# Abstract

This study reports results from peridotitic and eclogitic xenoliths and diamond samples from the Attawapiskat area to understand the processes of craton formation and modification in the Superior lithospheric mantle. These diamondiferous kimberlites also provide an opportunity to study the association of a primary diamond deposit (Victor) with a post-Archaean rift system - the Midcontinent Rift which impacted the southern Superior at  $\sim 1.1$  Ga. Existence of a depleted mantle reservoir beneath the Attawapiskat area since the Palaeoarchaeon is indicated by  $T_{RD}$  ages in sulphides and PGE's trapped in olivine. Mg# up to 93.6 in olivine indicates high degrees of partial melting leading to harzburgitic - dunitic residues. High Cr# in garnet and positive slopes in depleted garnet  $HREE_N$ , indicate that melting occurred during fractional polybaric melt extraction ending at low pressures. Low-Mg eclogites have shallow origins as plagioclase-bearing protoliths likely in former oceanic crust, emplaced into the SCLM by subduction during the Archaean. Partial melting of low-Mg eclogites and interaction of these melts with overlying peridotite in the mantle wedge resulted in the formation of the high-Mg eclogites and pyroxenites.  $T_{RD}$  ages of  $\sim 2.7$  Ga in peridotite with residual  $PGE_N$  patterns also indicate melting in the mantle related to subduction - accretion and hydrous melts infiltrating the overlying mantle wedge led to I-PGE alloy

formation. Diamond destruction occurred in the Attawapiskat lithospheric mantle due to the thermal impact of the Midcontinent Rift - seen in an elevated geotherm and narrow "diamond window" in 1.1 Ga kimberlites - with high mantle residence temperatures recorded in pre-rift diamonds. Rift basalts interacted with variably depleted peridotite, leading to P-PGE-enrichment and Mesoproterozoic  $T_{RD}$  ages. Older depleted domains are, however preserved. After the thermal impact of the rift subsided, diamond-stable conditions were extended to shallower depths in the lithosphere and diamonds sampled by post-rift kimberlites, formed after the Midcontinent Rift. These diamonds are likely to be both lherzolitic and eclogitic - pyroxenitic, as indicated by their  $\delta^{13}\text{C}$  compositions, and favourable high pressure compositions in both lherzolitic and high-Mg eclogitic - pyroxenitic garnets at Attawapiskat.

# Acknowledgements

Thank you to my PhD supervisor, Thomas Stachel, for his guidance during the past 4 years. His German precision greatly improved my writing and I thank him for being timely with edits to many drafts of this thesis, especially during the summer when much else was happening. Thank you also for paying me for half the time I was at U of A, so that I wouldn't have to TA...

Thank you also to Graham Pearson for all always having an open door and for the many discussions during my final year that helped me shape some of the ideas presented here.

De Beers Canada is thanked for collecting and donating samples from their Victor and Delta kimberlites. Stephan Kurszlaukis along with Alexandrina Fulop are thanked for making a sampling trip to the De Beers core shed in Sudbury possible.

Chuck Fipke and Chad Ulansky from Metalex Ventures are thanked for donating diamonds from their T1 and U2 kimberlites. Thank you also to Herman Grütter for his help in obtaining the diamonds from Metalex.

Sergei Matveev and Guangcheng Chen are thanked for support in the electron microprobe and quadrupole mass spectrometer laboratories. Jingao Liu, Krystle Moore, David van Acken, Sarah Woodland and Barbara Ziger kindly and patiently assisted in the clean and TIMS laboratories. Kathy Mather kindly offered her help with Fitplot geotherms.

Research funding was provided through the Geomapping for Energy and Minerals Programme (Diamonds) of the Geological Survey of Canada and an associated NSERC CRD grant with contributions from De Beers Canada. Through Thomas Stachel, funding was received from a NSERC Discovery Grant and the Canada Research Chairs Programme. Through Graham Pearson, funding for some data in Chapter 5 was received through the Canada Excellence Research Chairs Programme. Scholarships I received through the U of A are gratefully acknowledged.

My supervisors during my MSc research - John Gurney, Steve Shirey, Steve

Richardson and Anton le Roex - without whose friendly encouragement I probably wouldn't have considered a PhD. Thank you also for providing good (?) reference letters, because, I know I didn't study hard enough during my undergrad to make it to U of A without your support...

Thank you to everyone in Edmonton and at U of A for making my stay so memorable. In particular, my officemates at various times during my PhD - Katie Smart and Josh Davies - proved to be willing and able drinking buddies, and also valuable sounding boards for many ideas in this thesis. I appreciate you both allowing me to crash at your respective places during the beginning and end of my time in Edmonton!

wt%	Weight percent

# Chapter 1

## Introduction

### 1.0.1 The sub-continental lithospheric mantle

Old portions of continents that have been stable since the Archaean are known as cratons. Their longevity is due to presence of thick lithospheric roots, that have distinct thermal, chemical and seismic properties to the underlying asthenosphere. The sub-continental lithospheric mantle (SCLM) is predominantly composed of peridotite, that has been depleted through high degrees of melt extraction (removal of Al, Ca, Fe) to highly magnesian harzburgitic and dunitic residues (e.g., Boyd and Mertzman, 1987; Baker and Stolper, 1994; Walter, 1998). During melt extraction, the radiogenic elements (Th, U, K) and H<sub>2</sub>O are also efficiently removed, resulting in a residue that is cooler and has increased buoyancy and viscosity, and a lower density relative to the asthenosphere. These combined attributes contribute to the SCLM's long-term isolation from mantle convection (e.g., Jordan, 1975; Boyd and McCallister, 1976).

There are competing models for the formation of cratonic lithospheric roots. Melt depletion may have occurred at high pressures in a plume setting (e.g., Boyd, 1989; Arndt et al., 1998; Herzberg, 1999; Aulbach, 2012) or at lower pressures with initial melting at a mid-ocean ridge followed by later subduction-accretion (e.g., Helmstaedt and Schulze, 1989; Bulatov et al., 1991; Canil and Wei, 1992; Stachel et al., 1998; Canil, 2004; Bernstein et al., 2007; Pearson and Wittig, 2008; Herzberg and Rudnick, 2012).

Although mainly composed of depleted peridotite, the SCLM also contains a minor mafic component - in the form of eclogite, which consists of om-

phacitic clinopyroxene and garnet, with or without minor kyanite and coesite (e.g., Coleman et al., 1965; Carswell, 1990). Many kimberlite localities worldwide sample both low-Mg and high-Mg varieties, for example, Bellsbank and Premier on the Kaapvaal craton (Taylor and Neal, 1989; Neal et al., 1990; Dlodla et al., 2006), Koidu (Man craton; Barth et al., 2001, 2002a), Udachnaya (Siberian craton; Jerde et al., 1993; Beard et al., 1996; Snyder et al., 1997) and Diavik (Slave craton; Aulbach et al., 2007).

Eclogite can have variable origins, as high pressure mantle melts or former oceanic crust that was emplaced to the SCLM by subduction (e.g., O'Hara and Yoder, 1967; Caporuscio and Smyth, 1990; Helmstaedt and Doig, 1975; Jacob, 2004), therefore, the nature of its origin in the SCLM can provide important insights into the formation and evolution of the SCLM.

