was considered inactive in only one of 30 control patients who had not received gold injections. Gold ameliorated the course of the disease, not only in the advanced severe forms but also in the early cases of arthritis which were particularly responsive to gold treatment (Tarsy, 1940; Cecil, Kammerer & DePrume, 1942). However, the high incidence of toxicity

associated with gold in the doses recommended (100 mg weekly) still severely limited its use.

Patch and intradermal tests were not helpful in predicting which patients were likely to develop toxicity (Key, Rosenfeld & Tjoflat, 1939). High doses of calcium gluconate, and the vitamins C and D (administered simultaneously with the gold salts) were ineffective in preventing toxicity (Tarsy, 1940), and specific antidotes for gold toxicity were not yet available.

To try and reduce the incidence of toxicity, the weekly dose and total dose of gold were reduced (Freyberg, 1942; Price & Leichtentritt, 1943; Hartung, 1943). This reduced the incidence of toxicity and did not affect the therapeutic results. Reduction of dosage, more careful monitoring of patients for early symptoms of toxicity, and the intro- duction of cortisone (Hench, Kendall et al., 1949) and dimercaprol (British Anti-Lewisite, BAL) (Cohen, Goldman & Dubbs, 1948) as anti- dotes, greatly reduced the frequency of serious toxic reactions.

By the late forties, most investigators had realized the importance of carefully controlled studies and began comparing the effects of chrysotherapy with placebo (Fraser, 1945; Waine, Baker & Mettier, 1947; Adams & Cecil, 1950; Snorrason, 1952; Lockie, Norcross & Riordan, 1958). Favorable results following gold treatment were reported in most studies, but some investigators found no difference between the gold- treated and control groups (Merliss, Axelrod et al., 1951; Brown & Currie, 1953).

Because of the conflicting reports, the Empire Rheumatism Council (ERC), in 1960, conducted a multicentre double-blind clinical trial in an attempt to determine whether gold was effective in RA. In one group

of 99 patients with active RA, each received a total dose of 1.0 g of Myochrysine(R) in 20 injections of 50 mg im, weekly. In a second group of 100 arthritic patients (the controls), each received control injections containing Myochrysine(R) (0.01 mg). Patients were assessed before treatment began, at 3 months, at completion of the course of treatments, and at 18 and 30 months. Significant clinical improvement by all criteria used, except radiographic analysis, was observed more frequently among the gold-treated patients at 3, 6 and 18 months but little difference existed between the two groups at 30 months (ERC, 1961a).

Although earlier reports stressed the importance of continuing gold therapy (Forestier, 1935; Browning, Rice et al., 1947; Adams & Cecil, 1950; Freyberg, 1950; Lockie, Norcross & Riordan, 1958), the ERC did not continue gold maintenance therapy after the initial remissions. This could be the reason for the high number of relapses in the gold-treated patients at month 30.

In 1973, the Cooperative Clinics Committee (CCC) of the American Rheumatism Association conducted a similar double-blind controlled study of chrysotherapy. It differed from the ERC study in that phase II of the trial evaluated the benefit of continued therapy in prolonging remissions obtained with the initial course of gold. Half of the patients continued on gold therapy for an additional 18 months and the controls remained on placebo therapy. This maintenance program consisted of intramuscular injections of 50 mg of Myochrysine(R) every other week for 6 weeks followed by 6 more injections every third week and lastly, monthly injections for the rest of the 2 year study. Although the number of patients completing the trial was too small to

allow definite conclusions, the results suggested that maintenance
therapy was beneficial. The group in which therapy was continued
showed no increase in the number of joints involved, had an improved
grip strength and a fall in the erythrocyte sedimentation rate (ESR),
whereas the placebo group showed deterioration in all 3 parameters.
These results were confirmed in a 2-year double-blind study conducted
by Sigler and co-workers (1974). Although only 27 arthritic patients
were involved (13 received Myochrysine® and the others placebo), the
study demonstrated that long term gold treatment had altered the natural
course of the disease favorably, and, for the first time, radiographs
showed that chrysotherapy had slowed or arrested the progression of the
disease. More recently, Luukkainen and associates (1977 a,b) reported
significantly less joint destruction in gold-treated patients than in
controls who received less than 50 mg of Myochrysine® and had
terminated chrysotherapy because of side effects. Patients whose RA had
been active for less than 10 months initially showed greater improvement
than patients who had had the disease for a longer time before
commencing chrysotherapy. However, by the end of the follow-up period
(68 months), all 3 gold-treated groups had significantly less radio-
graphically demonstratable joint damage than the controls. Since then
more reports have been published which confirm the value of gold for the
treatment of RA (Schorn & Anderson, 1975; Majoos, Klemp et al., 1981).

Table I summarizes the results of studies published between 1935
and 1958. Freyberg (1966) provides a more complete review of the
literature. The benefits of chrysotherapy were evident in the majority
of arthritic patients treated with various gold compounds. The incidence
of gold toxicity was approximately 30%. This cumulative clinical

experience agrees well with the results of more recent controlled
studies.

Sabin & Warren (1940) and Preston, Block & Freyberg (1942)
demonstrated that the therapeutic effectiveness of gold preparations
depended on the gold in the molecule and not on sulphur or any other
constituents. Since then numerous gold(I) compounds have been used to
treat RA including sodium aurothiomalate (Myochrysine®), aurothioglucose
(Solganol®), gold thioglycoanilide (Lauron®) and gold sodium thiosulphate
(Sanochrysine®). Recently a gold(I) phosphine compound (Auranofin®)
has been developed for oral use and is currently undergoing clinical
trials (Finkelstein, Walz et al., 1976; Berglof, Berglof & Walz, 1978;
Weisman & Hannifin, 1979; Meyers & Klemp, 1981). The structural formulas
of these compounds are shown in Figure 1. Only the first two compounds
listed are commonly used in Canada and the United States. Sodium auro-
thiomalate (ATM) contains 45% Au and is available in aqueous solution
for im injection. Aurothioglucose (ATG), a water soluble organic compound,
contains 50% Au; it is available as an oily suspension for im injection.

Very few controlled studies have compared the efficacy and toxicity
of the various gold compounds. It is thought that ATM and ATG are
equally effective in the treatment of RA (Gottlieb, 1977), but in
several reports a lower incidence of toxicity has been noted with ATG
(Rothermich, Philips et al., 1976; Lawrence, 1976). Certain adverse
effects such as vasomotor (nitritoid) reactions (Lintz, 1941; Price &
Leichtentritt, 1943; Smith, Peak et al., 1958; Austad, 1970; Sharp,
Lidsky et al., 1977; Gottlieb & Brown Jr., 1977; Davison, 1980) and
non-vasomotor responses (Halla, Hardin & Linn, 1977) occur most
commonly with ATM. Unfortunately the use of ATG also has disadvantages.

Figure 1. Structural formulas of gold compounds used in the treatment
of RA. Compounds (1) and (2) are the most widely used and
are administered by intramuscular injection. Compounds (3)
and (4) are not used in Canada or the USA. Compound (5)
is active orally as is (6) which is undergoing clinical trials.

Intramuscular injections of ATG may cause more patient discomfort than ATM because it is suspended in a viscous oil. As well, firm masses have been observed at the sites of injection possibly due to the non-absorbed oil. Also, if the vial is not well shaken just prior to an injection to resuspend the ATG particles, the dose may be incorrect.

The triethylphosphine-gold compound (Auranofin®) contains 29% gold by weight and is well absorbed from the stomach. In preliminary studies, clinical improvement was evident after the fifth week of treatment and continued until the study was completed. Arthritic patients had reduced ESRs, fewer painful and swollen joints, and increased grip strengths. Patients had significantly lower blood gold concentrations after auranofin treatment (less than 100 μg/dl) than after parenteral administration of standard doses of ATM (more than 300 μg/dl) (Finkelstein, Walz et al., 1976; Berglof, Berglof & Walz, 1978). To date, very few side effects have been observed. Some reports suggest that the gold toxicity e.g. dermatitis, stomatitis, and proteinuria occurs less frequently with auranofin than with ATM but gastrointestinal disturbances are as common (Finkelstein, Walz et al., 1976; Berglof, Berglof & Walz, 1978). Mild diarrhea and abdominal cramps have occurred early in the course of treatment disappearing on continued administration of auranofin (Gottlieb, Riskin et al., 1980). Further experience is needed with this new drug before the complete spectrum of reactions is known.

Gold is indicated for active, progressive, erosive RA that can not be controlled adequately by more conservative measures such as non-steroidal anti-inflammatory drugs (NSAIDs), analgesics, physical therapy and rest. Early treatment is important since gold only suppresses the

inflammatory process and cannot repair previous damage to cartilage
and bone, nor can it restore deformed and ankylosed joints. It should
not be used in patients whose arthritis is no longer active, i.e. "burned
out" cases of arthritis (Gottlieb, 1977).

Chrysotherapy has been shown to be effective in the management of
juvenile rheumatoid arthritis (JRA) (Hicks, Hanson & Kornreich, 1970;
Ansell, 1972; Levinson, Balz & Bondi, 1977; Brewer Jr., Giannini &
Barkley, 1980). The dose is usually 1.0 mg/kg body weight administered
intramuscularly once a week with a maximum dose of 50 mg weekly for
larger children. Side effects appear to occur as frequently in children
as in adults and affect similar organs, even though lower doses are
employed.

Gold by itself is not the complete treatment for RA. It should be
part of a well planned program of therapy carefully adjusted to the
patient's needs. For progressive RA some physicians prefer to begin
treatment with penicillamine, but gold is generally considered before
other slow acting, remittive anti-rheumatic drugs such as chloroquine,
azathioprine, methotrexate and cyclophosphamide. These drugs are
effective in the treatment of RA and also are associated with a significant
number of complications (Currey, Harris et al., 1974; Huskisson, Gibson
et al., 1974; Dwosh, Stein et al., 1977; Husain & Runge, 1980).

Gold should not be administered to patients with a past history of
severe gold toxicity such as exfoliative dermatitis, blood dyscrasias
or persistent heavy proteinuria. Previous liver and kidney diseases
are not absolute contraindications unless the functions of these organs
are seriously impaired. Patients with existing abnormal liver and renal
function should be carefully monitored during treatment for a progression

or increase in these abnormalities indicative of gold toxicity. When other serious systemic diseases exist such as diabetes, hypertension, etc., they should be controlled prior to chrysotherapy. Patients with severe allergic diseases or those known to have an idiosyncracy to other drugs should be given gold with extreme caution. Chronic dermatitis is not a contraindication to gold therapy but may complicate the early recognition of gold rashes or could be aggravated by gold. Recently some skin disorders such as pemphigus have been successfully treated with gold salts (Penneys, Eaglstein & Frost, 1976). Traditionally chrysotherapy was not employed in pregnant or lactating women because the effect on the fetus or newborn infant was not known. Reports in the literature describing the outcome of pregnancies exposed to gold in utero are few. Hollander (1972) discussed a series of uneventful pregnancies in women receiving chrysotherapy but no long-term follow-up of the offspring has been reported. More recently Rogers, et al., (1980) reported the birth of an abnormal child resulting from a pregnancy inadvertently exposed to gold throughout the first and early part of the second trimester. The visible malformations included a cleft lip and palate, a flattened nose, crumpled ears and a short neck. The infant died on the fifth day. Other causes for these malformations have not been ruled out but a possible teratogenic effect of gold must be considered.

Age is not a contraindication to the use of gold since good results have been obtained in elderly patients with well established disease (Cecil & Kammerer, 1951) as well as in patients with juvenile rheumatoid arthritis (Hicks, Hanson & Kornreich, 1970; Ansell, 1972; Levinson, Balz & Bondi, 1977; Brewer Jr., Giannini & Barkley, 1980).

Administration of gold with other slow acting remittive drugs
(phenylbutazone, antimalarials, cytotoxic agents) is not recommended.
Since each drug alone may cause dermatitis, bone marrow depression or
proteinuria, potentiation of these effects may occur when these drugs
are used together. Potential drug interactions and increased toxicity
have not been studied, but must be considered when therapy with more
than one agent is contemplated (Gottlieb, 1981). The use of
penicillamine (a heavy metal chelating agent) along with gold is not
advised. Animal studies (Eyring & Engleman, 1963; Davidson & Engleman,
1964; Rubin, Sliwinski et al., 1967) and some human studies (Eyring &
Engleman, 1963; Davis, 1969) demonstrated that penicillamine
significantly increased the excretion of gold when administered in
doses larger than 1.0 g daily for at least 3-7 days. More recent work
(Davis & Barraclough, 1977; Biggs, Boland et al., 1979), however, does
not confirm the results obtained in earlier studies and the effectiveness
of D-penicillamine as a chelating agent for gold toxicity is questionable.
At one time concurrent use of systemic corticosteroids and gold was
believed to reduce the efficacy of the chrysotherapy, however no
evidence to substantiate this has been reported (Gerber & Paulus, 1975).
In fact, gold salts have been used to help reduce the corticosteroid
dosage in patients who have developed side effects (Ansell, 1972).

Current gold dosage schedules were derived empirically from the
clinical observations of patients over many years. A typical schedule
consists of an initial test dose of 10 mg of ATM or ATG followed in a
week by 25 mg. Provided that no adverse effects are observed, 50 mg
is then administered im weekly until a total dose of 1.0 g of gold
compound (500 mg of elemental gold) has been given or toxicity occurs.

If patients go into remission before completing the full 20 week course, gold is administered at progressively longer intervals, e.g. bi-weekly for a given period then tri-weekly and then monthly to reduce the chances of toxicity developing. Most patients require a minimum of two to three months of treatment (300—500 mg of gold compound) before the therapeutic effect is observed. If, and when, toxicity develops, treatment is temporarily or permanently discontinued depending upon the type and severity of the reaction. If improvement occurs after a cumulative dose of 0.5 g Au most rheumatologists recommend maintenance therapy in order to reduce the incidence of relapses. Typically, maintenance therapy consists of injections of 50 mg bi-weekly for a period of 2-20 weeks, then tri-weekly for several months and then monthly unless a "flare-up" occurs. Rothermich et al., (1976) claimed that injections at 4 week intervals or longer were insufficient to maintain remission. More recently Griffins et al., (1981) reported that patients receiving bi-weekly injections had a much higher incidence of toxic side effects (48%) than patients on monthly injections (22%). These results suggest that monthly maintenance therapy is as effective as bi-weekly and is less likely to cause toxicity. Srinivason and co-workers (1979) clearly demonstrated the value of maintenance therapy. They reported continued remissions in 73% of RA patients who received chrysotherapy for 3 years or longer compared to only 6% "spontaneous" remissions when gold therapy was stopped during the first 18 months. Unfortunately there is a tendency for some patients to deteriorate after prolonged periods of remission despite continued chrysotherapy (Rothermich, Philips et al., 1979). For these patients, administration of another remittive drug (penicillamine, methotrexate, azathioprine or

cyclophosphamide) is an alternative. If the maintenance dosage is inadequate, the disease will gradually reappear. Control can often be re-achieved by returning to weekly injections. If remission occurs, 50 mg doses should be administered bi-weekly, or larger doses (e.g. 75 mg) given tri-weekly (Smith, 1963; Sagransky & Greenwald, 1980).

After 0.5 g Au if a patient has not shown positive response, several alternatives are available. These include increasing the dosage of gold for a short time, continuing with the conventional gold dosage for a further period, or discontinuing chrysotherapy altogether. Smith et al., (1958) reported that 82% of patients unresponsive to weekly gold injections improved significantly when the dose was gradually increased at weekly intervals by 10 to 25 mg, until a maximum of 100 mg was reached. These patients were considered "hyper-excretors" of gold, and Smith recommended individualizing the dosage according to urinary excretion (1963). Unfortunately monitoring the urinary gold concentrations for all RA patients is not practical. Rothermich, et al., (1976) reported that 43% of patients who failed to respond to a conventional dose of gold improved when 1.5 to 2 times this dose was administered. Despite these larger than normal doses, side effects were observed in only 10% of the patients. Rather than gradually increasing the dosage, some physicians administer an additional 10-20 injections of 50 mg of gold (provided there are no toxic reactions) in the hope that a higher cumulative dose will be beneficial. Others discontinue chrysotherapy after administration of 0.5 g Au and begin treatment with another remittive agent.

Recently in several controlled studies, the effectiveness of the "conventional" schedule was compared to both higher and lower dosages.

Both Cats (1976), and Furst et al., (1977), demonstrated increased toxicity and no additional clinical benefit from 100 mg and 150 mg Au administered weekly. In another study, 25 mg ATM weekly was reported to be as effective as twice that amount administered on a flexible dosing schedule; this resulted in a reduction in total dosage but did not diminish the incidence of side effects (Sharp, Lidsky et al., 1977). Lorber and associates (1973) recommended individualizing the dosage of gold to maintain the serum gold concentrations above 300 ug/dl, because this concentration appeared to correlate well with a favorable clinical response. Because numerous other investigators have not been able to confirm any relationship of serum gold levels to either clinical response or toxicity, (Gerber, Paulus et al., 1972; Mascarenhas, Granda & Freyberg, 1972; Rubinstein & Dietz, 1973; Gottlieb, Smith & Smith, 1974; Furst, Levine et al., 1977), 50 mg of gold compound weekly has remained the accepted standard and is likely to remain so until more persuasive data is presented.

B. TOXICITY FROM GOLD THERAPY AND ITS TREATMENT

Controlled studies have demonstrated that chrysotherapy is of benefit to patients with progressive RA (see ERC, 1960; CCC, 1973; Sigler, Bluhm, et al., 1974). Remissions or marked improvement can be expected in 60-70% of patients, but side effects develop in about one third of these patients, resulting in discontinuation of treatment (Gibbons, 1979).

Gold causes many side effects (Table II). In most early studies, any adverse reaction or "disturbance" was attributed to gold toxicity

Table II.   Adverse Reactions Associated with Chrysotherapy

Mucocutaneous

> Pruritus
> Dermatitis
> Chrysiasis
> Stomatitis
> Vaginitis
> Ocular lesions

Renal

> Proteinuria
> Nephrotic syndrome

Hematologic

> Eosinophilia
> Thrombocytopenia
> Leukopénia
> Agranulocytosis
> Aplastic anemia

Miscellaneous

> Vasomotor (nitritoid) reactions
> Non-vasomotor reactions
> Diffuse pulmonary infiltrates
> GIT disturbances
> Enterocolitis
> Cholestatic jaundice
> Peripheral neuropathy

(Hartfall, Garland & Goldie, 1937b). The development of better diagnostic techniques, different classifications of the rheumatic diseases, and the recognition of similar side effects in placebo-treated patients, should have lowered the over-all incidence of toxicity. However, the incidence has not changed since the thirties when Forestier first popularized chrysotherapy. Freyberg (1966) reported an average incidence of 32% in over 7000 patients treated with gold salts between 1935 and 1958 which is comparable to the incidence observed in more recent studies (ERC, 1961b; Cats, 1976; Majoos, Klemp et al., 1980).

Most complications of chrysotherapy are mild, but approximately 5% of RA patients treated with gold will experience severe, life-threatening reactions such as exfoliative dermatitis, nephrotic syndrome or aplastic anaemia (Freyberg, 1966). The mortality rate in 1935 was reported to be as high as 3% (Hartfall, Garland & Goldie, 1937b), but is now estimated at about 0.4% (Gottlieb, 1981). This reduction in death rate can be attributed to the administration of lower doses of gold, limiting therapy to injections of ATM and ATG intramuscularly, earlier recognition of toxicity and improved treatment of the complications with corticosteroids, chelating agents, and advanced life support systems (Gottlieb, 1977).

Gold toxicity may appear at any time during treatment but is most common after the administration of 300-500 mg of Au (Jessop, 1972a; Smith, Peak et al., 1958). Patients who experience only minor side effects during the initial treatment with gold rarely experience toxicity during maintenance therapy (Cats, 1976; Kean & Anastassiades, 1979), or, when the dose of gold is increased to 50 mg weekly because of a flare-up (Sagransky & Greenwald, 1980).

Several early reports claimed a positive correlation between gold toxicity and therapeutic effect (Copeman & Tegner, 1937; Bayles & Fremont-Smith, 1956; Smith, Peak et al., 1958) but later controlled trials failed to confirm these observations (ERC, 1961a; Gottlieb, Smith & Smith, 1972; Cats, 1976). It is now generally agreed that toxicity is not a prerequisite for a favorable clinical response, and that gold toxicity may develop in the absence of any improvement (Gottlieb, 1979a).

No combination of laboratory tests and clinical examinations has been successful in predicting the development of gold toxicity. Results from patch and intradermal tests (Kay, Rosenfeld & Tjoflat, 1939; Walzer, Feinstein et al., 1972; Davis, Ezeoke et al., 1973; Penneys, Ackerman & Gottlieb, 1973), serum gold levels (Gerber, Paulus et al., 1972; Mascarenhas, Granda & Freyberg, 1972; Rubinstein & Dietz, 1973; Gottlieb, Smith & Smith, 1974; Furst, Levine et al., 1977), urinary excretion rates (Gottlieb, Smith & Smith, 1972), and gold tissue levels (Gottlieb, Smith et al., 1974b) can not be correlated with toxicity. Eosinophilia has been observed with equal frequency in patients with and without toxicity (Jessop, Dippy et al., 1974; Davis & Hughes, 1974), and in patients with active systemic RA who have not even received gold injections (Panush, Franco & Schur, 1971; Winchester, Litwin et al., 1971). Elevated serum IgM levels (Jalava, Luukkainen et al., 1977) and certain tissue antigens (HLA B12, DRW2, DRW3, DRW4) (Abruzzo, 1978; Panayi, Wooley & Batchelor, 1978; Majoos, Klemp et al., 1981) have been associated with the development of side effects in patients, however further investigation is required to establish the clinical relevance of these findings.

Attempts to prevent the development of gold toxicity by adminis-
tration of large doses of vitamins, liver extracts, calcium salts and
glucose have also proved unrewarding (Hartfall, Garland & Goldie, 1937b;
Tarsy, 1940). It therefore seems that the only useful criteria are
careful clinical and laboratory examinations of patients. Thus, during
chrysotherapy, patients should be carefully monitored for toxic symptoms
such as pruritus, skin rashes, sore mouths, bruising, or easy bleeding.
Urinalyses and blood counts should also be performed routinely. At the
first sign of a reaction, depending on the type and severity, the dosage
may be reduced (Burnstein, Staley & Calabro, 1979) or gold therapy
temporarily discontinued (Gottlieb, 1977; Rosenbaum, 1979). Once the
lesion(s) has cleared, gold therapy may be reinstituted beginning with
low doses, or if the side effect has been severe, treatment with gold
should be abandoned.

1. ORGAN SYSTEMS INVOLVED IN TOXICITY

a. MUCOCUTANEOUS

Toxic reactions to gold have been reported to involve most organs
in the body but the skin and mucous membranes are affected most often.
Between 15—30% of all patients given gold therapy experience
mucocutaneous reactions (Klinefelter, 1975; Davis, 1979). These include
nondescript skin lesions, and eruptions resembling lichen planus or
pityriasis rosea, which typically are pruritic (Penneys, Ackerman &
Gottlieb, 1974). Exfoliative dermatitis, a much more serious complication,
occurs rarely (Zvaifler, 1979; Gottlieb, 1981). Chrysiasis, the
deposition of gold particles in the skin resulting in hyper-pigmentation

of light exposed areas, occurs in some patients receiving prolonged treatment (Cox & Marich, 1973; Jeffery, Biggs et al., 1975). Lesions of the oral mucosa (stomatitis, glossitis, gingivitis) are uncommon and may be preceded by a sore mouth or a metallic taste (Freyberg, 1966). These reactions may occur alone, or, occasionally in association with dermatitis (Gibbons, 1979). Only one case of vaginitis associated with chrysotherapy has been reported in the literature (Webster & Juden, 1978). Ocular lesions (conjunctivitis, iritis and corneal ulceration) are infrequent (Hartfall, Garland & Goldie 1937b; Price & Leichtentritt, 1943), but corneal chrysiasis (accumulation of gold particles in the cornea) has been reported in 45-75% of patients receiving a cumulative dose of more than 1500 mg of gold (Hashimoto, Maeda et al., 1972; Gottlieb & Major, 1978).

The mechanism(s) responsible for these types of gold toxicity are unknown. Denman and Denman (1968) and Walzer and associates (1972) suggested that certain reactions to gold (e.g. dermatitis) were immunologically mediated. Although eosinophilia and/or elevated serum IgE levels have been observed in association with gold dermatitis — suggesting a Type I hypersensitivity reaction (Jessop, Dippy, et al., 1974; Davis, Ezeoke et al., 1973), similar changes have been reported in patients with active RA who have not received gold treatment (Panush, Franco & Schur, 1971; Winchester, Litwin et al., 1971; Hunder & Gleich, 1974; Grennan & Palmer, 1979). Also, patch and intradermal skin tests have been negative in most patients with gold dermatitis, and inconclusive results have been obtained in lymphocyte transformation tests (Penneys, Ackerman & Gottlieb, 1974). Because cutaneous reactions often develop after the patient has received multiple gold injections (400—800 mg

cumulative dose), a direct toxic effect on the skin has been suggested.
Chrysiasis has been considered an example of a cumulative toxic effect
(Cox & Marich, 1973; Stone, Claffin et al., 1973). Skin biopsies
of patients with chrysiasis were found to contain high levels of gold,
but these patients had had no dermatitis since developing chrysiasis
(Jeffrey, Biggs et al., 1975). Other investigators reported that skin
from lesions and unaffected areas in the same patient contained similar
amounts of gold, and these levels were comparable to those found in the
skin of patients without dermatitis (Gottlieb, Smith et al., 1974b;
Ghadially, DeCoteau, et al., 1978). These findings suggest that some-
thing more than the deposition of gold is required for cutaneous
lesions. The possibility that skin lesions are an idiosyncratic
reaction to gold has also been suggested because many patients
experience toxicity after receiving only a single small dose of gold
(Saphir & Ney, 1966).

Most authorities recommend the discontinuation of gold therapy
when cutaneous or mucous membrane lesions occur. These manifestations
generally resolve spontaneously within 3-4 months, depending on the
severity, however, a few eruptions can persist much longer (Gibbons,
1979). Antihistamines may be useful for pruritus and topical steroid
preparations have been used for symptomatic relief of dermatitis,
stomatitis and vaginitis, but there is no evidence that they shorten the
rate of resolution of these lesions substantially (Penneys, Ackerman &
Gottlieb, 1974). More serious complications, such as exfoliative
dermatitis, require the discontinuation of chrysotherapy and
administration of systemic corticosteroids. Dimercaprol and
penicillamine have been used successfully in the past (Ragan & Boots,

1947; Montgomery, 1950) but are only recommended for severe reactions unresponsive to corticosteroid therapy (Davis, 1969). Chrysiasis

appears to be a long-lasting pigmentation (Jeffery, Biggs et al., 1975) of cosmetic importance only. Corneal chrysiasis does not cause visual disturbances or other ocular symptoms and does not require discontinuation of treatment. Unlike skin chrysiasis, the deposits of gold in the cornea have been reported to disappear within 3—5 months after termination of gold treatment (Hashimoto, Maeda et al., 1972). Even if the occurrence of mucocutaneous reactions leads to the discontinuation of chrysotherapy, many patients will tolerate further therapy after their lesions clear. Chrysotherapy was reinstituted successfully in 28 of 30 patients who had previously developed rash, stomatitis, or both (Kleinfelter, 1975). In some of these patients mucocutaneous reactions recurred but did not require stopping therapy. Further gold treatment for patients who have experienced severe cutaneous reactions i.e. exfoliative dermatitis is contraindicated (Penneys, Ackerman & Gottlieb, 1974).

b. RENAL

The association of renal lesions with the administration of gold in animals (Ganote, Beaver & Moses, 1966; Stuve & Galle, 1970; Nagi, Alexander & Barabas, 1971; Thompson, Blaszak et al., 1978) and in RA patients (Brun, Olsen et al., 1964; Lee, Dushkin et al., 1965; Silverberg, Kidd et al., 1970) is well documented. The most common complication is proteinuria; the incidence ranging between 0 and 26% (Table III). Proteinuria has also been observed in about 3% of placebo-treated patients (ERC, 1960; CCC, 1973). Possible causes

Table III. Incidence of Proteinuria During Chrysotherapy

Investigator	Year	Conventional Gold Dose		No Gold	
		Number of Patients Toxic/Treated	Percent Toxic	Number of Patients Toxic/Treated	Percent Toxic
ERC	1960	4/99	4	3/100	3
Silverberg et al.	1970	5/75	7	--	--
CCC	1973	0/36	0	1/32	3
Cats	1976	4/119	3	--	--
Rothermich et al.	1976	2/55	4	--	--
Sharp et al.	1977	6/38	16	--	--
Furst et al.	1977	6/23	26	--	--

include contaminated specimens, urinary tract infections (Davis, 1979),

or other drugs used to treat arthritis i.e. analgesic nephropathy

(Lancet, 1966). Nephrotic syndrome, a more serious renal complication,

is much less common, reported in only 0.2-2.6% of arthritic patients

on chrysotherapy (Silverberg, Kidd, et al., 1970; Vaamonde & Hunt, 1970;

Tornroth & Skrifvars, 1974). Besides gold, other causes for nephrotic

syndrome include amyloidosis (Nagy El Mahallawy & Sabour, 1959;

Allander, Bucht et al., 1963) and lupus nephritis (Pollack, Pirani,

et al., 1962; Schreiner & Maher, 1965); therefore careful diagnosis is

important. The mechanism(s) responsible for the production of renal

lesions is not known. Gold deposits have been detected in renal tubules,

interstitial tissues and glomerular tufts in kidney biopsies obtained in

patients with gold-induced proteinuria or nephrotic syndrome (Silverberg,

Kidd et al., 1970; Viol, Minielly, et al., 1977). Immunoglobulins

(IgG, IgM), and complement deposits containing electron-dense gold

particles were also observed within the glomeruli (Katz & Little, 1973;

Yaram, Stein, et al., 1975; Skrifvars, Tornroth & Tallquist, 1977)

supporting the hypothesis that immune complexes are involved in the

pathogenesis of gold-induced nephropathy. Another hypothesis which

warrants further investigation is that RA itself can induce membranous

nephritis (Samuels, Lee et al., 1977).