The Superior is the largest exposure of Archaean crust on Earth (see map of worldwide cratonic regions in Bleeker, 2003). However, its SCLM has not been studied to the same extent as, for example, the Kaapvaal, Slave and Siberian cratons, and consequently, details of the composition of the lithospheric root and the mechanism of its formation are sparse (see for example, reviews on craton formation by Pearson et al., 2003; Carlson et al., 2005; Pearson and Wittig, 2013).

## 1.0.2 Attawapiskat kimberlites

Here we study samples from the Jurassic Attawapiskat kimberlites in the western Superior Province, including Victor which is the first diamond mine on the Superior craton. These diamondiferous kimberlites provide an opportunity to study the association of a primary diamond deposit with a post-Archaean rift system. The cratonic root in the the southern Superior is significantly thinned compared to the rest of the craton (Kopylova et al., 2011; Miller et al., 2012; Schaeffer and Lebedev, 2013; Zartman et al., 2013) and may be due to the Midcontinent Rift which affected the southern margin of the Superior Craton at  $\sim 1.1$  Ga (e.g., White, 1972; van Schmus and Hinze, 1985).

Kimberlites on the Superior craton that erupted syn- and post- rift sample distinctive lithosphere compositions. The Kyle Lake kimberlites, which are

coeval with the Midcontinent Rift, sample predominantly harzburgitic lithosphere with an elevated geothermal gradient and a resulting small diamond window (Sage, 2000; Grütter, 2009). The nearby kimberlites at Attawapiskat were emplaced during the Jurassic, subsequent to the Rift. These kimberlites sample a lithosphere with a cooler geotherm and a larger diamond window. Garnet xenocrysts at Victor have predominantly lherzolitic compositions - perhaps due to refertilisation related to Midcontinent Rift magmas (Sage, 2000; Scully et al., 2004).

Samples from the Attawapiskat area include: Victor eclogite and pyroxenite xenoliths, Delta peridotite xenoliths, Victor peridotite xenocrysts, and diamonds from the T1 and U2 kimberlites (which are the same age as the Kyle Lake and Attawapiskat kimberlites, respectively).

During the course of this study, the main aims were to address the following:

1.) *What was the process for melt extraction to form the proto-cratonic lithospheric root?* Did initial melt extraction occur at high pressures in a plume-like setting or at low pressures in a setting similar to modern Mid-Ocean Ridges? How depleted were these residues? Are the lherzolitic compositions at Attawapiskat due to refertilisation or did the lithosphere below Attawapiskat never experience high degrees of melting to the point of clinopyroxene exhaustion (leading to depleted harzburgitic or dunitic residues)?

2.) *How old is the lithosphere below the Superior?* Palaeoarchaeon crustal rocks have been identified at Assean Lake in Manitoba and at Inuukjuak in Quebec. Complimentary compositional relationships between cratonic residues and non-arc basalts found in Archaean greenstone belts has been suggested by Herzberg et al. (2010) and Herzberg and Rudnick (2012) and complimentary age relationships should therefore also exist (e.g., Pearson et al., 2007).

On the Kaapvaal craton, however, the majority of peridotite Re-Os  $T_{RD}$  ages are between  $\sim 2.9$  and 2.7 Ga (Pearson et al., 1995; Carlson et al., 1999; Menzies et al., 1999; Irvine et al., 2001; Carlson and Moore, 2004; Simon et al., 2007) - significantly younger than crustal ages (3.7 - 3.2 Ga; Armstrong et al.,

1990; Kroner et al., 1993). These  $T_{RD}$  ages, however, overlap with the  $\sim 2.9$  Ga collision of the Witwatersrand and Kimberley blocks of the Kaapvaal (Schmitz et al., 2004). This suggests that (additional?) mantle melting, to create residual peridotite, occurred at this time, likely in an arc environment.

Through combined PGE analyses and  $T_{RD}$  determinations of Delta peridotite xenoliths, the aims here are to assess depletion and enrichment processes in the Attawapiskat lithosphere and to provide constraints on the timing of these processes.

3.) *What was the role of eclogite in craton formation / modification?* Seismic profiles in the Abitibi-Grenville (Calvert et al., 1995) and western Superior (White et al., 2003; Musacchio et al., 2004) that trace dipping subduction zones in the lower crust and upper mantle have provided firm support for craton formation involving subducted slabs (Helmstaedt and Schulze, 1989). However, there is evidence from other cratons that subduction may contribute to craton destruction through the release of fluids from the subducting slab into the overlying mantle wedge (e.g., the eastern block of the North China craton; Peng et al., 1986; Ling et al., 2013). Here the aim is to investigate whether the Victor eclogites provide any evidence for subduction of oceanic crust into the Superior lithospheric mantle and to understand how subduction may have modified the compositions of the Attawapiskat SCLM.

4.) *What was the impact of the Midcontinent Rift on the Superior lithosphere?* The lithosphere in the southern Superior may have been thinned, but the impact of the Midcontinent Rift on the lithosphere below Attawapiskat is not fully understood. Here we investigate to what extent basaltic melts related to the Midcontinent Rift may have overprinted the lithosphere. Are depleted domains still preserved?

Some diamond destruction must have occurred due to the thermal impact of the rift and the narrowing of the diamond window at 1.1 Ga (Sage, 2000; Grütter, 2009); however, diamonds at Attawapiskat are mined from Jurassic kimberlites. Are these old diamonds that survived any melt metasomatic impact of the Midcontinent Rift? Or are they a younger generation of lherzolitic or eclogitic - pyroxenitic diamonds that formed after 1.1 Ga?

5. *What are the diamond stable portions in the lithosphere?* Victor is a productive diamond mine, yet the typical depleted harzburgite signature that is normally expected (e.g. Sobolev, 1977; Gurney, 1984a), is missing. The xenocryst population is predominantly lherzolitic and eclogitic - pyroxenitic (Sage, 2000). Here we investigate whether depleted peridotite compositions such as harzburgite and dunite are present at Attawapiskat, and discuss the likely diamond stable portions of the lithosphere.

### 1.0.3 Layout

An overview of the crustal geology of the Superior craton and previous studies on the underlying lithospheric mantle is given in Chapter 2. The main part of this thesis is formed by three scientific papers, submitted (or to be submitted) to peer-reviewed journals.

**Chapter 3:** Major element, trace element and isotopic study of eclogite and pyroxenite xenoliths from Victor to assess their formation processes and emplacement into the SCLM.

A modified version of this chapter has been submitted to *Geochimica et Cosmochimica Acta*: *Smit, K.V., Stachel, T., Creaser, R.A., Ickert, R.B., Dufrane, S.A., Stern, R.A. and Seller, M. Origin of eclogite and pyroxenite xenoliths from the Victor kimberlite, Canada, and implications for Superior craton formation.*

**Chapter 4:** Nitrogen aggregation characteristics and carbon isotopic compositions of diamonds from Attawapiskat in order to constrain their timing of formation relative to the Midcontinent Rift.

A modified version of this chapter is intended to be submitted as: *Smit, K.V., Stachel, T. and Stern, R. A. Multiple generations of diamond in the Attawapiskat area of the Superior craton (Canada).*

**Chapter 5:** Major element, trace element and Re-Os-PGE study of peridotite xenocrysts and xenoliths to constrain the nature of melt depletion and

enrichment processes of the SCLM and their timing.

A modified version of this chapter is intended to be submitted as: *Smit, K.V., Pearson, G.P., Stachel, T. and Seller, M. Attawapiskat peridotites preserve evidence for the Palaeoarchaeon origin and Proterozoic reworking of lithospheric mantle below the Northern Superior Superterrane, Canada.*

## Chapter 2

### Superior craton

#### 2.1 Evolution of the Superior craton

The Superior craton is the largest exposure of Archaean crust on Earth, with several continental nuclei separated by numerous terranes of plutonic complexes and magmatic arc material (e.g., the Berens River subprovince of the North Caribou superterrane), and turbidite sequences (e.g., the English River terrane) (Figure 2.1). Continental nuclei of the Superior craton include the Northern Superior superterrane (3.8-3.5 Ga - Böhm et al., 2000; Skulski et al., 2000); the Inukjuak domain of the northeastern Superior superterrane ( $\sim$ 3.8 Ga - David et al., 2002, 2009); the Winnipeg River terrane ( $\sim$ 3.4 Ga - Beakhouse, 1991; Tomlinson et al., 2004); the Marmion terrane (3.0-2.8 Ga - Davis and Jackson, 1988; Stone et al., 2002; Tomlinson et al., 2003, 2004); the Minnesota River Valley terrane (3.5-2.8 Ga - Goldich et al., 1984; Bickford et al., 2006; Schmitz et al., 2006) and the North Caribou superterrane (3.0-2.9 Ga - Corfu and Wood, 1986; Thurston et al., 1991; Stevenson, 1995).

An accretionary model for Superior craton amalgamation was first suggested by Langford and Morin (1976) due to similarity of the geologic features with those of the Canadian Cordillera. The Superior craton amalgamated between 2.72 and 2.68 Ga during several discrete orogenies, which in the past have been collectively termed the Kenoran orogeny (e.g., Langford and Morin, 1976, and references therein). In the western Superior Province, tectonism started in the North and continued southward over a period of 40 million years (e.g., Stott and Corfu, 1988, 1991; Percival et al., 2006b).

The Northern Superior superterrane contains the oldest rocks in the West-

ern Superior province - the 3.8 - 3.5 Ga gneisses at Assean Lake in Manitoba (Böhm et al., 2000; Skulski et al., 2000). Their correlation with the Inukjuak domain of the northeastern Superior province of Quebec ( $\sim 3.8$  Ga - David et al., 2002, 2009) is speculative and has not been established. The Northern Superior superterrane subducted southward below the combined Oxford Stull domain and North Caribou superterrane during the Northern Superior orogeny (2.72-2.71 Ga; Corkery et al., 2000; Skulski et al., 2000; Craven et al., 2004; Parks et al., 2006). The North Kenyon Fault marks the current boundary between the Northern Superior and the Oxford-Stull domain to the south. The Oxford-Stull, along with the Molson Lake and Island Lake domains, have oceanic crust affinities that presumably developed on the margin of the North Caribou superterrane (Skulski et al., 2000; Parks et al., 2006).

The North Caribou superterrane is subdivided into the Sachigo, Berens River and Uchi subprovinces. It comprises  $\sim 3.0$  - 2.8 Ga granite-greenstones which were substantially reworked during  $\sim 2.7$  Ga continental arc magmatism (Thurston et al., 1991; Stevenson, 1995; Henry et al., 2000; Percival et al., 2006b). To the north-east and east the combined Oxford Stull and North Caribou terrane is bounded by the Winisk River Fault (e.g., Sage, 2000), a dextral strike-slip fault that developed in response to the  $\sim 1.8$  Ga Trans Hudson Orogen (Gibb, 1983). However, other authors suggest that the North Caribou superterrane persists to the east of the Winisk River fault (Stott and Berdusco, 2000).

The English River terrane to the south of the North Caribou superterrane is considered to be the suture zone for the northward accretion of the  $\sim 3.4$  Ga Winnipeg River terrane beneath the North Caribou superterrane during the Uchian Orogeny (Beakhouse, 1991; Corfu et al., 1995; Tomlinson et al., 2004). Arc magmatism as a precursor to the Uchian Orogeny is evident in the Berens River subprovince of the North Caribou superterrane ( $\sim 2.75$ -2.71 Ga; e.g., Corfu and Stone, 1998).

The Shebandowanian orogeny subducted the Abitibi-Wawa terrane beneath the composite terranes to the North at  $\sim 2.7$  Ga (Corfu and Stott, 1986; Stott, 1997), with final amalgamation of the Minnesota River Valley oceanic terrane to the composite Superior superterrane occurring during the  $\sim 2.68$  Ga Min-

nesotan Orogeny (e.g., Percival et al., 2006b, and references therein). These composite terranes of the Superior craton have since remained a coherent unit.

This plate tectonic model has been accepted for the Superior craton, due also to seismic profiles in the Abitibi-Grenville (Calvert et al., 1995) and western Superior (White et al., 2003), that trace dipping subduction zones to depths of at least 30 km, and is in agreement with the generalised model for Archaean terrane formation by imbrication of subducted oceanic lithosphere, advocated by e.g., Helmstaedt and Schulze (1989). A schematic figure illustrating the accretionary growth of the western Superior Province is given in Percival et al. (2006b). The interpreted seismic section of the western Superior Province, illustrating the inferred subduction polarities during craton amalgamation, is shown in Figure 2.2.

## **2.2 Proterozoic orogenies marginal to the Superior craton**

The Superior craton, together with the Nain, Churchill and Slave cratons and their bounding Proterozoic orogens comprise the Canadian Shield (e.g., Hoffman, 1990). The Superior craton is bounded on all sides by Proterozoic orogens, namely the Trans-Hudson, New Quebec, Penokean and Grenville orogens (e.g., Hoffman, 1990). These are briefly outlined below.

The Trans-Hudson orogen extends along the western and northern margin of the Superior craton and marks its collision with the composite Churchill province to the north-west, between 1.83 and 1.80 Ga (e.g., Bickford et al., 1990). Seismic profiling below the Trans-Hudson orogen has identified the Sask craton at depth, and traced it to the surface where it outcrops in small areas in the Glennie and Flin Flon Domains (Lucas et al., 1993). Subduction polarity of the Trans-Hudson orogen has been difficult to decipher, with early seismic reflection profiles showing dip to both the northwest and southeast beneath the bounding cratons (Lewry et al., 1994). Subsequently, the southeast dipping reflectors have been related to an early accretionary phase, whereas the northwest dipping reflectors relate to terminal collision of the Churchill, Sask and Superior cratons (Corrigan et al., 2005; Hajnal et al., 2005). A cross-section illustrating the tectonic evolution of both the accretionary and

collisional phases in the Trans-Hudson orogen is given in Corrigan et al. (2005).