Since most patients are asymptomatic, regular urinalyses are

required to detect gold-related proteinuria and nephrotic syndrome

(Davis, 1979). A trace amount of protein in the urine is not an

indication to discontinue gold treatment but persistent proteinuria,

in the absence of a urinary tract infection or other cause, may be an

early sign of gold nephropathy, and injections should be stopped

(Jessop 1972; Gibbons, 1979). Proteinuria and nephrotic syndrome may
not require treatment other than the discontinuation of chrysotherapy,
but in more severe cases corticosteroids should be administered
(Vaamonde & Hunt, 1970; Davis, 1979). There is no evidence that
dimercaprol or penicillamine are helpful, but in cases unresponsive to
corticosteroids these agents may be tried (Gibbons, 1979). Gold therapy
may be reinstituted once the proteinuria has resolved but is not given
again to patients who have experienced more serious renal side effects.

c. HEMATOLOGIC

Hematologic disorders resulting from chrysotherapy include
eosinophilia, thrombocytopenia, leukopenia or agranulocytosis and
aplastic anemia. The most common hematological change associated with
gold is eosinophilia which has been reported in 40—45% of gold-
treated patients (Davis & Hughes, 1974; Jessop, Dippy, et al., 1974).
Thrombocytopenia is a less common complication of gold treatment
occurring in 1-3% of patients (Gottlieb, 1981) and leukopenia may
develop during treatment owing to granulocytopenia or agranulocytosis.
The exact incidence is not known but is probably < 1% (Gibbons, 1979).
The most serious complication is aplastic anemia. It is rare, but is
associated with a 60% mortality rate (McCarty, Brill & Harrop, 1962;
Kay, 1976).

An immunologic mechanism has been suggested as the cause of some
of the gold-related hematological side effects. Bone marrow biopsies
from patients with gold-induced thrombocytopenia have been found to
contain normal or increased numbers of megakaryocytes. These data
suggest that thrombocytopenia is most likely due to peripheral

destruction of platelets (Stavem, Stromme & Bull, 1968; Deren, Masi,
et al., 1974) even though anti-platelet antibodies have not been demon-
strated (Levin, McMillan, et al., 1975). A direct toxic effect on
the bone marrow has also been suggested (Howell, Gumpel & Watts, 1975;
Kurnick, Robinson & Dickey, 1971).

The clinical significance of eosinophilia and leukopenia is not
known. Both conditions have been reported to occur in the absence of
chrysotherapy (Panush, Franco & Schur, 1971; Winchester, Litwin, et al.,
1971; Barnes, Turnbull & Vernon-Roberts, 1971) and arthritic patients
with pre-existing leukopenia have been successfully treated with gold
salts without adverse hematologic effects (Gowans & Salami, 1973).
Eosinophilia and leukopenia can be considered indications to discontinue
chrysotherapy temporarily (Gottlieb, 1977), but gold can be continued
in full or reduced dosage unless the situation worsens. Thrombocytopenia,
an unpredictable potentially life-threatening complication, usually
requires immediate termination of therapy and administration of steroids,
but it can resolve spontaneously (Kay, 1976; Davis, 1979). For cases
unresponsive to steroids, splenectomy (Watson, 1953; McCarty, Brill &
Harrop, 1962), dimercaprol (Lockie, Norcrosse & George, 1947; Thompson,
Sinclair & Duthie, 1954; Hazlett & Yendt, 1958; Saphir & Ney, 1966;
Stavem, Stromme & Bull, 1968; England & Smith, 1972; Stafford & Crosby,
1978), D-penicillamine (Bluhm, Sigler, et al., 1962; Harth, Hickey
et al., 1978) and vincristine (Ahn, Harrington, et al., 1974; Ball,
1977) have been used with some success. Marrow aplasia is also
unpredictable and a progressive drop in hematologic values should result
in cessation of chrysotherapy and immediate investigation of the bone
marrow (Baldwin, Storb, et al., 1977; Davis 1979). There are no specific

measures for the treatment of agranulocytosis and bone marrow aplasia but patients may benefit from corticosteroids, androgens and transfusions. Dimercaprol and D-penicillamine have been used as chelating agents although there is little evidence that they are of benefit (Kay, 1976). Generally, gold-induced aplastic anemia has a poor prognosis even with these treatments. More recently, peritoneal dialysis (Combs, Dentino, et al., 1976) and bone marrow transplantation (Baldwin, Storb, et al., 1977) have been used. For patients who have experienced hematologic complications, further gold therapy is contra-indicated.

d. OTHER GOLD-INDUCED SIDE EFFECTS

Vasomotor (nitritoid) reactions have been observed in 34% of RA patients treated with ATM (Furst, Levine, et al., 1977) however in most studies the incidence of this reaction has not been determined. Symptoms usually occur shortly after the administration of ATM and consist of facial flushing, sweating, weakness, and giddiness (Austad, 1970; Sharp, Lidsky, et al., 1977). The etiology of this reaction is not known but may involve hypersensitivity to the compound, the preservative, or the vehicle. The reaction is usually mild and passes in a short time but in some patients it is severe enough to warrant a reduction in dosage or a change to another gold compound. Subsequent reactions occur rarely. Gottlieb and Brown Jr. (1977) and Harris (1977) each reported a single case of an acute myocardial infarction as a consequence of a gold-induced vasomotor reaction.

Non-vasomotor (postinjection) reactions consisting of increased stiffness, arthralgias, myalgias, joint pain and constitutional symptoms, developed in 15% of patients treated with ATM in one study

(Halla, Hardin & Linn, 1977). The cause(s) is/are not known but the results from one study suggested that these side effects were the result of a transient inhibitory effect of ATM on the reticuloendothelial system (Williams, Lockwood & Pussell, 1979). These manifestations are well tolerated usually, but in patients who find the symptoms distressful, often ATG can be substituted without further reactions developing.

Other organ systems infrequently affected by gold include the lungs, the gastrointestinal tract, the liver and the peripheral nervous system. Acute respiratory distress associated with diffuse pulmonary infiltration has only recently been described (Winterbauer, Wilske & Wheels, 1976; Geddes & Brostoff, 1976; Gould, McCormack & Palmer, 1977; James, Whimster & Hamilton, 1978; Smith & Ball, 1980; Podell, Klinenberg, et al., 1980). Gastrointestinal side effects which have been observed frequently during gold therapy include anorexia, nausea, diarrhea and abdominal cramps (Freyberg, 1966) but only a few cases of enterocolitis have been reported in the literature (Kaplinsky, Pras & Frankl, 1973; Stein & Urowitz, 1976). Cholestatic jaundice associated with chrysotherapy is also uncommon (Favreau, Tannenbaum & Lough, 1977) as is involvement of the peripheral nervous system (VanSlype & Burniat, 1964; Walsh, 1970; Katrak, Pollack, et al., 1980). The etiology of these rare manifestations of gold toxicity has not been determined. Discontinuation of chrysotherapy and administration of systemic corticosteroids is usually effective in the treatment of pulmonary infiltrates and enterocolitis. Jaundice and peripheral neuropathies usually resolve slowly after gold treatment has been stopped. Chryso-therapy is not reinstituted in patients who have developed these side

effects.

C. GOLD PHARMACODYNAMICS

---

1. ABSORPTION

The pharmacodynamics of gold are related at least in part to the physical properties of the carrier molecule (e.g. water solubility, particle size). The water soluble compounds such as ATM and ATS are rapidly absorbed from the injection site after intramuscular administration (Block, Buchanan & Freyberg, 1941). ATG in an oily suspension is more slowly absorbed from the injection site but otherwise behaves similarly to ATM and ATS administered in aqueous solutions (Freyberg, Block et al., 1941; 1942). Calcium aurothiomalate which is less soluble than ATM and ATS, follows an intermediate pattern between the soluble and insoluble gold compounds (Block, Buchanan & Freyberg, 1942). Tissue-distribution studies in animals revealed that large amounts of gold (especially colloidal gold) remained at the injection site for as long as 85 days after the last dose was administered (Block, Buchanan & Freyberg, 1941; 1942; 1944). In RA patients given ^{198}Au-ATM im, considerable activity at the injection site was encountered for up to 20 days (Lawrence, 1961). Since gold compounds are usually poorly absorbed from the gastrointestinal tract after oral administration (Sairanen & Vahatalo, 1973) gold compounds were developed that were active orally (Sutton, McGusty et al., 1972). Examples of these compounds include triethylphosphine gold chloride and auranofin® (S-triethylphosphine gold 2,3,4,6-tetra-o-acetyl-1-thio-β-D-glucopyranoside) (Figure 1). Oral administration of these compounds

to guinea pigs inhibited erythema as effectively as a similar dose of ATM administered intramuscularly (Kamel, Brown et al., 1978a) and in RA patients, auranofin (3 mg two or three times daily) was well-absorbed and well tolerated (Finkelstein, Walz et al., 1976). Gold was detected in the serum as early as the seventeenth day, however, significantly lower levels were observed than after parenteral gold therapy (Walz, DiMartino et al., 1972; 1976). Intra-articular administration of gold salts has received little attention although a few physicians have reported success when ATM was injected into the knee joint(s). In addition to the reduction of inflammation in the knees, some patients experienced a generalized improvement in their condition indicating that ATM was absorbed systemically (Ansell, Crook et al., 1963; Lewis & Ziff, 1966).

2. SERUM PHARMACODYNAMICS

After intramuscular administration of ATM or ATS, an immediate rapid rise in plasma (serum) gold concentration is observed. Peak levels of 400-800 µg/dl are usually reached within six hours of injection and fall gradually over the next week (Freyberg, Block & Levey, 1941; Gerber, Paulus et al., 1972a; Mascarenhas, Granda & Freyberg, 1972; Jessop & Johns, 1973; Palmer & Dunckley, 1973; Lorber, Atkins et al., 1973; Harth, 1974; Gottlieb, Smith & Smith, 1974a). The lowest concentration is observed usually on the seventh day just before the next injection (Krusius, Markkanen & Peltola, 1970; Lorber, Atkins et al., 1973; Leroy, Bureau et al., 1978). Lower plasma-gold levels are observed when ATG is administered (about one-third less than with ATM or ATS) because of the slower absorption from the oil-based

injection, but at the end of one week, plasma gold levels are comparable for all three compounds (Freyberg, Block & Wells, 1942; Mascarenhas, Granda & Freyberg, 1972; Rubinstein & Dietz, 1973). With increasing weekly dosages, a stepwise increase in plasma gold concentration is observed but by the sixth to eighth injection, a plateau is reached (Freyberg, Block & Levey, 1941; Mascarenhas, Granda & Freyberg, 1972; Jessop & Johns, 1973; Palmer & Dunckley, 1973; Lorber, Atkins et al., 1973; Leroy, Bureau et al., 1978). As treatment continues with a constant dose, gold does not accumulate further in the plasma. Considerable individual variation exists and plasma gold levels are affected by the nature of the gold compound administered, the dose, the frequency of dosing, the time of sampling and patient weight (Leroy, Bureau et al., 1978). At steady state, serum gold levels have ranged from 150—600 µg/dl (Gerber, Paulus et al., 1972a; Lorber, Atkins et al., 1973; Jessop & Johns, 1973; Lorber, 1977a). When the period between injections is lengthened (i.e. maintenance therapy), there is a steady drop in plasma gold until the next injection. Serum gold concentrations remain between 75 and 125 µg/dl when 50 mg of gold (ATM) was administered every third or fourth week (Gottlieb, Smith & Smith, 1974a). When gold therapy is discontinued plasma gold levels follow a pattern similar to maintenance therapy but small amounts of gold are still detectable in the plasma months or even years later (Freyberg, Block & Levey, 1941; Rubinstein & Dietz, 1973; Vernon-Roberts, Dore et al., 1976). Blood-Au levels of 300 µg/dl were observed in one patient who had died two years after receiving her last injection of gold, eventhough she had had numerous transfusions (11.1 L of packed cells) (Kamel, Brown et al., 1976a). These findings indicate that gold

from the tissues must pass extremely slowly into the bloodstream for excretion. In guinea pigs, after oral administration of triethyl-phosphine gold chloride (18.7 mgAu/kg), serum gold levels peaked within 4 to 5 hours but were significantly lower than those following injection of ATM (15 mgAu/kg, im). However, at 24 hours, the serum gold levels were comparable (Kamel, Brown et al., 1978a). In RA patients on auranofin therapy, whole blood-gold concentrations rose steadily during the 12 week clinical trial, reaching a maximum of 90 µg/dl with 6 mg per day dosing and 120 µg/dl with 9 mg per day. After 7 weeks of treatment, all patients had a gold level of at least 300 µg/dl in blood, however, auranofin blood gold levels did not reach a steady state or plateau, unlike ATM (Finkelstein, Walz et al., 1976; Berglof, Berglof & Walz, 1978). After terminating auranofin therapy, serum gold levels declined slowly (Berglof, Berglof & Walz, 1978).

Numerous studies in vitro and in vivo have shown that at gold concentrations reached during chrysotherapy, 85-95% of the gold in the circulation is bound to albumin (Sliwinski, 1968; McQueen & Dykes, 1969; Mascarenhas, Granda & Freyberg, 1972; Danpure, 1974; Mason & McQueen, 1976; Kamel, Brown et al., 1977; Ward, Danpure & Fyfe, 1977; Schattenkirchner & Grobenski, 1977; Lawson, Danpure & Fyfe, 1977; Francois, Goldberg et al., 1978; Van de Stadt & Abbo-Tilstra, 1980). Plasma and serum gold levels are similar indicating no appreciable binding by fibrinogen (Sliwinski, 1968; McQueen & Dykes, 1969; Mascarenhas, Granda & Freyberg, 1972; Schattenkirchner & Grobenski, 1977; Francois, Goldberg et al., 1978; Van de Stadt & Abbo-Tilstra, 1980) contrary to the findings of Lawrence (1961). Small amounts of gold (<10%) have been reported to bind to globulins (Simon, 1954;

Sliwinski, 1968; McQueen & Dykes, 1969; Mascarenhas, Granda & Freyberg, 1972; Kamel, Brown et al., 1977; Lawson, Danpure & Fyfe, 1977) including α_1 globulin (Lawrence, 1961) ß-lipoprotein, and 7Sγ globulin (Coke, 1963). At higher plasma gold concentrations (300-700 μg/dl), there was an increased binding of gold to immuno-globulins and complement (Lorber, Bovy & Chang, 1972; Schultz, Gottlieb & Arnold, 1973; Ward, Danpure & Fyfe, 1977; Burge, Fearon & Austen, 1978; Hasselbacher, 1981). Also, a small amount of a low molecular weight (l.m.w.) gold-containing fraction was detected in the serum (Ward, Danpure & Fyfe, 1977; Francois, Goldberg et al., 1978; Danpure, Fyfe & Gumpel, 1979). This fraction, sometimes mislabelled as "free gold" (Danpure, 1977) disappeared within 30 to 100 min. after adminis-tration (Danpure, Fyfe & Gumpel, 1979) which probably accounts for the failure of previous workers to detect it (Libenson, 1945; Kamel, Brown et al., 1976b). When ATM (30 mg/kg) was administered to guinea pigs, this l.m.w. fraction contained considerable amounts of gold 30 minutes after the injection, and it was still detectable after 24 hr. (Kamel, Brown et al., 1978a). It has been suggested that the high levels of gold observed immediately after injection are due to unchanged ATM in the serum and that cysteine and/or glutathione-gold complexes released from the tissues, are responsible for the small amounts observed in the l.m.w. fraction after 24 hr. (Danpure, 1977; Lawson, Danpure & Fyfe, 1977; Danpure, Fyfe & Gumpel, 1979).