Along the northeastern boundary of the Superior craton is the southeastern Churchill Province (SECP). The SECP comprises the New Quebec and Torngat orogens as well as an Archaean block, termed the Core Zone ( $\sim 3.0$ - $2.7$  Ga tonalitic to granitic gneisses; Wardle et al., 2002, and references therein), which has previously been considered a continuation of the Rae craton (e.g., Hoffman, 1990; Scott, 1998). The Torngat orogen formed by collision and subduction of the Core Zone under the Nain craton between  $\sim 1.9$  and  $1.85$  Ga; the New Quebec orogen formed during  $1.82$ - $1.77$  Ga collision between the Core Zone and the Superior craton (Wardle et al., 2002).

The Penokean orogen along the Southern margin of the Superior craton formed between  $1.89$  and  $1.83$  Ga (Hoffman, 1988; Schulz and Cannon, 2007). This orogen marks the end of southward subduction and the subsequent collision of the Superior craton with the Pembine-Wausau magmatic arc terrane, and the Archaean Marshfield Terrane (Schulz and Cannon, 2007, and references therein). The Grenville orogen along the south-eastern margin of the Superior craton, is part of an orogenic belt which runs from southern Greenland in the north to Mexico in the south (e.g., Rankin et al., 1993). It is part of a world-wide series of orogenic belts related to the formation of the Rodinia supercontinent at  $\sim 1.1$  Ga (e.g., Hoffman, 1988). The Grenville Orogeny lasted more than 100 million years, with peak metamorphism at  $\sim 1.09$ - $1.02$  Ga and final collision and contraction at  $1.00$ - $0.98$  Ga (Hynes and Rivers, 2010, and references therein). A schematic illustrating the plate tectonic model for the Grenville Orogeny is given in Hynes and Rivers (2010).

### **2.3 The Midcontinent Rift**

The Midcontinent Rift is a tectonothermal event that impacted the Superior craton at  $\sim 1.1$  Ga, after accretion of the Superior craton. It is one of the world's major continental rifts, extending for 2300 km through central North America, though rifting ceased before significant crustal separation occurred (White, 1972; Halls, 1978; Wold and Hinze, 1982; van Schmus and Hinze, 1985). Exposures of rift successions are found only in the Lake Superior region, though the length of the rift can be traced through the presence of arcuate

gravity and magnetic anomalies from Kansas to Michigan.

The rift successions are composed of two major suites: a volcanic sequence with an overlying clastic sedimentary sequence, the Midcontinent Rift Intrusive Supersuite and Keweenawan Supergroup, respectively (Morey and Grenn, 1952; Miller et al., 2002). The volcanics comprise a bimodal sequence of tholeiitic flood basalts (90%) and rhyolite (10%), with magmatism occurring in two major pulses, from 1109 to 1105 Ma and from 1100 to 1094 Ma (U-Pb zircon; Paces and Miller, 1993). The main phase of rifting is also characterised by coeval alkaline intrusions (e.g., ~1105 Ma Nemegosenda carbonatite, ~1100 Ma Lackner Lake carbonatite, ~1108 Ma Coldwell alkaline gabbro; Heaman and Machado, 1992; Heaman et al., 2007). Also related to the Midcontinent Rift is ultramafic lamprophyre (UML) magmatism, occurring a few million years prior to the main phase of rift volcanism. These are recognised in the Wawa area and, on the basis of U-Pb perovskite and Rb-Sr phlogopite dating, intruded at 1147 to 1141 Ma (Queen et al., 1996). The Pele Mountain UMLs, also in the Wawa area, are slightly older, with an age of ~1172 Ma (Heaman et al., 2004).

Initiation of Midcontinent rifting has been related to the Keweenawan hot spot, on the basis of both geophysical and geochemical evidence (e.g., Hinze et al., 1972; Burke and Dewy, 1973; Green, 1983; Hutchinson et al., 1990; Nicholson and Shirey, 1990; Cannon and Hinze, 1992), with failure of the rift due to coeval compression related to the Grenville orogeny (e.g., Cannon, 1994; Manson and Halls, 1997). The ~1141 Ma Abitibi diabase dyke swarm (Krogh et al., 1987), which is of similar age to the early stages of UML magmatism, further supports the involvement of a mantle plume in the rift formation (e.g., Ernst and Bleeker, 2010, and references therein). Donaldson and Irving (1972), as well as Gordon and Hempton (1986) supported an alternative, collision-induced origin for rifting, possibly in a back-arc setting related to the Grenville orogeny.

In the southern Superior craton, basalts related to the Midcontinent Rift are found along the shores of Lake Superior and include the the Mamainse Point Formation - the most complete record of igneous activity in the Midcontinent Rift (e.g., Paces and Bell, 1989; Klewin and Berg, 1991; Shirey et al., 1994).

From the Nd isotopic composition and trace element chemistry of these basalts, Shirey et al. (1994) concluded that the early stage melts (high MgO picrites with low Al and enriched/unradiogenic  $^{143}\text{Nd}/^{144}\text{Nd}$ ) have mainly lithospheric sources, whereas the late stage melts (tholeiitic basalts with higher Al and depleted/radiogenic  $^{143}\text{Nd}/^{144}\text{Nd}$ ) have plume and asthenospheric sources.

The shear wave velocity structure for the mantle below the Superior craton shows lower velocities in the southern Superior which may be related to the effect of the Midcontinent Rift (Schaeffer and Lebedev, 2013). In the Attawapiskat area, the thermal impact of the Midcontinent Rift on the lithospheric mantle is evident in the elevated local geotherm determined from clinopyroxene xenocrysts from the 1.1 Ga Kyle Lake kimberlites (Sage, 2000; Heaman et al., 2004).

## 2.4 Kimberlites on the Superior craton

The Superior craton is host to several kimberlite fields, which, can be divided into three broad groups on the basis of their age (e.g., Heaman et al., 2004). The oldest kimberlites are the  $\sim 1.1$  Ga Kyle Lake and Bachelor Lake clusters, in Ontario and Quebec, respectively, which have been linked to the failed Midcontinent Rift (Heaman et al., 2004, and references therein). The Renard and Lac Beaver kimberlite clusters of the Otish mountains in Quebec, intrude the Opinaca Subprovince at  $\sim 640$ - $630$  Ma and  $\sim 550$  Ma, respectively, and are associated with rifting and opening of the Iapetus Ocean (Moorhead et al., 2003; Birkett et al., 2004; Fitzgerald et al., 2009).

The Timiskaming (155-127 Ma; Heaman and Kjarsgaard, 2000), Kirkland Lake (157-152 Ma; Heaman and Kjarsgaard, 2000) and Attawapiskat (180-155Ma; Kong et al., 1999; Heaman and Kjarsgaard, 2000; Januszczak et al., 2013) kimberlite fields have been temporally linked to the track of the Great Meteor hotspot. Kimberlite magmatism along this track can be traced for over 2000 km, with the youngest kimberlites intruding the southern Superior province and the oldest kimberlites intruding the Churchill province at Rankin Inlet (214-196 Ma; Miller et al., 1998; Heaman and Kjarsgaard, 2000).

### 2.4.1 Attawapiskat and Kyle Lake kimberlites

The Attawapiskat kimberlite field is a cluster of 21 known kimberlites that occur  $\sim 100$  km west of the Attawapiskat community in the James Bay Lowlands, northern Ontario. They were first discovered in 1987 by De Beers Canada Exploration (then Monopros Limited) (Kong et al., 1999). The kimberlites were emplaced during the Jurassic between 180 and 156 Ma (Rb-Sr phlogopite; U-Pb perovskite; Kong et al., 1999; Heaman and Kjarsgaard, 2000; Januszczak et al., 2013), near the boundary of the North Caribou and Northern Superior superterranes, and are orientated on strike with the Winisk River Fault (Figure 2.1b). The nearby Kyle Lake kimberlites ( $\sim 100$  km west of the Attawapiskat cluster) are much older than the Attawapiskat kimberlites and erupted during the Proterozoic at  $\sim 1.1$  Ga (Rb-Sr phlogopite; U-Pb perovskite; Heaman et al., 2004). These kimberlites intrude the North Caribou superterrane to the west of the Winisk River Fault (Figure 2.1b).

The T1 and U2 kimberlites at Attawapiskat were discovered in 2005 by Metalex Ventures after core drilling of aeromagnetic anomalies. Bulk sampling of these kimberlites is currently underway. There is no published age information on the T1 and U2 kimberlites, their age can, however, be inferred from stratigraphic relationships. The Kyle Lake Mesoproterozoic kimberlites are overlain by Palaeozoic limestone cover; whereas the younger Jurassic kimberlites at Attawapiskat, including Victor, break through this cover (Figure 2.3). Identical stratigraphic relationships suggest that T1 belongs to the Kyle Lake (1.1 Ga) kimberlite field and U2 to the Attawapiskat field (180 - 156 Ma).

## 2.5 Lithospheric mantle beneath the Superior craton

The Superior craton is underlain by relatively cold, high velocity, lithospheric mantle to depths of more than 200 km (e.g., Grand, 1987; Hoffman, 1990; van der Lee and Nolet, 1997). In the northwestern Superior Province, the North Caribou and Northern Superior superterranes are characterised by lithospheric mantle with higher velocity than the terranes to the southwest (e.g., Percival et al., 2006b, and references therein). Seismic anisotropy in the lithosphere is inherited from late Archaean tectonism and occurs sub-parallel to Archaean crustal subprovinces (Silver and Chan, 1988, 1991).

Considering the size of the Superior craton, the composition of the lithospheric mantle is still poorly constrained, largely due to the scarcity of large suites of mantle xenoliths. Sage (2000) analysed xenocrysts from several Superior craton kimberlites, including Kyle Lake and Attawapiskat. The Kyle Lake kimberlites are the only intrusion on the Superior craton that contain abundant harzburgitic garnets, though these may represent garnets derived from just a few xenoliths or disaggregated grains. A subset of this collection was analysed for trace elements by Scully et al. (2004), who concluded that younger kimberlite pipes on the Superior craton (Kirkland Lake, Timiskaming and Lake Ellen) sampled SCLM compositions that become more fertile with depth whereas the Proterozoic Kyle Lake kimberlite shows depleted portions to greater depths.

Numerous peridotites (and two eclogite) xenoliths from Attawapiskat were described by Schulze and Hetman (1997) and Scully (2000) and analysed for their major elements. Along with harzburgitic garnets, olivine grains with Mg# from 90.1 to 92.7, indicate a highly depleted lithosphere. Heavy mineral concentrate from the AT56 kimberlite, part of the Attawapiskat cluster, is predominantly lherzolitic, but also includes minor diamond-stable harzburgite and pyroxenite (Armstrong et al., 2004).

Garnet lherzolite xenoliths from the Kirkland Lake kimberlites in the Abitibi terrane were analysed for their petrography and major elements (Meyer et al., 1994; Vicker, 1997), along with  $^{187}\text{Os}/^{188}\text{Os}$  for three xenoliths that indicate Palaeoproterozoic  $T_{RD}$  ages (Pearson et al., 1997). Peridotitic diamond inclusions from Wawa indicate the presence of a pre-2.7 Ga diamondiferous SCLM below this area that was subsequently destroyed (Stachel et al., 2006; Miller et al., 2012). Other evidence for the presence of a depleted SCLM in the Wawa terrain are  $\sim 2.7$  Ga sanukitoids that were derived from depleted mantle that experienced LILE-enrichment prior to eruption (Shirey and Hanson, 1984). In the eastern Superior, Hunt et al. (2012a) constrained a minimum age of 2.7 Ga for the SCLM below the Opinaca terrain based on Pb-Pb isotopic compositions of Renard clinopyroxene xenocrysts.

Previous work on eclogitic material from Attawapiskat included major element analyses of garnet xenocrysts from the AT56 kimberlite (Armstrong et al.,

2004) as well as petrography, major element analyses and geothermobarometry on four eclogite xenoliths (forming part of a predominantly peridotitic xenolith collection; Schulze and Hetman, 1997; Scully, 2000). Eclogite and pyroxenite xenoliths also occur at Renard in the Opinaca subprovince of the eastern Superior province (major/trace element analyses of eight xenoliths; Hunt et al., 2012b) (Figure 2.1). U-Pb crystallisation ages of  $\sim 2.8 - 2.6$  Ga have been reported for zircon from lower crustal granulite xenoliths from the Attawapiskat and Kirkland Lake kimberlites (Moser et al., 1997; Moser and Heaman, 1997). These may be the equivalent to eclogite and pyroxenite at lower metamorphic grade (e.g., Green and Ringwood, 1972; Toft et al., 1989) and suggest eclogites may have been emplaced into the SCLM below Attawapiskat at this time.