Freyberg et al., (1941; 1942), using a colorimetric micro-chemical method found very little gold in the blood cells of patients on chryso-therapy. However, with more sensitive and sophisticated techniques such as atomic absorption spectroscopy (AAS) and neutron activation analysis

(NAA), varying amounts of gold have been detected in the cellular fractions of blood (Lawrence, 1961; Kamel, Brown et al., 1976b; Francois, Goldberg et al., 1978; Van de Stadt & Abbo-Tilstra, 1980).

In two studies, 40-45% of RA patients given ATM or ATG had measurable amounts of gold in their red cell fractions (Smith, Smith & Gottlieb, 1973; Van de Stadt & Abbo-Tilstra, 1980). The amount of gold bound to erythrocytes ranged from 0-131 µg/dl of the washed red cell fraction (Smith, Smith & Gottlieb, 1973; Moller Pedersen & Moller Graabaek, 1980). ATM did not penetrate the erythrocyte membrane but appeared to be bound to it (Jellum, Munthe et al., 1979) and could not be removed by washing with free cysteine or albumin-containing media, indicating very strong binding (Kamel, Brown et al., 1976b; Van de Stadt & Abbo-Tilstra, 1980). The chrysotherapy program, the patients' blood groups and types, and results of their serologic tests, did not correlate with gold uptake into red blood cells (Van de Stadt & Abbo-Tilstra, 1980). Gold was barely detectable in red cell fractions eight hours after injection, but reached a maximum concentration by day 7 suggesting that gold is incorporated into the red cell precursors in the bone marrow and subsequently released into the circulation. This hypothesis is also supported by the findings that patients with and without red cell gold have similar serum gold concentrations (Smith, Smith & Gottlieb, 1973). In addition to gold binding by erythrocytes, Lorber and associates (1975; 1977b) have observed an increase in cell-gold content when lymphocytes were incubated with high concentrations of gold (300-700 µg/dl). Also, a fourfold increase in lymphocyte gold was observed in 10 of 17 RA patients after an im injection of ATM (Lorber, Wilcox et al., 1979). The clinical significance of these findings is

not known.

After oral administration of auranofin, the distribution of gold in blood is different than after intramuscular administration of ATM. The absolute amount of gold (auranofin) bound to albumin is lower than after ATM (Walz, DiMartino et al., 1976), but the albumin, α_1, α_2 and β globulin fractions contain similar percentages of the total serum gold. The γ globulin-gold concentration was three times greater in triethylphosphine gold chloride-treated animals (Kamel, Brown et al., 1978b). Kamel et al., (1978b) reported that 25% of serum gold in the ATM, and 100% in the triethylphosphine gold-treated animals was protein bound 30 minutes after administration. However, after 24 hr., 88% of the gold (ATM) was bound to the serum proteins. Only 4% of gold as ATM has been reported to bind to the cellular fraction(s) in blood (Kamel, Brown et al., 1977) compared to 52-57% to the formed elements of the blood with auranofin (Walz, Griswold et al., 1979). ^{31}P nuclear magnetic resonance (nmr) studies demonstrated triethylphosphine gold chloride membrane-binding to the sulphydryl groups of glutathione and hemaglobin and possibly to the cell membrane(s) (Malik, Otiko & Sadler, 1980). Gold compounds which can be absorbed orally have a much higher affinity for lymphocytes than ATM for example. Four weeks after the start of auranofin therapy, lymphocyte gold content approached that obtained with ATM despite significantly lower plasma gold levels. These results suggest that as auranofin treatment continues, lymphocyte-membrane sites may eventually become saturated (Walz, Griswold et al., 1979).

Following the demonstration that gold in plasma or serum was bound mainly to albumin (McQueen & Dykes, 1969; Mascarenhas, Granda & Freyberg,

1972; Danpure, 1974) numerous investigators examined the binding

parameters of this reaction. Libenson (1945) was the first to suggest

that sulphydryl groups of proteins were involved in the gold binding.

This was confirmed by Gerber (1964) and Danpure (1976a) who demonstrated

that gold (ATM) was bound to the cysteine-34 of mercaptalbumin

(Cornell & Kaplan, 1978 a,b). However, until recently, the role of

carrier ligands in the gold-albumin reactions was unclear. Using nmr

(Isab & Sadler, 1976), extended x-ray absorption fine structure analysis

(Mazid, Razi & Sadler, 1980), and Mössbauer spectroscopy (Brown, Parish &

McAuliffe, 1981), it was shown that the gold(I) atom in ATM and ATG

was bonded to two bridging sulfur atoms, and that a linear 2-coordinated

gold(I) structure was the most stable and therefore the most favored.

When these compounds reacted with a protein such as albumin (Gerber,

1964) or a non-protein thiol such as cysteine (Danpure, 1976b) or

glutathione, the bridging sulphurs were displaced to form

bis-thiolato-gold(I) complexes as shown in Figure 2a (Shaw, 1979). A

further reaction with non-protein thiols could lead to displacement of

the thiomalate carrier ligand (Figure 2b). This was observed when

^{35}S-labelled ATM was incubated with human serum $\underline{in\ vitro}$ and then

fractionated by gel chromatography (Jellum, Aasethe & Munthe, 1977).

Following the administration $\underline{in\ vivo}$ of doubly labelled ATG, different

amounts of ^{198}Au and ^{35}S-thioglucose accumulated in mouse organs,

indicating dissociation of the thioglucose from gold (Swartz, Christian &

Andrew, 1960). Also, in studies involving both RA patients treated with

Myochrysine® (Heininger, Munthe et al., 1978), and mice given ^{195}Au-

^{14}C-thiomalate (Jellum, Munthe et al., 1979; 1980), free thiomalate

was detected in the urine 12 to 24 hr. after administration, but not

    2b. Involvement of a second thiol-containing compound (RSH) with release of free thiomalate (TM-SH)

    2c. Displacement of gold from protein in the presence of excess thiol (RSH)

in serum or synovial fluid. Indirect evidence for thiomalate-Au splitting was reported by Griffin and Stevens (1982). In the presence of N-acetyl-cysteine or bovine serum albumin, ATM dissociated inhibiting the enzymatic activities of trypsin. Inhibition was reversed when high concentrations of imidazole was added to the system presumably because imidazole acted as a competitive binding agent for gold. The thiol-containing enzyme papain was reactivated in the presence of low concentrations of ATM due to dissociation of gold from thiomalate, but at higher concentrations the gold bound to the thiol in the active centre of the enzyme causing inhibition. Displacement of gold from the protein (Figure 2c) is another possible reaction in the presence of excess thiol (Shaw, 1981). Studies with penicillamine (Brown, McKinley & Smith, 1978; Biggs, Boland et al., 1979; Schaeffer, Shaw et al., 1980) and N-acetylcysteine (Lorber, Baumgartner et al., 1973), the structures of which are shown in Figure 3, demonstrated that substantial excesses of thiol were required to compete effectively with the protein(s) for gold. This may result from the larger binding constants for gold-protein complexes than simple thiols (Schaeffer, Shaw et al., 1980) or from sulphydryl-disulphide interchange reactions of thiols with proteins (Lorber, Chang et al., 1970).

The kinetics of gold binding to albumin have not been examined in detail. Danpure et al., (1979) demonstrated that the rate of binding of ATM to albumin in vivo was much faster (100 min.) than binding in vitro, which required approximately 5 hr. to attain equilibrium. When commercially-prepared human albumin or stored serum was used, the rate of binding to albumin was even slower. Shaw (1979) suggested that the faster reaction in vivo was due to the reaction of ATM with non-protein

thiols to form complexes which reacted more readily with the albumin.
Others (Isab & Sadler, 1976; Petering, 1976) proposed that the polymeric
structure of ATM was the cause of the slow reaction with albumin. How-
ever, conformational changes in albumin e.g. the rearrangement of the
disulphide bridges to an aged form (Danpure & Fyfe, 1976; Cornell &
Kaplan, 1978a,b) are other possible causes for the slow reaction.
Recently, several investigators (Mason, 1977a; Biggs, Boland et al.,
1979; Moller Pederson, 1981) have measured the binding constants of ATM
and human serum albumin (HSA). Widely divergent results were reported,
and the only point of agreement was that there were at least two classes
of binding sites. One class with a single binding site has a high
affinity for gold. The intrinsic association constant was reported as
$6.1 \times 10^3 M^{-1}$ (Mason, 1977a), $1.75 \times 10^6 M^{-1}$ (Biggs, Boland et al., 1979),
and $3.0 \times 10^4 M^{-1}$ (Moller Pederson, 1981). The second class, consisting
of one or more binding sites, was reported to have a lower affinity for
gold with intrinsic association constants of $2.35 \times 10^2 M^{-1}$ (Mason, 1977a)
or in the order of $10^3 M^{-1}$ (Moller Pederson, 1981). The heterogeneity
of serum albumin in vivo was probably not taken into account in these
investigations and probably accounts for the discrepancies (Danpure
1976a; Danpure & Fyfe, 1976).

3. TISSUE DISTRIBUTION

In animals receiving ATM or other gold compounds by injection
(Block, Buchanan & Freyberg, 1941; 1942; 1944; Bertrand, Waine &
Tobias, 1948; Jeffrey, Freundlich & Bailey, 1958; Ganz & Brucer, 1958;
Swartz, Christian & Andrew, 1960; Tonna, Brecker et al., 1963;

McQueen & Dykes, 1969; Sugawa-Katayama, Koishi & Danbara, 1975), and
in RA patients receiving standard chrysotherapy (Lawrence, 1961;
Silverberg, Kidd et al., 1970; Kantor, Harley et al., 1971; Gottlieb,
Smith & Smith, 1972a; Grahame, Billings et al., 1974; Kamel, Brown
et al., 1976a; Vernon-Roberts, Dore et al., 1976), tissue distribution
studies have shown that the highest concentrations of gold are found
in the organs containing reticuloendothelial cells such as the kidney,
liver, spleen, bone marrow, adrenals and lymph nodes. Small amounts of
gold also have been detected in the heart, lungs, brain tissue (Jeffrey,
Freundlich & Bailey, 1958; Kamel, Brown et al., 1978b) muscle (Grahame,
Billings et al., 1974), synovia (Freyberg, Block & Levey, 1941;
Bertrand, Waine & Tobias, 1948; Lawrence, 1961; Gottlieb, Smith & Smith,
1972a; Gerber, Paulus et al., 1972a; Grahame, Billings et al., 1974).
After prolonged chrysotherapy, skin contains considerable amounts of
gold (Freyberg, Block & Wells, 1942; Bogg, 1958; Cox & Marich, 1973;
Gottlieb, Smith et al., 1974b; Jeffrey, Biggs et al., 1975; Penneys,
Kramer & Gottlieb, 1975). These studies all indicate that gold is
widely distributed in the body. When gold was administered orally as
triethylphosphine gold chloride or auranofin, different tissue distribu-
tions were observed. Stomach gold levels were very high immediately
after administration of the oral gold compounds but the gold concentra-
tions in the kidney, liver and spleen were exceptionally low, even after
7 days (Walz, DiMartino et al., 1972; 1976). These results suggest
that the tissue concentrations are controlled by the rate of
gastrointestinal absorption and not by the rate of renal elimination
as in the case of the injected soluble gold compounds (Kamel, Brown
et al., 1978b).

a. KIDNEY

The kidney contained the highest concentrations of gold as early
as 48 hours after the administration of ATM (Sharma & McQueen, 1980),
but maximal concentrations in subcellular organelles were found only
after a considerable time (>1 month) (Mason, Sharma & McQueen, 1981).
Deposits of gold were seen occasionally·in the epithelial cells of the
glomeruli (Brun, Olsen et al., 1964; Strunk & Ziff, 1968; 1970;
Silverberg, Kidd et al., 1970), particularly during the first 2 days
(Yarom, Stein et al., 1975a) indicating movement of gold through the
capillary membranes. However, most gold deposits were detected in the
epithelial cells of the proximal tubules (Stuve & Galle, 1970; Nagi,
Alexander & Barabas, 1971; Yarom, Stein et al., 1975a,b) within hours of
the administration of gold salts (Brun, Olsen et al., 1964; Ganote,
Beaver & Moses, 1966) whatever the route of administration (Yarom,
Stein et al., 1975a). The high concentrations of gold in the proximal
tubular cells were correlated with the renal clearance of gold (Lorber,
Atkins et al., 1969; Kamel, Brown et al., 1978b) supporting the suggestion
that the accumulation was due to a high luminal concentration (Ganote,
Beaver & Moses, 1966). Small amounts of gold were found in the
epithelial cells of the distal tubules (Nagi, Alexander & Barabas, 1971;
Vernon-Roberts, Dore et al., 1976) even 1 to 4 yrs. after the last
injection (Brun, Olsen et al., 1964) indicating very slow mobilization
of gold from the kidney. After the administration of ATM, gold was
present in most of the subcellular organelles (Sharma & McQueen, 1979)
and in the cytoplasm of renal cortex cells (Thompson, Blaszak et al.,
1978). However, the gold in the nuclear fraction was shown later to be