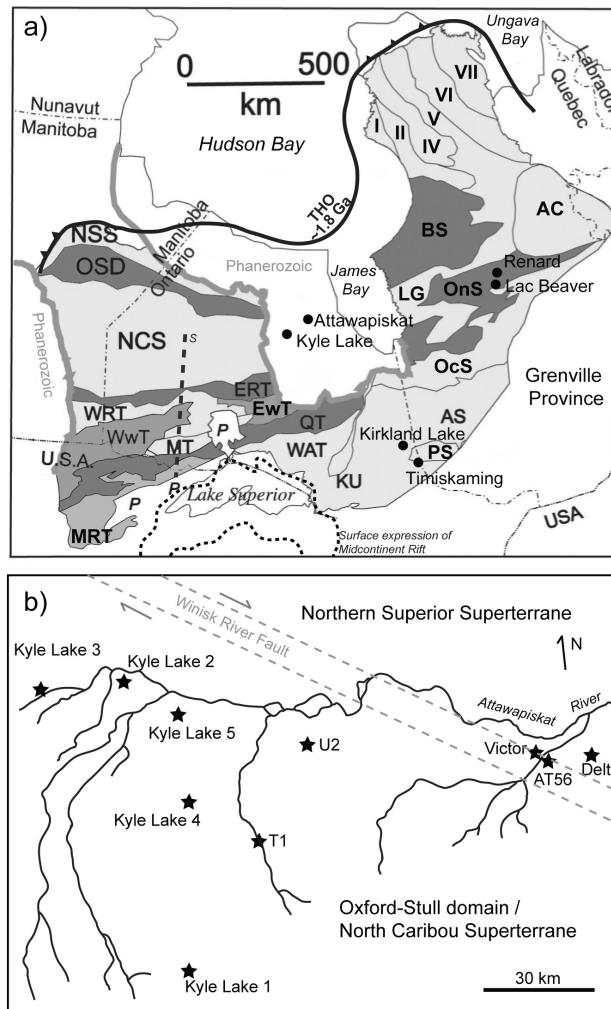

Figure 2.1: a) Subdivisions of the Superior craton (after Percival et al., 2006b, and references therein), with kimberlite localities indicated. Surface expression of the Midcontinent Rift from Ojakangas et al. (2001). Location and subduction polarity of the  $\sim 1.8$  Ga Trans Hudson Orogen (THO) from Berman et al. (2005). "s" indicates the approximate location of the seismic profile in Figure 2.2. Abbreviations used: AC - Ashuanipi complex; AS - Abitibi subprovince; BS - Bienville subprovince; ERT - English River terrane; EwT - East Wabigoon terrane; KU - Kapuskasing uplift; LG - La Grande subprovince; MT - Marmion terrane; MRT - Minnesota River Valley terrane; NCS - North Caribou superterrane; NSS - Northern Superior superterrane; OcS - Opatoca subprovince; OnS - Opinaca subprovince; OSD - Oxford-Stull domain; PS - Pontiac subprovince; QT - Quetico terrane; WAT - Wawa-Abitibi terrane; WRT - Winnipeg River terrane; WwT - West Wabigoon terrane; I - Inukjuak domain; II - Tikkerutuk domain; IV - L. Minto domain; V - Goudalie domain; VI - Utsalik domain; VII - Douglas Harbour domain. b) Locations for selected Attawapiskat and Kyle Lake kimberlites, in relation to the Attawapiskat river. Kimberlite co-ordinates from Sage (2000) and the Ontario Geological Survey website at [www.geologyontario.mndm.gov.on.ca](http://www.geologyontario.mndm.gov.on.ca).

Figure 2.2: Tectonic interpretation of seismic data (Percival et al., 2006b, using seismic data from White et al. (2003)) for a section through the western Superior Province, from the Wawa-Abitibi terrane in the south to the North Caribou superterrane in the north. The Uchi and Berens River domains are part of the North Caribou superterrane shown in Figure 2.1. Suture 1 and Suture 2 are interpreted to represent the northward subduction of the Uchian and Minnesotan Orogens, respectively.

Figure 2.3: Simplified stratigraphic relationships for the Proterozoic Kyle Lake and Jurassic Attawapiskat kimberlites (not to scale) modified after Webb et al. (2004), Thomas (2004) and Hattori and Hamilton (2008). The kimberlites at Attawapiskat (including Victor) were emplaced between 180 and 156 Ma (Rb-Sr phlogopite; U-Pb perovskite; Kong et al., 1999; Heaman and Kjarsgaard, 2000) and intrude through the Palaeozoic sediments. The older Kyle Lake kimberlites do not penetrate the Palaeozoic cover, with kimberlite emplacement dated at  $\sim 1.1$  Ga (Rb-Sr phlogopite; U-Pb perovskite; Heaman et al., 2004). Though no published age information exists for the T1 and U2 kimberlites, stratigraphic relationships suggest that they are similar age as the Kyle Lake and Attawapiskat kimberlites, respectively.

## Chapter 3

# Origin of eclogite and pyroxenite xenoliths from Victor and implications for Superior craton formation

### 3.1 Introduction

The origin and development of sub-continental lithospheric mantle (SCLM) is still debated, with arguments for both subduction-accretion models (Helmstaedt and Doig, 1975; Helmstaedt and Schulze, 1989; Stachel et al., 1998; Canil, 2004; Pearson and Wittig, 2008) and mantle plume residue models (MacGregor and Carter, 1970; Griffin et al., 1999; Wyman and Kerrich, 2002; Aulbach, 2012). In the Superior craton, an accretionary tectonic model has been widely accepted based on numerous studies of crustal geology (e.g., Langford and Morin, 1976; Card, 1990; Percival et al., 2006b); however, there are no detailed studies on mantle eclogite xenoliths from the Superior craton to verify a possible subduction origin.

Eclogites are a minor component of the SCLM and are brought up as xenoliths in the majority of kimberlites worldwide. Despite their paucity, the study of eclogites can provide important insights into the composition and evolution of the SCLM. Two main competing models for eclogite formation are generally considered: an *in situ* origin from high pressure mantle melts (e.g., O'Hara and Yoder, 1967; Caporuscio and Smyth, 1990) and an origin as former oceanic crust, emplaced into the SCLM during subduction (e.g., Helmstaedt and Doig, 1975; Jacob, 2004).

Strong support for the latter model comes from stable oxygen isotopes. Eclog-

ite xenoliths have a more diverse range in  $\delta^{18}\text{O}$  than peridotite xenoliths, which have a narrow range corresponding to the accepted value for the upper mantle ( $\delta^{18}\text{O} = 5.5 \pm 0.2 \text{ ‰}$ ; Matthey et al., 1994). Significant fractionation of oxygen isotopes cannot occur at high temperatures in the mantle (e.g., Eiler, 2001), but occurs only due to water-rock interactions at crustal temperatures (Muehlenbachs and Clayton, 1972a,b). Jagoutz et al. (1984) and MacGregor and Manton (1986) were the first to recognise eclogites as rocks with a crustal prehistory based on the similar range in  $\delta^{18}\text{O}$  of Roberts Victor eclogites to ophiolites that had undergone alteration by seawater (Muehlenbachs and Clayton, 1976).

In this contribution we present major and trace element analyses of a suite of eclogite and pyroxenite xenoliths from the Victor kimberlite (Superior craton), along with their oxygen, strontium and osmium isotopic compositions. Through these combined analyses, we aim to understand the formation of eclogites and pyroxenites - from either oceanic crustal protoliths or high pressure melts - and their emplacement into the SCLM. This suite of xenoliths provides an opportunity for the first time to evaluate the involvement of crustal components in the genesis of the lithospheric mantle below the Superior craton.

### 3.2 Samples and analytical techniques

The sample suite comprises 30 non-diamondiferous eclogite and pyroxenite xenoliths. These are mostly biminerally composed of clinopyroxene and garnet; eight xenoliths are additionally orthopyroxene-bearing. Accessory rutile, ilmenite and sulphides are present in most samples. The majority of the samples were large enough for thin section preparation (ranging between  $\sim 2$  and 5 cm in diameter), whereas six eclogite samples were too small ( $< 1.5$  cm in diameter) and grain mounts of constituent garnet and clinopyroxene were prepared. The samples have no layering at the scale observed and generally display granoblastic textures. Garnet and clinopyroxene grain boundaries display  $120^\circ$  angles, although these may vary to more rounded grain boundaries throughout each sample. Photos of representative thin sections are shown in Figure 3.1.

### 3.2.1 Major elements

Major element compositions were measured using a JEOL8900R electron microprobe at the University of Alberta, operating at 20 kV accelerating voltage, 20 nA probe current and 1  $\mu\text{m}$  beam diameter. Peak count times varied between 30 and 60 seconds, and half that for background count times (Table A.1). Both natural and synthetic standards were used for calibration with matrix corrections following Armstrong (1995) (Table A.2). Multiple analyses for each mineral grain were averaged after those with low totals ( $< 98.5\%$ ) and poor stoichiometry were removed. Detection limits were below 100 ppm for all oxides, apart from 200 ppm for  $\text{Na}_2\text{O}$  and 250 ppm for  $\text{P}_2\text{O}_5$ .