an artifact of the fractionation procedure, resulting from gold-
containing lysosomes, "aurosomes" (Ghadially, Thompson & Lalonde, 1977),
which pelleted with the nuclei because of their greater mass and density
(Mogilnicka & Piotrowski, 1979; Shaw, Thompson et al., 1981). When
intact rat-kidney slices were examined by energy dispersive x-ray
analysis (Ghadially, 1979) and electron microscopy (Shaw, 1981), gold
deposits were not observed in the nuclei. The association of gold with
nuclear membranes is suggested by indirect evidence only from in vitro
studies (Vernon-Roberts, Jessop & Dore, 1973; Shaw, 1981). Electron
microscopy and electron probe examinations have shown that gold is
present in the mitochondria of renal cells (Stuve & Galle, 1970; Nagi,
Alexander & Barabas, 1971; Yarom, Stein et al., 1975b). This could be
an effect of the carrier ligand on a transport system into the mito-
chondria as is believed is the case with sodium aurothiopropanol-
sulphonate, Allochrysine®, (Stuve & Galle, 1970) or it could be due to
the anomalous behavior of aurosomes (Shaw, 1981). Indirect evidence
suggests the interaction of gold complexes with the mitochondria in
various tissues (Block & Knapp, 1945; Whitehouse, 1964; Whitehouse &
Bostrom, 1965; Abou-Khalil, Yunis & Abou-Khalil, 1981). Gold deposits
have also been found in the lysosomes of kidney cells (Ganote, Beaver &
Moses, 1966; Strunk & Ziff, 1970; Yarom, Stein et al., 1975b) and gold
may act to stabilize the membranes or inhibit various lysosomal enzymes
(Persellin & Ziff, 1966; Ennis, Granda & Posner, 1968; Davies, Lloyd &
Beck, 1971; Vernon-Roberts, Jessop & Dore, 1973). Recently substantial
amounts of gold have been found in the cytoplasm of renal cortex cells
after the administration of gold chloride (Mogilnicka & Piotrowski,
1977; 1979; Thompson, Blaszak et al., 1978), AIM (Thompson, Blaszak

et al., 1978; Sharma & McQueen, 1980; Schmitz, Minkel et al., 1980),

ATG (Thompson, Blaszak et al., 1978) and triethylphosphine gold chloride

(Thompson, Blaszak et al., 1978). At least 4 forms of gold were

resolved by fractionation using gel-permeation chromatography. Two

were high molecular weight (h.m.w.) gold-binding fractions

(MW > 100,000 daltons), one eluted with an apparent molecular weight

of 10-12,000 daltons and resembled metallothionein (MT) and the last,

was a l.m.w. non-protein species (Thompson, Blaszak et al., 1978). This

was thought at first to be a gold-glutathione complex because

glutathione was most abundant in the cells (Winge, Premakumar &

Rajagopalan, 1975) but it has since been identified as L-cysteinato-

gold(I) (Shaw, 1979). The relative amounts of the 4 forms of gold have

been shown to depend on the extent of kidney accumulation and not on the

differences among the gold compounds (Shaw, 1979). Also it was

demonstrated that the gold in the cytosol was in labile equilibrium

with protein and non-protein binding sites. At low kidney gold

concentrations, e.g. with triethylphosphine gold chloride, approximately

equal amounts of gold were measured in the h.m.w. and MT peaks. When

higher doses were administered gold was found in the l.m.w. non-protein

fraction (Shaw, Thompson et al., 1981). A similar pattern was

reproduced in vitro by varying the concentration of ATM in the cytosol

(Thompson, Blaszak et al., 1978). At very high concentrations, the h.m.w.

fractions became saturated with a subsequent increase in the binding of

gold to MT and the l.m.w. form. Addition of cysteine or glutathione

to the cytosol caused a redistribution of gold from the h.m.w. proteins

to the l.m.w. non-protein fraction without significantly altering MT-

bound gold (Thompson, Blaszak et al., 1978). These findings support the

concept of dynamic chemical equilibrium between gold and cytosolic proteins. Of the 4 cytosolic fractions, MT, the 10-12,000 dalton species has received the most attention. This protein which has an unusually high cysteine content (Kagi, Himmelhoch et al., 1974; Kagi, Kojima et al., 1980) can be induced in vivo in the kidney and liver of man (Pulido, Kagi & Vallee, 1966; Buhler & Kagi, 1974) and other animals (Webb, 1972; Weser, Donay & Rupp, 1973; Kagi, Kojima et al., 1980), and in cell cultures (Rugstad & Norseth, 1975; Onosaka & Cherian, 1981) after exposure to certain metals such as cadmium (Nordberg, Piscator & Lind, 1971; Webb, 1972; Winge & Rajagopalan, 1972; Weser, Donay & Rupp, 1973; Piotrowski, Trojanowska et al., 1974; Winge, Premakumar & Rajagopalan, 1974; 1978), mercury (Webb, 1972; Piotrowski, Trojanowska et al., 1974; Winge, Premakumar & Rajagopalan, 1974; 1978), silver (Winge, Premakumar & Rajagopalan, 1974; 1978), bismuth (Piotrowski & Szymanska, 1976; Szymanska, Mogilnicka & Kaszper, 1977), and zinc (Webb, 1972; Winge, Premakumar & Rajagopalan, 1974; Cherian, 1977). Various stressful conditions such as starvation (Bremner & Davies, 1975), cold exposure, strenuous exercise, CCl_4 intoxication (Oh, Deagan et al., 1978), and inflammation (Sobocinski, Canterbury et al., 1978) also were shown to induce the synthesis of zinc-thionein. These findings have suggested the involvement of MT in the homeostatic regulation of zinc metabolism. Other functions suggested for MT include heavy metal detoxification and poisoning-prophylaxis (Kimura, Otaki et al., 1974; Webb, 1975; Cherian & Goyer, 1978). Pretreatment of animals with low doses of cadmium prevented some of the toxic effects of a later higher dose (Nordberg, Piscator & Lind, 1971). Metal storage (Cherian, 1977), and transport (Weser, Rupp et al., 1973) also have been suggested as

functions of MT.

The possibility of a gold-MT complex has been investigated only in the last 5 to 6 yrs. Gold chloride was shown to elevate the amount of a MT-like protein in rat kidney (Mogilnicka & Piotrowski, 1977; 1979), and rat liver cytosol (Winge, Premakumar & Rajagopalan, 1978). Gold(III) is considerably more toxic than gold(I) (Sa███████n., 1940; Libenson, 1945), thus, a non-specific str█████████could be involved (Shaw, 1979; 1981) as has been █████████r zinc-thionein (Bremner & Davies, 1975; Oh, Deagan et al., 1978; Sobocinski, Canterbury et al., 1978). However, studies with gold(I) drugs (ATM, ATG, triethylphosphine gold chloride), also observed a 10,000 molecular weight gold-binding protein in kidney (Thompson, Blaszak et al., 1978) and liver cytosol (Lawson, Danpure & Fyfe, 1977; Sharma & McQueen, 1980, Schmitz, Minkel et al., 1980). Although only a small amount of total gold (15-20%) was bound to this protein (Thompson, Blaszak et al., 1978) possibly indicating a low specificity for gold (Schmitz, Minkel et al., 1980), it was identified as MT because of its distinctive properties. These included: its exceptionally high cysteine content accounting for about 30% of the total amino acid residues, its ability to incorporate 7-8 mole of metal (gold, cadmium, zinc, copper) per mole of protein, its relative molecular weight (Kagi, Himmelhoch et al., 1974; Kagi, Kojima et al., 1980), and its heat stability (Webb, 1972; Shaikh & Smith, 1976; Cherian, 1977). The reaction of ATM with purified MT from horse kidney demonstrated unambiguously that gold was bound to this protein forming a gold-thionein complex (Schmitz, Minkel et al., 1980; Shaw, 1981). Gold(I)-MT was present in the kidney and liver cytosol within one-half hour of the administration of ATM (Sharma & McQueen,

1980) suggesting that gold is incorporated into formed MT. Turkall
et al., (1977) also reported binding of gold to presynthesized MT, but
prolonged treatment of mice with ATM alone did not induce synthesis of
a MT-like protein. Thus it is unclear whether gold(I) is capable of
stimulating MT synthesis. The observation of the binding of gold to
MT, particularly in the kidney, suggests that MTs may have a role in
the sequestration and localization of gold. It is possible that
protection against gold toxicity might be conferred by pretreatment
with low doses of gold and/or other MT-inducing agents such as zinc
son, Sharma & McQueen, 1981). This would account for the lower
incidence of gold toxicity both in patients receiving low doses of gold,
and in patients receiving oily suspensions of gold salts as opposed to
more rapidly absorbed aqueous solutions (Lawrence, 1976). Another
possibility that has been suggested is that gold acts by interfering
with zinc-and-copper-metabolism (Schmitz, Minkel et al., 1980; Mason,
Sharma & McQueen, 1981). Both copper and zinc have been implicated in
the etiology of RA and may be involved in the mechanism of action of
gold (Shaw, 1981).

b. LIVER

Within 24 hr. of the administration of ATM, gold was detectable
in the liver. However, the amount was 14x less than in kidney tissue
(Sharma & McQueen, 1980). The Kupffer cells preferentially accumulated
gold (Yarom, Stein et al., 1975b; Vernon-Roberts, Dore et al. 1976)
but the hepatocytes, because of their numbers contained most of the
total gold (Penneys, McCreary & Gottlieb, 1976). Subcellular
distribution studies in rat liver showed gold present in the cytosol

(Penneys, McCreary & Gottlieb, 1976; Lawson, Danpure & Fyfe, 1977;
Mason, McQueen & Sharma, 1977; Turkall, Bianchine & Lerber, 1977;
Schmitz, Minkel et al., 1980; Sharma & McQueen, 1980), lysosomes
(Davies, Lloyd & Beck, 1971; Penneys, McCreary & Gottlieb, 1976;
Lawson, Danpure & Fyfe, 1977), nuclei (Penneys, McCreary & Gottlieb,
1976; Mason, McQueen & Sharma, 1977), and mitochondria (Penneys,
McCreary & Gottlieb, 1976; Abou-Khalil, Yunis & Abou-Khalil, 1981).
Mason et al., (1977) and Lawson et al., (1977) noted a high
concentration of gold in the cytosol at first; this rapidly declined
over the next few days. The reduction in cytosolic gold was associated
with an increase in gold in the lysosomal fraction. It has been
suggested that this might account for the delayed therapeutic effect
of the various gold compounds used in the treatment of RA (Penneys,
McCreary & Gottlieb, 1976; Lawson, Danpure & Fyfe, 1977). The gold
found in both the nuclear and mitochondrial fractions of liver, as in
kidney, is believed to be in the form of aurosomes (Lawson, Danpure &
Fyfe, 1979). Gel-permeation chromatography of the liver cytosol showed
that gold was associated with 3 or 4 species similar to those found in
kidney cytosol (Lawson, Danpure & Fyfe, 1977). It has been established
that the l.m.w. gold-binding protein present in liver cytosol is MT
(Sharma & McQueen, 1979; Schmitz, Minkel et al., 1980). Because gold
has a strong preference for a linear 2-coordinate geometry, it has been
postulated that the gold binds to a single sulphydryl group of MT with
retention of the thiomalate carrier ligand, or more likely, that it is
chelated by two sulphydryl residues on MT with loss of the thiomalate
moiety (Schmitz, Minkel et al., 1980).

c. SYNOVIAL TISSUE .

After it was shown that gold salts were concentrated in inflamed

areas (Bertrand, Waine & Tobias, 1948; Jeffrey, Freundlich & Bailey,

1958), investigators examined the joints and synovia of gold-treated

animals (Tonna, Brecker et al., 1963; Norton & Ziff, 1966; Norton, Lewis

& Ziff, 1968), and RA patients on chrysotherapy (Inoune, 1968; Gottlieb,

Smith & Smith, 1972a; Grahame, Billings et al., 1974). After

administration of ATM or other gold compounds, more gold was found in

inflamed than unaffected joints (Lawrence, 1961; Kantor, Bishko et al.,

1970; Sairanen & Vahatalo, 1973; Vernon-Roberts, Dore et al., 1976).

This could result from the increased blood flow to the inflamed joints.

Gold diffused rapidly into the synovial fluid and a steady state

equilibrium was established within a few hours between gold in serum

and synovial fluid (Freyberg, Block & Levey, 1941; Gerber, Paulus

et al., 1972a; Grahame, Billings et al., 1974). In some reports, the

gold concentrations were the same in synovial fluid and serum

(Freyberg, Block & Levey, 1941) but in most, synovial concentrations were

50 to 60% of those in serum (Smith, Peak et al., 1958; Lawrence, 1961;

Sliwinski, 1968; Kantor, Harley et al., 1971; Gerber, Paulus et al.,

1972a). Synovial-fluid gold concentrations were lower during auranofin

treatment than during parenteral chrysotherapy (Thomas & Ghadially, 1977).

After conventional chrysotherapy, less gold was found in the joints than

in the reticuloendothelial system, but the synovial fluid and membrane

contained more gold than other articular tissue (Gottlieb, Smith &

Smith, 1972a; Grahame, Billings et al., 1974). Gold deposits were

identified in the lysosomes of type A synovial lining cells and the

subsynovial macrophages by electron microscopy and electron probe x-ray

analysis (Tonna, Brecker et al., 1963; Ghadially & Roy, 1967; Norton,

Lewis & Ziff, 1968; Inoune, 1968; Ghadially, Oryschak & Mitchell, 1976;

Oryschak & Ghadially, 1976a,b; Nakamura & Igarashi, 1977). The gold-

containing lysosomes (aurosomes) had a characteristic appearance

(Ghadially, Thomas & Lalonde, 1977) that was unaffected by the gold

compound used (ATM, ATG, ATS) (Ghadially, Thomas & Lalonde, 1977), the

route of administration (im, ia) (Oryschak & Ghadially, 1976a,b), the

site of localization e.g. synovial membrane, kidney, liver, or skin

(Yaron, Stein et al., 1975b; Lawson, Danpure & Fyfe, 1977; Ghadially,

DeCoteau et al., 1978), and species (rat, rabbit, man) (Ghadially, 1979).

Triethylphosphine gold chloride po induced aurosomes similar to those

induced by other soluble gold compounds (Thomas & Ghadially, 1977).

However, intra-articular injections of colloidal gold induced aurosomes

of different morphology than those seen after soluble gold compounds

(Yaron, Hall et al., 1973). Ghadially et al., (1976) suggested that

gold entered pre-existing lysosomes. Besides gold, sulphur and

phosphorus were detected in the lysosomes using energy dispersive x-ray

analysis (Nakamura & Igarashi, 1977; Ghadially, Lalonde et al., 1978).