### 3.2.2 Trace elements

Microbeam trace element analyses were carried out at the University of Alberta, using a Nd:YAG UP213 nm laser ablation system (New Wave Research) connected to a Perkin Elmer Elan 6000 Quadrupole ICP-MS. The NIST612 glass standard was used for calibration and optimisation of instrument parameters. Samples were typically ablated for 50 seconds, with a spot size of 150  $\mu\text{m}$ , 5 Hz repetition rate and energy density of  $\sim 13 \text{ J/cm}^2$ . Backgrounds were measured for 20 seconds prior to each analysis. Garnet grains (PN1 and PN2) that have been well characterised using several techniques (INAA, SIMS, LA-ICP-MS; Tappert et al., 2005) were ran as secondary standards. Average concentration values obtained for these garnets overlap within error to the recommended values (Tappert et al., 2005). Data reduction and concentration determinations, using EPMA-determined Ca concentrations in garnet as internal standard, were obtained using GLITTER laser ablation software (van Achterbergh et al., 2001).

### 3.2.3 Strontium isotopes

#### Chemical dissolution and TIMS

Strontium isotopic compositions of clinopyroxene picked from six samples were measured by isotope dilution thermal ionisation mass spectrometry (ID-TIMS). Between  $\sim 3 \text{ mg}$  and  $\sim 30 \text{ mg}$  clinopyroxene were picked, depending on Rb and Sr concentrations in individual samples (determined through laser ablation ICP-MS). These grains were leached for two hours in 1 ml cold 2N HCl,

to remove any grain boundary contamination (e.g., Wittig et al., 2009). After pipetting the leachate and rinsing three times with MilliQ, a spike solution was added and the samples digested on a hotplate for one day in 1 ml HF / 1 ml HNO<sub>3</sub>. Following dry down, HCl was added overnight and subsequently dried down, which brings the digested sample into chloride form ready for column chemistry. Rubidium and Sr were separated by conventional column chromatographic techniques using AG50W-X8 cation resin and then loaded on Re filaments with Ta activator and analysed on a Thermo Scientific Triton at the University of Alberta. The <sup>85</sup>Rb signal was used to correct for the isobaric interference of <sup>87</sup>Rb, using the normal <sup>85</sup>Rb/<sup>87</sup>Rb ratio of 2.5906. Analyses were corrected for minimum procedural blanks of 243 pg Sr and 1270 pg Rb. Strontium blank contributions range between 0.001 and 0.008 % and Rb blank contributions between 0.6 and 5 %. 2 standard error (SE) uncertainties are reported as the in-run precision and are in the range 0.004 to 0.15%.

### ***In situ* MC-ICP-MS**

Strontium isotopic compositions for nine samples were obtained using a Nd:YAG UP213 nm laser ablation system (New Wave Research) coupled to a NuPlasma multicollector-ICP-MS, following procedures modified from Schmidberger et al. (2003). Line scans were ablated on clinopyroxene and collected in static multi-collector mode using Faraday detectors. The <sup>85</sup>Rb signal was used to correct for the isobaric interference of <sup>87</sup>Rb. Durango apatite, analysed by both TIMS and LA-ICP-MS (<sup>87</sup>Sr/<sup>86</sup>Sr (TIMS) = 0.706327; <sup>87</sup>Sr/<sup>86</sup>Sr (LA-ICP-MS) = 0.70680 ± 0.00002 (2SD) Horstwood et al., 2008), was used as a secondary standard. Eleven analyses of Durango apatite on the first day of analyses gave <sup>87</sup>Sr/<sup>86</sup>Sr = 0.70620 ± 0.0006 (2SE) and five analyses on the second day gave <sup>87</sup>Sr/<sup>86</sup>Sr = 0.70632 ± 0.00066 (2SE). The apatite data were corrected for REE<sup>2+</sup> interferences offline, whereas the clinopyroxene data were not, due to much lower REE contents. The weighted average for *n* line scans per sample are reported along with the in-run precision (2SE), which is typically between 0.001 and 0.033 %.

### **3.2.4 Oxygen isotopes**

Oxygen isotopic analyses on garnet were performed on a IMS1280 multicollector ion microprobe at the Canadian Centre for Isotopic Microanalysis

(CCIM) at the University of Alberta. Garnet grains about  $\sim 300 \mu\text{m}$  and less, were picked under the microscope and mounted in epoxy. Analytical protocols and data correction follow methods outlined in Ickert and Stern (2013).

$^{18}\text{O}/^{16}\text{O}$  data were collected during a one-day session, using a  $15 \mu\text{m}$  diameter  $\text{Cs}^+$  primary beam and dual Faraday cups. During the analytical session, the primary beam intensity was  $\sim 2.8 \text{ nA}$ , yielding  $\sim 3.3 \times 10^9$  counts per second  $^{16}\text{O}$ . The energy slit was fully opened. Data collection consisted of a 30 second raster (pre-sputtering), followed by secondary beam centering in the field aperture, and twenty, 5 second integrations for a total count time of 100 seconds. Amplifier baselines were measured before the session and subtracted from the ion beam intensities of each analysis.

The primary reference material to correct for instrumental mass fractionation (IMF) is UAG, a pyrope garnet from Gore Mountain with  $\delta^{18}\text{O}$  of  $5.72 \pm 0.13 \text{ ‰}$  ( $2\sigma$ ; Ickert and Stern, 2013). All results are reported relative to the international VSMOW standard. During the analytical session, the repeatability of UAG on the same mount as the unknown garnet material was  $0.38 \text{ ‰}$  ( $2\text{SD}$ ,  $n=32$ ).

Any mineral that has wide variation in major element compositions, may exhibit variation in matrix-controlled instrumental mass fractionation (IMF). Vielzeuf et al. (2005) and Page et al. (2010) have documented the effect of Ca content ( $X_{\text{Ca}} = \text{Ca}/(\text{Ca}+\text{Mg}+\text{Fe})$ ) of garnet on instrument fractionation. We utilise a matrix correction substantially similar to Page et al. (2010), described by Ickert and Stern (2013) to correct for matrix effects based on the relative Ca abundances. The magnitude of the matrix correction varies from  $-0.25 \text{ ‰}$  to  $+1.71 \text{ ‰}$ , but is mainly  $<1 \text{ ‰}$ . The uncertainty on the matrix correction is propagated onto the final results. Secondary reference material S0088B, a near end-member Ca-Al (grossular) garnet was embedded in the same mount as the unknown garnet to check the accuracy of the matrix correction. Eight analyses of S0088B during the analytical session yielded a mean  $\delta^{18}\text{O}$  value of  $+4.05 \pm 0.16 \text{ ‰}$  ( $2 \text{ SE}$ ;  $n=8$ ) after a matrix correction of  $+2.96 \text{ ‰}$ , which agree with the value determined by laser fluorination of  $4.13 \pm 0.09 \text{ ‰}$  ( $2\sigma$ ).

Two to three analyses per sample were performed. The total uncertainty

( $2\sigma$ ) on each analytical spot varies between  $\pm 0.36$  and  $\pm 0.55$  ‰ and is the combination of uncertainty on the mean UAG value for the session and uncertainty in the matrix correction. Analyses for each sample were averaged, with the uncertainty for each sample given as the largest error of the single spot analyses.

### 3.2.5 Rhenium and osmium isotopes

Each sample was broken into small fragments and then powdered using an agate mill. Quartz was powdered as a pre-clean and the milling equipment cleaned between samples using water, ethanol and compressed air. Between 0.5 and 1 g sample powders were added to Carius tubes with a mixed  $^{190}\text{Os}$  -  $^{185}\text{Re}$  spike and digested in reverse Aqua Regia (1:2 HCL:HNO<sub>3</sub>) for five days at 240 °C (following Shirey and Walker, 1995). This was followed by solvent extraction of Os, first into CHCl<sub>3</sub> and then by back-extraction into HBr (Cohen and Waters, 1996). Re was recovered from the reverse Aqua Regia split after the first extraction, dried down and then separated by anion exchange chromatography (Morgan and Walker, 1989; Walker, 1988) using Eichrom AG1-X8 resin, followed by a single bead extraction. Os was purified using micro distillation techniques (Roy-Barman and Allègre, 1994; Birck et al., 1997). 20  $\mu\text{L}$  HBr was added to the tip of a conical beaker and 30  $\mu\text{L}$  CrO<sub>3</sub>/H<sub>2</sub>SO<sub>4</sub> solution to the dried down Os fraction. The inverted beaker was placed on a hotplate for three hours at 75 °C . The HBr drop was dried down and the distillation procedure repeated.

Isotopic compositions of Re and Os were measured by negative thermal ionisation mass spectrometry (N-TIMS) on a Thermo Scientific Triton at the University of Alberta. Rhenium and Os were loaded on Ni and Pt filaments, respectively. Barium, as Ba(NO<sub>3</sub>)<sub>2</sub> or Ba(OH)<sub>2</sub> was added onto the filaments as an electron donor to aid with ionisation. Oxygen was leaked into the source during Os runs in order to improve ionisation efficiency. Rhenium isotopes were collected using Faraday cups and Os isotopes using an electron multiplier. Mass spectrometer fractionation was corrected by normalising  $^{192}\text{Os}/^{188}\text{Os}$  to 3.08261 (Creaser et al., 1991). As Re and Os were run as negative oxides, data were corrected for interferences from three O isotopes, with  $^{17}\text{O}/^{16}\text{O} = 0.0003$  and  $^{18}\text{O}/^{16}\text{O} = 0.0020$ . Analyses were corrected for procedural blanks of 0.37

pg Os and 0.67 pg Re.

$^{187}\text{Re}/^{188}\text{Os}$  and  $^{187}\text{Os}/^{188}\text{Os}$  2SE errors include the in-run precision, the uncertainty in the concentration and isotopic composition of the blank and the uncertainty in the spike calibration. 2SE uncertainties in  $^{187}\text{Os}/^{188}\text{Os}$  are typically between  $\pm 0.4$  and  $0.7\%$ , with  $^{187}\text{Re}/^{188}\text{Os}$  uncertainties between  $\pm 0.4$  and  $1.4\%$ .

### 3.3 Results

#### 3.3.1 Mineral major and trace element chemistry

Eclogites and pyroxenites from Victor were classified based on clinopyroxene composition - 16 pyroxenites contain diopside ( $\text{Na}/\text{Na}+\text{Ca} < 0.2$ ) whereas 17 eclogites contain omphacite ( $\text{Na}/\text{Na}+\text{Ca} > 0.2$ ), consistent with commonly used definitions for eclogite (e.g., Coleman et al., 1965; Carswell, 1990; Pearson et al., 2003).

The samples in this study have a wide compositional range, comprising both low-Mg and high-Mg varieties, common for eclogite suites from many localities worldwide. For example, Bellsbank and Premier on the Kaapvaal craton (Taylor and Neal, 1989; Neal et al., 1990; Dlodla et al., 2006), Koidu (Man craton; Barth et al., 2001, 2002a), Udachnaya (Siberian craton; Jerde et al., 1993; Beard et al., 1996; Snyder et al., 1997) and Diavik (Slave craton; Aulbach et al., 2007). Major and trace element compositions are given in Table A.3 to Table A.11 and Table B.1 to Table B.6. In addition to division into eclogites and pyroxenites, eclogites are also sub-divided into three groups based on similar major (Figure 3.2 and Figure 3.3) and trace element compositions (Figure 3.4).

#### High-Ca eclogites

The single calcium-rich sample has garnet with  $\text{CaO} = 15.7$  wt%,  $\text{MgO} = 9.9$  wt%,  $\text{FeO} = 10.9$  wt%,  $\text{Cr}_2\text{O}_3 = 0.1$  wt% (Figure 3.2 and Figure 3.3) and the lowest REE abundances in the suite (Figure 3.4). Garnet trace element patterns are extremely LREE depleted with  $\text{Ce}_N/\text{Sm}_N = 0.003$ , have a positive Eu anomaly ( $\text{Eu}/\text{Eu}^* = 1.45$ ) and decrease again to the HREE ( $\text{Lu}_N/\text{Gd}_N =$

0.44) (Figure 3.4).  $\text{Eu}/\text{Eu}^*$  is calculated as  $\text{Eu}_N/\sqrt{\text{Sm}_N\text{XGd}_N}$  (e.g., Kemp and Hawkesworth, 2003) and  $\text{REE}_N$  refers to normalisation to CI chondrite (Sun and McDonough, 1989).

Omphacite has  $\sim 7$  wt%  $\text{Na}_2\text{O}$  (Figure 3.2) and is LREE depleted with  $\text{Ce}_N/\text{Sm}_N = 0.03$ . It has a negative slope in the MREE to HREE (with an upward kink to Lu) and a slight positive Eu anomaly ( $\text{Eu}/\text{Eu}^* = 1.17$ ) (Figure 3.4). This sample has accessory kyanite. The temperature of last equilibration is  $980^\circ\text{C}$ , based on Fe-Mg exchange between clinopyroxene and garnet and calculated at 5 GPa (Krogh, 1988).

### Low-Mg eclogites

Eight samples classify as low-Mg eclogites. Garnets are Fe-rich with  $\text{FeO} = 17.5\text{-}24.4$  wt%,  $\text{MgO} = 6.7\text{-}10.3$  wt% and  $\text{CaO} = 5.7\text{-}10.6$  wt%. They have the lowest  $\text{Cr}_2\text{O}_3$  content of the entire suite (0.01-0.04 wt%). Garnets have normal  $\text{REE}_N$  patterns with depleted LREE (average  $\text{La}_N/\text{Sm}_N = 0.006$ ), relatively flat MREE to HREE (average  $\text{Lu}_N/\text{Gd}_N = 1.32$ ), and slight negative Eu anomalies (average  $\text{Eu}/\text{Eu}^* = 0.96$ ; range  $\text{Eu}/\text{Eu}^* = 0.86\text{-}1.12$ ). Clinopyroxenes have omphacitic compositions with 3.5-6.8 wt%  $\text{Na}_2\text{O}$