Because the sulphur/gold ratio was higher than the ratio in ATM, it

was suggested that binding of gold to MT occurred in the lysosomes

(Nakamura & Igarashi, 1977). During chrysotherapy the gold lysosomal

deposits became progressively denser with time. When chrysotherapy

was stopped, the number of aurosomes in the synovium decreased

(Nakamura & Igarashi, 1977) but they were still present in subsynovial

macrophages (Vernon-Roberts, Dore et al., 1976) 2 yrs. after the last

injection (Ghadially, Lalonde et al., 1978). These findings suggest

that the beneficial, therapeutic effects of gold salts may be mediated
through an action on macrophages. There is evidence that gold salts
not only suppress the activity of lysosomal enzymes of macrophages
(Persellin & Ziff, 1966; Paltemaa, 1968), but also suppress their
phagocytic activity (Vernon-Roberts, Jessop & Dore, 1973).

d. SKIN

Using NAA, trace amounts of gold were detected in skin, hair, and
nails of normal adults not receiving gold compounds. During the first
3-12 weeks of chrysotherapy, gold concentration increased 2-5x
(Gottlieb, 1977). Freyberg et al., (1942) reported that weekly doses
of 10 to 100 mg of various gold compounds produced skin gold levels of
0-40 µg/g. Lawrence (1961) and Gottlieb, Smith and Smith (1972a)
reported similar levels in patients receiving approximately the same
total doses of gold. A correlation between skin gold concentration and
total gold dose was observed despite variations among patients (Penneys,
Kramer & Gottlieb, 1975). Patients on long-term chrysotherapy had high
skin gold levels ranging from 20-80 µg/g after a cumulative total dose
of 3-6 g of gold (Gottlieb, 1977). Patients with chrysiasis had even
higher skin gold levels (50-140 µg/g) but they generally had received
more gold (Jeffery, Biggs et al., 1975). Gold was found in the skin of
patients with and without dermatitis (Lawrence, 1961). Biopsies of skin
lesions and 'normal' skin from the same patient contained similar amounts
of gold (Gottlieb, Smith et al., 1974b). In most studies no relationship
was found between skin reactions and gold content, except for chrysiasis
(Jeffery, Biggs et al., 1975). Studies of skin using a suction blister
technique showed that gold was largely confined to the dermis (Penneys,

Kramer & Gottlieb, 1975). Using a laser microprobe, electron-dense particles containing gold were detected in the lysosomes (i.e. aurosomes, Ghadially, DeCoteau et al., 1978) of dermal cells (Cox & ...ch, 1973). The finding of low gold levels in the epidermis (Penneys, Kramer & Gottlieb, 1975) supports previous findings (Gottlieb, Smith et al., 1974b) that keratinous tissues have little affinity for gold. This is in contrast to heavy metals such as lead and arsenic which accumulate in keratinous tissues and reflect accurately the total body burden (Gottlieb, Smith et al., 1974b). Gold was detected in the skin of some patients as late as 20 yrs. after the discontinuation of chrysotherapy (Cox & Marich, 1973) indicating very slow mobilization of gold.

e. HAIR, NAILS AND OTHER TISSUES

In post-mortem specimens from a patient with RA who had received a total of 5 g of ATG, very low concentrations of gold were present in the hair (5 μg/g) and nails (2 μg/g) (Gottlieb, Smith & Smith, 1972a). In another study by Gottlieb (1974b) slight increases in both hair and nail gold concentrations were observed during chrysotherapy. These results however were inconsistent and it was concluded that they were of little value in assessing total body gold in individual patients. In a study involving chrysiasis patients (Jeffery, Biggs et al., 1975), considerably more gold was measured in nails (1-4 μg/g) than in hair (0.2-0.7 μg/g) contrary to the results of Gottlieb (1972a) but in agreement with the findings of Kamel et al., (1976a). Since most studies have involved only small groups, more patients need to be studied to confirm these results. It is generally accepted that hair and nails

contain low levels of gold because of the low affinity of keratinous tissues for gold (Gottlieb, Smith et al., 1974b; Penneys, Kramer & Gottlieb, 1975). Small amounts of gold have also been found in the crystalline lens of the eye. (Hashimoto, Maeda et al., 1972; Gottlieb & Major, 1978). This appears to be dose dependent, developing in approximately 40% of patients receiving more than 1500 mg of ATM. However, it does not cause visual disturbances and disappears when chrysotherapy is stopped (Hashimoto, Maeda et al., 1972; Gottlieb & Major, 1978).

4. METABOLISM

The first "metabolism" studies (Block, Buchanan & Freyberg, 1941; 1942; 1944; Freyberg, Block & Wells, 1942) were actually distribution studies because available methods were only capable of detecting gold and not the chemical compounds with which it might be combined. Only recently has the actual metabolism or biotransformation of gold compounds been investigated. Danpure and coworkers demonstrated that ATM bound to l.m.w. thiols (cysteine) and disulphides (cystine) in vitro (Danpure, 1976b; Danpure & Lawson, 1977) and suggested that similar, but probably more complex, reactions would occur in the body because of the numerous SH-containing proteins. Evidence supporting this suggestion was provided by Isab and Sadler (1976). Nmr studies showed the presence of mixed thiols in slow exchange reactions with cysteine, glutathione and other SH-containing compounds with the release of some of the bound thiomalate. Studies with $^{195}Au-^{14}C$-thiomalate also demonstrated that gold and thiomalate separated rapidly in vivo. Twenty hours after the administration of double labelled ATM, 90% of the ^{14}C-thiomalate

remained in the body, especially the kidney and liver, with the balance excreted in the urine (Jellum, Munthe et al., 1979; 1980). The gold moiety, which is widely distributed throughout the body, has only recently been isolated from urine as a protein-bound and a l.m.w. form (Schaeffer, Shaw et al., 1980). The protein-bound form has been identified as albumin but the l.m.w. complex has not yet been identified. It could be several substances including ATM or gold-sulphur complexes formed by reactions with endogenous thiols, e.g. aurocysteine or S-auroglutathione (Danpure, 1976b). Further work is in progress to identify this/these urinary gold metabolites. In other studies, a similar l.m.w. gold-complex was detected in serum (Ward, Danpure & Fyfe, 1977; Francois, Goldberg et al., 1978; Danpure, Fyfe & Gumpel, 1979), and in the cytoplasm of both kidney (Thompson, Blaszak et al., 1978) and liver cells (Lawson, Danpure & Fyfe, 1977). The serum-gold complex was at first believed to be "free" gold, or unchanged ATM, but it has since been suggested that gold is released back into the blood from tissues in the form of a l.m.w. thiol such as aurocysteine or gold-glutathione (Danpure, 1977) and that this/these metabolites may then be filtered by the kidney and excreted in the urine.

5. EXCRETION

Gold was detected in the urine and feces of both animals (Block, Buchanan & Freyberg, 1941; 1942; 1944) and patients on chrysotherapy (Hartung, Cotter & Gannon, 1941; Freyberg, Block et al., 1941; 1942) after the injection of various gold compounds. Considerable variation was observed, but usually more gold was excreted in urine than in feces (Gottlieb, 1977). Peak urinary excretion occurred within 24 hrs of the

administration of gold and declined over the next week (Freyberg,
Block et al., 1941; 1942; Bertrand, Waine & Tobias, 1948; Smith, Peak
et al., 1958; Lawrence, 1961; Sliwinski, Zvaifler & Rubin, 1966;
Mascarenhas, Granda & Freyberg, 1972; Harth, 1974; Leroy, Bureau
et al., 1978). By contrast fecal gold excretion reached a maximum on
the second or third day (Mascarenhas, Granda & Freyberg, 1972). Fecal
gold content was variable and was affected by variations in intestinal
transit time, bowel habits, frequency of elimination, and stool mass
(Rencher & Beeler, 1969). During the first weeks of conventional
chrysotherapy approximately 15% of the administered dose was excreted
in the urine (Freyberg, Block & Levey, 1941; Smith, Peak et al., 1958;
Lawrence, 1961). However, at steady state, 35-50% of the administered
dose was excreted per week (Lorber, Atkins et al., 1969; 1973; Gottlieb,
Smith & Smith, 1972b; Mascarenhas, Granda & Freyberg, 1972; Gerber,
Paulus et al., 1972b), two-thirds of this being in the urine. Long-term
metabolic studies of a single dose revealed that 16% of the administered
dose was excreted in the second week, 12% in the third week and 10% in
the fourth week following injection (Gottlieb, Smith & Smith, 1972b).
These results were confirmed by Mascarenhas et al., (1972) who reported
that patients on maintenance therapy excreted an average of 77% of an
administered dose per month. Because gold accumulates in the body on
a weekly or even on a monthly dosage schedule, excretion of small
amounts of gold in the urine and feces has been reported to continue
for months after the last gold injection (Freyberg, Block & Levey, 1941).
The retention of gold in, and its slow excretion from the body has been
suggested as the reason for delayed toxicity in some patients.

The importance of fecal excretion of gold has been recognized only

recently. Several investigators (Gottlieb, Smith & Smith, 1972b; Mascarenhas, Granda & Freyberg, 1972; Harth, 1974) have shown that fecal excretion accounts for 30% of total gold excreted, contrary to earlier reports suggesting that only small "insignificant" amounts of gold were excreted in feces (Freyberg, Block & Levey, 1941; Lawrence, 1961). It has been demonstrated that biliary secretion is involved in the elimination of heavy metals such as mercury (Norseth & Clarkson, 1971; Cherian & Vostal, 1973), lead (Klaassen & Shoeman, 1974), cadmium (Cikrt & Tichy, 1974), and platinum (Casper, Kelsen et al., 1979) in the feces. This may be the mechanism by which gold enters the gastrointestinal tract. However, one study involving a patient with biliary t-tube drainage indicated that less than 50% of the fecal gold came from bile (Kapelowitz, Nelp et al., 1964).

Following the administration of auranofin, 95% of the gold was excreted in the feces with only 5% eliminated in the urine (Gottlieb, 1979b). These findings are considerably different from those after parenteral chrysotherapy. Here, 70% of the injected dose is excreted in the urine and 30% in the feces (Gottlieb, Smith & Smith, 1972b; Mascarenhas, Granda & Freyberg, 1972). Incomplete absorption, absorption onto intestinal mucosal cells with subsequent shedding into the lumen, and secretion through the intestinal wall have been suggested as possible sources of the high fecal gold content after auranofin (Gottlieb, 1979b). Secretion via the biliary tract has also been suggested (Gottlieb, 1979b), but was not confirmed, nor was there any evidence of an enterohepatic circulation of gold (Weisman, Hardison et al., 1980).

Other routes of excretion of gold investigated include saliva

(Hartung, Cotter & Gannon, 1941), breast milk (Blau, 1973), and hair and nail (Gottlieb, Smith et al., 1974b). In an early study involving two patients who received approximately 500 mg of ATM, no gold was detected in the saliva (Hartung, Cotter & Gannon, 1941). Recent studies have not examined saliva or tears, so the concentration of gold in these is unknown. After a total dose of 135 mg of ATG administered post-partum, significant concentrations of gold were found in breast milk and trace amounts were detected in the nursing infant's blood (Blau, 1973), indicating that gold can pass from the maternal bloodstream into the milk and hence the child's serum. Only minute amounts of gold were excreted in the hair and nails (Gottlieb, Smith et al., 1974b) compared to urine and feces (Gottlieb, Smith & Smith, 1972b), demonstrating the insignificant excretory function of these tissues.

6. CORRELATION STUDIES

Many attempts have been made to correlate plasma and serum gold concentrations with therapeutic effect or toxicity. Some investigators have reported that plasma gold levels were higher in patients who responded to treatment or who experienced toxicity compared to non-responders or patients who encountered no side effects (Krusius, Markkanen & Peltola, 1970; Lorber, Atkins et al., 1973). However, most investigators found no relationship between gold concentration, therapeutic effect, and the development of toxicity (Silverberg, Kidd et al., 1970; Sharp, Lidsky et al., 1977; Van de Stadt & Abbo-Tilstra, 1980). Patients displaying a therapeutic response had similar serum gold levels to patients who did not respond. Also, no significant differences among serum gold levels were found in patients who

experienced gold toxicity and those who did not (Mascarenhas, Granda & Freyberg, 1972; Gerber, Paulus et al., 1972b; Jessop & Johns, 1973; Rubinstein & Dietz, 1973; Gottlieb, Smith & Smith,1974a).

The relationships among gold excretion, therapeutic effect and toxicity have also been examined. Although some studies have indicated a correlation between urinary excretion rate (Smith, Peak et al., 1958; Krusius, Markkanen & Peltola, 1970; Leroy, Bureau et al., 1978), or fecal excretion rate (Gottlieb, Smith & Smith, 1972b) and therapeutic response, most studies have found no such relationship (Lawrence, 1961; Jones, Ahmed et al., 1971; Mascarenhas, Granda & Freyberg, 1972; Billings, Grahame et al., 1975; Sharp, Lidsky et al., 1977). Also, similar urinary, and total weekly excretion rates (Silverberg, Kidd et al., 1970; Gottlieb, Smith & Smith, 1972b) have been reported in patients experiencing toxicity and those who did not, contrary to the findings of Smith (1958) and Lawrence (1961).

7. KINETICS

Since the concentration of gold in body fluids did not correlate well with therapeutic response or toxicity, investigators began to study relationships among gold concentrations in different tissues. Various pharmacokinetic models have been used in an attempt to understand the distribution and excretion patterns of gold.

In most studies following administration of ATM, a biphasic decrease in serum gold concentration was observed (Figure 4; Harth, 1974). The initial decline in serum concentration comprises both the distribution of gold throughout body tissues and elimination. Later phases of the decline represent mostly elimination. A and B are

62

Figure 4. Semilogarithmic plot of serum gold disappearance curve after injection, showing a biphasic decline. (Harth, 1974)
regression lines drawn from observed values. Line C is obtained by
the method of residuals (Gibaldi & Perrier, 1975). Using the above
technique, serum half-lives ranged from 4.4 to 7.4 days (Gerber,
Paulus et al., 1972a; Harth, 1974; Gottlieb, Smith & Smith, 1974a;
Sharp, Lidsky et al., 1977). By contrast Walz et al. (1980), reported
a half-life for blood and serum of 3 and 2.6 days respectively, after
a single dose of ATM. Shorter half-lives (2.3 and 2.1 days, respectively)
were observed following repeated administration (3 mg Au/kg/day,im for
4 days), indicating that the excretion rate can be altered during
multiple dosing. In a 30-day study in two patients Waller et al. (1979)
found the elimination half-life to be 9.7 and 10.4 days. Visual
inspection of the terminal phase showed it became linear about 14 days
after administration of ATM. Thus, 7 to 10-day studies may be too
short to detect the true "terminal" excretion phase and may explain the
differences among the elimination half-lives reported.

Waller et al. (1979) re-examined serum concentration—time curves
from data gathered in single dose studies by Gottlieb et al. (1974a)
and Palmer & Dunckley (1973) and found that elimination half-life
increased with time. They concluded that studies must be conducted
for an extended period of time in order to detect the terminal excretion
phase. More recently a triphasic decline in serum gold concentration
was observed after a subcutaneous injection of ^{195}Au-ATM in rats and
terminal half-life calculated as 26.5 days (Mason et al., 1977c; 1979;
1981).

The pharmacokinetic behavior of auranofin, an orally active gold
compound, was shown to be different from ATM (Walz, Griswold et al., 1980).
After a single oral dose, blood and serum gold levels declined log-

linearly. The half-life of gold was calculated as 1.8 days (blood) and

1.2 days (serum). The difference between blood and serum half-lives

was attributed to extensive binding of auranofin to the formed elements

of the blood. Multiple dosing did not alter the elimination half-lives

significantly.

OBJECTIVES

65

From the literature review it will be apparent that gold is excreted

mostly in the urine of animals and humans after administration of ATM.

However, the importance of fecal gold excretion has recently been

recognized. Biliary secretion is known to be involved in the fecal

elimination of heavy metals such as cadmium, mercury, platinum and

lead, and it may be the mechanism which results in significant amounts

(30%) of gold being found in feces. Another possibility that has not

been examined is the role of metallothioneins in the excretion of gold

in feces. We decided to:

1. Examine the dose-dependency of the urinary and
   fecal excretion of gold given as sodium auro-
   thiomalate (ATM).

2. Examine whether repeated administration of ATM
   influences the excretion of gold.

3. Determine the pharmacokinetic indices for the
   excretion of gold in urine and feces.

4. Examine the effect of the cholestatic agent
   alpha-naphthylisothiocyanate (ANIT) on the
   fecal elimination of gold, and

5. Examine the involvement of metallothioneins
   in the excretion of gold.

METHODS AND MATERIALS

A. IRRADIATION PROCEDURE

Radioactive ^{198}Au-labelled sodium aurothiomalate (ATM) was prepared by irradiation of ^{197}Au - ATM[a] according to reaction 1 (Chart of the Nuclides, 1977).

$$^{197}\text{Au} + n \rightarrow \ ^{198}\text{Au} + \gamma \dots \dots \dots \dots \dots \dots \dots (1)$$
n = neutrons

γ = gamma rays of 412 KeV energy

$T_{\frac{1}{2}}$ = 64.7 hr for ^{198}Au

Samples were irradiated for 1 or 2 hr in a thermal neutron flux of 10^{12} n/cm^{2}sec^{-1} in the University of Alberta SlowPoke nuclear reactor. Since the compound contains sodium, radioactive ^{24}Na was produced simultaneously according to reaction (2) (Chart of the Nuclides, 1977).

$$^{23}\text{Na} + n \rightarrow \ ^{24}\text{Na} + \gamma \dots \dots \dots \dots \dots \dots \dots (2)$$

n = neutrons

γ = gamma rays of 1368 and 2754 KeV energies

$T_{\frac{1}{2}}$ = 15.0 hr for ^{24}Na

Following irradiation the samples were stored for a minimum of three days to allow most of the short-lived isotopes, especially ^{24}Na, to decay minimizing interference with the measurement of gold. Solutions of the drug were then prepared in 0.9% saline[b] for use in the animal experiments.

B. ACUTE AND CHRONIC STUDIES

Groups of 4 male Sprague Dawley rats[c] weighing 250-550 g were used. A single dose of 0.5 mg or 1.0 mg Au/kg of ^{198}Au-ATM in a maximum volume of 0.2 ml of saline was injected[d] into the extensor quadriceps femoris muscles (Greene, 1955) of the hind leg of rats. For the chronic studies, "cold" ^{197}Au-ATM (1.0 mg Au/kg) was injected into alternate quadriceps muscles for 13 consecutive weeks with the last dose being ^{198}Au-ATM (1.0 mg Au/kg, im). After the administration of radioisotope, rats were placed in metabolism cages[e] and allowed food[f] and water[g] ad libitum.

Urine and fecal specimens were collected at 24 ± 4 hr intervals and analyzed for ^{198}Au activity. Samples collected 24 hr before injection, containing no gold, were the time zero controls. The ^{198}Au activity of all specimens was measured by counting the 412 KeV gamma emissions using a 3x3 inch NaI (Tl) well counter with an automatic sample changer[h]. The gamma spectrometer was set for an energy range of 390-440 KeV, well below the 511 KeV shoulder or peaks due to ^{24}Na. ^{24}Na interference and background radioactivity was negligible. The samples were counted with a statistical counting error of less than 5% (Early, Razzak & Sodee, 1975). To account for the decay of the radio-

[g] tap water

[h] Model 1185, Searle Automatic Gamma Counting System calibrated monthly so that 1KeV corresponded to 1 channel

isotope, corrections were made using equation (3) (Early, Razzak &
Sodee, 1975).

$$A_t = A_o e^{-\lambda t} \quad \dots\dots\dots\dots\dots\dots\dots\dots\dots \quad (3)$$

where

A_t = the ^{198}Au activity (cpm) at time t (hr) obtained by
counting the specimens

A_o = the ^{198}Au activity (cpm) injected into the rat

λ = the decay constant found by calculating 0.693/$T_{1/2}$

$T_{1/2}$ = the half-life of the ^{198}Au isotope (64.7 hr)

t = the time (hr) elapsed since administration of ^{198}Au
and the minus sign (-) indicates decreasing activity

For each rat the actual amount (μg) of gold excreted in the urine
and feces during each 24 hr period was then calculated using equation (4).

$$Amount \ (\mu g) = \frac{D \times A_t}{A_o} \quad \dots\dots\dots\dots\dots\dots\dots \quad (4)$$

where

D = the dose administered (μg)

A_t = the ^{198}Au activity (cpm) in the urine or feces for
each 24 hr period

A_o = the ^{198}Au activity (cpm) injected into the rat

To determine the kinetic parameters, urinary and fecal excretion
rates were calculated for each 24 hr period and plotted on semilog
paper (ordinate) vs the mid-time of each collection period (abscissa).
Data were entered into the AUTOAN program (Sedman & Wagner, 1974)
assuming first order elimination. Data were then entered into the NONLIN
program (Metzler, 1968). A line was fitted through the last 3,4 and 5
data points. Using the correlation coefficients the best line was
determined and the overall elimination rate constant (K) and $T_{1/2}$
computed (Gibaldi & Perrier, 1975).

Student's $\underline{t}$ test and analysis of variance were used to determine statistical significance at the .95% level (p < 0.05). When appropriate, Duncan's multiple range test was performed (Snedecor & Cochran, 1967).

C. EXPERIMENTS WITH ANIT

The cholestatic agent alpha-naphthylisothiocyanate[1] (ANIT) was used to determine whether biliary secretion was involved in the fecal elimination of gold. Doses in excess of 150 mg/kg po were reported to cause complete biliary stasis within 18-24 hr (Griffiths, Rees & Sinha, 1961; Goldfarb, Singer & Popper, 1962), lasting from 3 to 5 days (Indacochea-Redmond & Plaa, 1971; Plaa & Priestly, 1976). Therefore, 24 hr before the administration of [198]Au-ATM (1.0 mg Au/kg, im) rats were gavaged[j] with ANIT in doses of 150 mg and 300 mg/kg. Because ANIT is insoluble in water (Merck Index, 1968), it was suspended in 1% carboxymethyl cellulose[k] (CMC) or dissolved in peanut oil[l]. Control animals were given CMC or peanut oil alone. Then the rats were placed in metabolism cages and urine and fecal samples collected at 24 ± 4 hr intervals and assayed for [198]Au activity as before.

D. PRELIMINARY STUDIES OF METALLOTHIONEIN

1. ANIMAL EXPERIMENTS

A single injection or 14 consecutive weekly injections of ATM[a] (1.0 mg Au/kg) was/were administered intramuscularly into the hind leg(s) of rats (250-550 g) as before. 24 hr after the last injection, the rats were killed[m] and the kidneys and livers removed immediately. The renal cortex and any visible fatty tissue was cleared from the kidneys and livers which were then washed in chilled isotonic saline and weighed[n]. These tissues were either fractionated immediately using the method of Shaikh and Smith (1976) or were quick-frozen (-40°C) and analyzed later.

2. TISSUE PREPARATION

The procedure used to isolate MT was similar to the method of Shaikh and Smith (1976) (Figure 5). 5mM 2-mercaptoethanol[o] was added to the homogenates to maintain the reducing conditions normally found in the cellular environment and to prevent the oxidation of MT with redistribution of metals during isolation (Minkel, Poulsen et al., 1980). A 20% w/v homogenate of the kidney or liver tissue was prepared in 1mM Tris-HCl buffer[p], pH 8.6. Tissue was finely minced for 15 seconds in a Waring blender and then homogenized at

4^oC using a glass homogenizer[q] and teflon pestle. The homogenate was heated to 85^oC for 10 mins in a water bath[r] to coagulate h.m.w. proteins and to stop enzymatic reactions (Webb, 1972; Shaikh & Smith, 1976). Since MT is heat stable, it is not affected by this procedure. The homogenate was then cooled and centrifuged[s] at 10,000g for 10 mins at 4^oC. The supernatant containing the MT fraction was collected and the protein pellet discarded. MT was then isolated from the supernatant using gel filtration chromatography.

3. COLUMN CHROMATOGRAPHY

10 ml of liver supernatant and 5 ml of kidney supernatant were applied respectively to 2.6 x 90 cm and 1.6 x 90 cm plastic columns packed with Sephadex G-75[t]. The samples were eluted from the columns with 1mM Tris-HCl buffer pH 8.6, containing 0.02% sodium azide[u] as a preservative. Using peristaltic pumps[v] the flow rates of the 2.6 x 90 cm and 1.6 x 90 cm columns were maintained at 28 ml/hr and 13 ml/hr ± 1 ml/hr respectively. 5 ml (liver) and 2.5 ml (kidney) fractions were collected[w] and their absorbance at 254 nm and 280 nm

measured[x]. Protein concentration of each peak was measured by the colorimetric method[y] of Bradford (1976) and gold concentration was determined using NAA[z]. The columns were calibrated using blue dextran (MX 2 x 10[6]), ovalbumin (43,000), chymotrypsinogen A (25,000) and ribonuclease A (13,700), and the MW of MT estimated using these markers (Figure 6) (Andrews 1964). Further fractionation of the crude MT or other tests to positively identify the l.m.w. gold-binding protein as MT were not performed.

[x] Gilford double beam spectrophotometer 250 or Unicam SP1800 UV Spectrophotometer.

[y] The protein reagent containing Coomassie Brilliant Blue G250 (10 mg) (Selva, Heidelberg) was prepared as a solution containing 95% ethanol (5 ml), 85% w/v phosphoric acid (10 ml) (Fisher Scientific Co.), and demineralized distilled water (85 ml). One ml of protein reagent was added to test tubes containing 0.1 ml of protein solution (eluate) and the absorbance at 595 nm was measured. Using a calibration curve of absorbance values vs concentration of bovine serum albumin (2-20 μg/100 μl) (Sigma Chemical Company), the concentration of protein in each peak was determined.

[z] 5 μl samples of gold chloride standard (0.25-10 μg/ml concentration Harleco Gold Standard) in 0.1 mM Tris-HCl buffer, pH 8.6, and protein eluate samples were pipetted onto millipore filter discs (0.45 μM pore size, type HA, Millipore Corporation) and air dried. These discs were then packed into an irradiation capsule (standards interspersed among protein samples) and irradiated in the SlowPoke reactor for 1 hr in a thermal neutron flux of 10^{12} n/cm^2 sec^{-1}. After 3 days, the ^{198}Au activity was measured by counting the 412 KeV gamma emission using the Searle (Model 1185) Automatic Gamma Counting System. Based on the gold chloride calibration curve the concentrations of gold in the protein eluates was determined.

Figure 6. Graph shows elution volume of five materials plotted against the logarithm of their MWs. Materials were separated on a Sephadex G-75 column (2.6 x 90 cm) using 1mM Tris-HCl buffer, pH 8.6.

RESULTS

77
A. ACUTE STUDIES

After the administration of single doses of ^{198}Au-ATM (0.5 mg and 1.0 mg Au/kg, im) the highest amounts of gold were found in urine during the first 24 hr. Amounts declined over the next 7 days. Fecal gold content reached a maximum by the second day and declined similarly over the next 7 days. Cumulative amount excreted/time plots are shown in Figures 7 and 8. In each 24-hr period, about twice as much gold was excreted in the urine and feces of rats given the 1.0 mg, as compared to 0.5 mg, Au/kg dose (Table IV). However, because of the small number of animals used and the large inter-animal variation, statistically significant differences were not observed for each time period. After 0.5 mg Au/kg, the total amount of gold excreted in the urine in 168 hr was 43.52 ± 7.21 µg (mean $\pm$ se, n = 4). This was significantly less than after the 1.0 mg Au/kg dose $(92.78 \pm 18.99$ µg). The total amount of gold excreted in the feces after these two doses was not significantly different. About one third of the administered dose was recovered in the urine and feces over the 7-day period. Urinary excretion accounted for 71-74% of the gold excreted (Table V).

In rats given single injections of either 0.5 mg or 1.0 mg Au/kg a plot of rate of gold excreted in urine and feces vs time was curvilinear. Urinary and fecal excretion data vs time plots were obtained for each rat, and the apparent elimination rate constants calculated from the terminal portion of the graph and mean values obtained (Table VI). Plots of mean urinary and fecal data vs time are shown in Figures 9 and 10. Similarly K was calculated after the single dose of 1.0 mg Au/kg (Table VI).

B. CHRONIC STUDIES

After 13 weekly injections of ATM (1.0 mg Au/kg,im) and one injection of ^{198}Au-ATM (1.0 mg Au/kg,im), urinary and fecal excretion of ^{198}Au was similar to the acute studies. Urine specimens collected 24 hr after the injection of ^{198}Au-ATM contained the most gold and fecal gold content peaked on the second day. More gold was excreted in the urine and less in the feces for each 24 hr period but amounts were not significantly different from single dose studies (Table VII). The cumulative amounts of gold excreted per 7 day in the urine and feces were similar for both the acute and chronic studies (Figures 11 and 12; Table VII). As in the acute studies, one third of the administered dose was measured in the urine and feces after 7 days (Table V). Semilog urinary and fecal excretion-rate plots were curvilinear (Figures 13 and 14). Mean values of K for both urine and feces were significantly different from those from the 1 mg-acute studies (Table VI).

Data from individual rats are tabulated in Appendix A (Table A1-A4).

C. EXPERIMENTS WITH ANIT

Administration of ANIT in CMC and peanut oil 24 hr before ATM injection appeared to cause jaundice as judged by the yellowing of the sclera and feces, and the rats' lethargic behavior. Patterns of the excretion of urine were similar in test and control animals, but

the excretion of feces fell significantly in the first 72 hr after administration of ANIT. Urine contained the most gold 24 hr after the administration of ATM and declined over the 7 day study period. Although fecal excretion was erratic, fecal gold content generally reached a maximum by the second day. Cumulative amount excreted/time plots after ANIT in CMC and peanut oil are shown in Figures 15-18. ANIT pre-treatment did however alter the total amount of gold excreted in the first 24-48 hr after ATM administration. During this period, 8.4% more gold was excreted in the urine and 11.5% less (both significant, $p < 0.05$) in the feces of ANIT-treated rats than controls that received only CMC or oil (Tables VIII and IX). After 72 - 96 hr, ANIT-treated and control rats excreted similar amounts of gold in the urine and feces. The total amount of gold excreted after 168 hr was also similar for ANIT-treated and control animals (Tables VIII and IX). As in the acute studies, only 27-32% of the administered dose of gold was recovered after one week — 73-76% in the urine and the remainder in the feces (Table X). Rats given ANIT (300 mg/kg,po) before injection of ATM excreted slightly more of the dose of gold in the urine (79%) but significantly less in the feces (21%). Figures 19 and 20 show that these rats defecated significantly less excreta in the first 72 hr than did controls. During this same period, rats given ANIT (150 mg/kg po) defecated more than those who had received the 300 mg/kg dose but again this was significantly less than controls (Table XI). Differences were observed between the vehicles CMC and oil but these were not statistically significant.

As in acute studies, semilog plots of urinary excretion rates (Figures 21 and 22) and fecal excretion rates (Figures 23 and 24)

were curvilinear. Mean values of K are summarized in Table XII. No significant differences were found between ANIT-treated and control rats.

Data from individual rats is tabulated in Appendix A (Tables A5-A14).

D. ISOLATION AND IDENTIFICATION OF GOLD METALLOTHIONEIN

Figure 25 shows a typical elution profile of rat liver supernatant after a single im injection of ATM (1.0 mg Au/kg). Peak I eluted at the column void volume and was found to contain protein(s) with a MW greater than or equal to 70,000 daltons (the exclusion limit of Sephadex G-75). Peak II, which was not completely separated from Peak I, had an elution volume similar to chymotrypsinogen A suggesting protein(s) with a MW of 25,000 daltons. However, a reduced absorbance at 280 nm was observed for Peak II. A protein, such as MT, that contains few or no aromatic amino acids could account for this reduction in absorbance. The last fraction eluted from the column (Peak III) contained l.m.w. amino acid fragments and the added mercaptoethanol. Using Bradford's microprotein assay, Peaks I, II and III had protein concentrations of 0.133, 0.064 and 0.004 mg/ml, respectively. Flameless AAS was too insensitive to measure gold concentration but NAA showed that all peaks contained gold. The exceptionally high concentration of gold in Peak III could be due to generalized binding to the protein fragments or to displacement of gold from proteins in the first two peaks by the isolation technique. A similar gel filtration pattern (Figure 26) was observed for rat liver supernatant after 14 weekly injections of ATM (1.0 mg Au/kg, im). Three peaks were separated and correspond to h.m.w.

proteins (Peak I), l.m.w. proteins including MT Peak (II) and l.m.w.
peptides (Peak III). Although more total gold was administered, protein
and gold concentrations were similar to those measured after a single
injection of ATM (Figure 25). These data indicate that other tissues
must store much of the gold (ATM) administered over a prolonged period
because the concentration of soluble proteins in the liver did not
increase in response to the increased amount of gold in the body.

Figure 27 shows a typical elution profile of rat kidney supernatant
after a single injection of ATM (1.0 mg Au/kg,im). The h.m.w. protein
Peak (I) and the l.m.w. protein Peak II were barely discernable above
background. Since less kidney supernatant was applied to the column the
peak generally contained less protein than did the corresponding peaks
of the rat liver supernatant after a single injection of ATM (Figure 25).
However, significantly more gold was measured in each of the kidney
supernatant peaks indicating that the soluble proteins of the kidney
may have a greater affinity for gold (ATM) than those in the liver.
Column chromatography of rat kidney supernatant after repeated
administration of ATM (14 weekly injections) again gave 3 distinct
peaks (Figure 28). These peaks contained similar amounts of protein
but significantly less gold than after a single ATM injection
(Figure 27).

DISCUSSION

Rats excreted gold in both urine and feces after injections of sodium aurothiomalate,im. The urinary and fecal excretion patterns were similar to those reported for RA patients treated with various soluble gold compounds (Freyberg, Block et al., 1941; 1942; Smith, Peak et al., 1958; Sliwinski, Zvaifler & Rubin, 1966; Mascarenhas, Granda & Freyberg, 1972; Harth, 1974; Leroy, Bureau et al., 1978).

A. ACUTE STUDIES

After single injections of ATM (0.5 mg and 1.0 mg Au/kg,im) urinary gold excretion peaked within 24 hr and fecal excretion reached a maximum by day 2. The gold concentrations in urine and feces then declined over the next week. After single doses, total amounts of gold recovered in urine and feces over 7 days were dose-related. However, this was not always obvious because of inter-animal variation. Mean values for K obtained from both urinary and fecal data were similar for single-dose studies.

B. CHRONIC STUDIES

After 13 weekly injections of ATM (1.0 mg Au/kg,im) rats given 1.0 mg ^{198}Au-ATM excreted amounts of ^{198}Au in urine and feces similar to those found in the 1.0 mg — acute studies. However, mean values of K, determined from urinary and fecal data were significantly increased in agreement with Walz, Griswold et al. (1980). This indicates that during multiple dosing, more of the current dose of gold is excreted in a given time, in comparison with previous doses. It is important to recognize that only ^{198}Au in urine and feces was measured, not total

gold; thus ^{198}Au excretion will represent only a portion of the <u>total</u> gold excreted in urine and feces and result in an <u>apparent</u> increase in K.

It is evident from the curvilinear nature of the excretion-time plots that equations describing the excretion process must contain at least two exponentials. However, the variance of the data did not allow definition of more than one of these exponentials (i.e. K). In hindsight, the experiments could have been improved by also measuring blood or serum gold concentrations after ^{198}Au iv and im, as well as urinary and fecal concentrations. Determination of the kinetics of gold disposition in more detail would then have been possible, in particular, determination of urinary (K_u) and fecal (K_f) excretion rate constants. The data only allowed me to use the intercept of the terminal excretory phases to estimate the ratio between K_u and K_f. Thus in each rat, the intercept of the urinary or fecal excretion/time plot at time zero was obtained. Assuming that the same processes of distribution and absorption apply in each animal for both urinary and fecal excretion, the ratio of the two intercepts should provide an indication of the difference between K_u and K_f. Using this technique, K_u/K_f was 1.51 ± 0.07. It must be stressed that this intercept is a composite of several functions (Gibaldi & Perrier, 1975) and may not represent the 'true' value of the ratio.

The experiments could also have been improved by extending the observation time. As indicated earlier, the terminal half-life of gold may be > 20 days (Mason <u>et al.</u>, 1977c; 1979; 1981). If gold does undergo the triphasic excretion process described by others, then my experiments would only have detected the first and second phases, and the

'terminal' half-life observed is not the true terminal half-life, but the half-life of the 'β' phase. The problem inherent in my experiments is the use of the readily accessible gold isotope ^{198}Au. Its half-life is too short to permit meaningful experiments of longer than 10 days duration. Others (Gerber, Paulus et al., 1972a; 1974; Gottlieb, Smith & Smith, 1974; Mason et al., 1977c; 1979; 1981) have used ^{195}Au which can be followed for > 6 months because of its long half-life. However, ^{195}Au decays to ^{195}Pt and thus as the experiment progresses, results could be influenced by the presence of ^{195}Pt. Some authors have noted minor differences in elimination rate constants when ^{195}Au, compared to ^{197}Au, is used (Gottlieb, Smith & Smith, 1974).

Inter-animal variation is always a problem in experiments in which urinary and fecal excretion of a drug are measured. My estimates of K should not be affected by the sampling time since this was sufficiently frequent to reduce this type of variation to insignificant levels when one considers the value of K (Gibaldi & Perrier, 1975). However, urine and feces do show diurnal excretion patterns. This potential problem was overcome by starting each experiment at the same time of the day. The inter-animal variation observed in these experiments is similar to that observed by others in studies of gold excretion in both animals and man (Gottlieb, 1977). Thus, my estimates of K, though obviously estimates are within the range reported by others (Gerber, Paulus et al., 1972a; Harth, 1974; Walz, Griswold et al., 1980).

C. EXPERIMENTS WITH ANIT

Although our results indicate urine as the primary route of elimination of soluble gold complexes, a significant amount, about 6 - 8% of the dose, is excreted in the feces. Biliary secretion into the gastrointestinal tract could contribute to this. Several investigators have examined the biliary excretion of heavy metals such as mercury (Norseth & Clarkson, 1971; Cherian & Vostal, 1973), lead (Klaasen & Shoeman, 1974), and cadmium (Cikrt & Tichy, 1974), but few have studied gold. When T-tube drainage of the bile duct was instituted in a patient being treated with ATM, less than half the amount of gold formerly excreted in the feces was recovered from bile (Kapelowitz, Nelp et al., 1964). In a more recent study in rats, bile duct cannulations performed before the administration of auranofin showed that enterohepatic circulation was not the cause of the elevated serum and blood gold levels observed 24-48 hrs post-administration (Walz, Griswold et al., 1980). No similar studies however have been reported for ATM or other injectable gold compounds. ANIT is a cholestatic agent. Doses in excess of 150 mg/kg induce biliary stasis, complete within 24 hr and lasting 3 to 5 days (Plaa & Priestly, 1976). If gold were excreted via the bile, ANIT would be expected to reduce this until bile flow returned to normal, and, during biliary stasis, more gold might be excreted in the urine to compensate for this reduction.

In the first 72 hr, significantly more gold was recovered from urine, and significantly less from feces, of ANIT-treated rats than controls. This initial reduction in fecal gold content appeared to correspond to a reduction in the amount of feces excreted by treated rats, and the greater excretion of gold in the urine at this time may

have been compensatory. After 72 hr, the amount of gold in the feces was similar for both treated and control rats. Thus, the amount of gold excreted in the feces appears to be related to the amount of feces produced and the biliary tract may participate in the transport of gold into the gastrointestinal tract. The relative contributions of biliary secretion and transport were not measured because bile duct cannulations were not performed.

In animals pretreated with ANIT, mean values of K were not significantly different from controls.

D. ISOLATION AND IDENTIFICATION OF GOLD METALLOTHIONEIN

Since the discovery and characterization of MT, this unique l.m.w. cytoplasmic metal-binding protein has received much attention. In various animal tissues its synthesis has been induced (at the transcriptional level) in response to bivalent metals such as cadmium, mercury, silver, bismuth and zinc (Kagi & Nordberg, 1978; Foulkes, 1982). Gluco-corticoid hormones have also been shown to regulate MT synthesis (Etzel & Cousins, 1981). These observations suggest that MT has an important although as yet undefined biological function. The most widely accepted proposal is that MT functions both in regulating the metabolism and homeostasis of the essential metals and as a detoxifying agent by sequestering toxic metals (Kagi, 1980; Whanger, Oh & Deagen, 1981).

Gold(III) has been shown to elevate the amount of MT in rat-kidney (Mogilnicka & Piotrowski, 1977; 1979) and liver (Winge, Premakumar & Rajagopalan, 1978) but MT-induction in response to gold(I) has not yet been demonstrated (Turkall, Bianchine & Leber, 1977; Thompson, Blaszak

et al., 1978). If small amounts of gold(I) were capable of inducing

MT synthesis, this might explain the reduced toxicity observed in some

patients receiving low doses of ATM/ATG at the beginning of treatment

(Lawrence, 1976). Another possibility is that protection against chronic

toxicity of gold might be conferred by pre-treatment with MT-synthesizing

agents such as zinc (Mason, Sharma & McQueen, 1981).

After exposure to ATM, fractionation of liver and kidney super-

natants by gel permeation chromatography resulted in the separation of

three peaks as has been reported by others (Lawson, Danpure & Fyfe, 1977;

Thompson, Blaszak et al., 1978). The first fraction, eluting at the

column void volume, corresponded to h.m.w. protein(s) (MW > 70,000

daltons). Chromatographic behavior of the second fraction indicated the

presence of a protein with a MW of about 25,000 daltons. This fraction

was also thought to contain MT since absorbance at 280 nm was reduced

indicating a protein with few or no aromatic amino acids. However, to

confirm the presence of MT in Peak II, extensive purification of this

fraction would be required before conclusive tests such as measurement

of cysteine content, amino acid analysis, and gel electrophoresis, could

be performed. In these preliminary studies unequivocal identification

of this fraction as MT was not possible. Peak III, the last fraction

eluted from the column, was found to contain predominantly amino acid

fragments.

Following administration of a single dose of ATM, Peak I (for both

liver and kidney supernatant) contained approximately twice as much

protein as Peak II, and Peak III contained almost none. However, in all

three kidney supernatant fractions, gold concentration was considerably

higher than in the corresponding fractions of the liver supernatant.

These data suggest that kidney tissue has a much greater affinity for gold than liver, and confirms results (unpublished) that we observed when autopsies were performed on rats 72-120 hrs after administration of ANIT and ^{198}Au-ATM. After 14 weekly injections of ATM, protein and gold concentrations for all fractions of liver and kidney supernatant were not increased. Thus, administration of gold for prolonged periods does not appear to induce the synthesis of MT-like proteins in the liver or kidney, even though these organs have been reported to concentrate gold (Block, Buchanan & Freyberg, 1941; 1942; Swartz, Christian & Andrews, 1960; McQueen & Dykes, 1969; Gottlieb, Smith & Smith, 1972a; Kamel, Brown et al., 1978b; Mason & Kingsford, 1979).

In summary, these investigations have shown:

1. That the excretion of ATM in urine and feces is dose-dependent, the amount excreted being directly proportional to the dose administered.

2. That repeated administration of ATM may induce an "apparent" increase in K.

3. That ANIT reduces fecal excretion of gold in the first 72 hrs probably because of a constipating effect. A compensatory increase in urinary gold excretion is observed during this time period. After 72 hrs, defecation and fecal gold elimination returns to normal.

4. That biliary secretion of gold may account in part for the excretion of gold in feces, and

5. That a l.m.w. gold-binding protein, resembling MT, can be isolated from rat-kidney and liver cytosol.

CURRICULUM VITAE

EDUCATION:

Degrees	Year	Field	Institution
B.Sc. with Distinction	1978	Pharmacy	University of Alberta

AWARDS:

Alberta Heritage Foundation for Medical Research Studentship 1980-1982

RELATED WORK EXPERIENCE:

1978-present: Licensed Pharmacist (APhA)
1979-1981:   Graduate Teaching Assistant (GTA)
1978-1983:   Research Training (M.Sc. program)
1974-1978:   Training for B.Sc. Pharmacy

PAPERS:

Biggs DF, Boland DM, Davis P, Wakaruk J:
In vitro binding and pharmacokinetics of gold salts in plasma proteins
and chelating agents. J Rheumatol (Suppl 5) 6: 68-73, 1979.

ABSTRACTS:

Wakaruk J, Biggs DF, Davis P:
The effect of penicillamine on the binding of gold compounds to plasma.
Can J Pharm Sci 13: 100-101, 1978.

Wakaruk J, Biggs DF, Davis P:
Comparison of the methods used in the determination of gold in blood,
serum and urine by flameless atomic absorption spectrometry.
27th A.F.P.C. Research Conference.

Wakaruk J, Maslyk SJ, Biggs DF, Davis P:
Pharmacodynamics of gold in the rat. First Annual Heritage Medical
Research Days, 1981.

Wakaruk J, Maslyk SJ, Biggs DF, Davis P:
Gold metallothionein(s). Second Annual Heritage Medical Research
Days, 1982.
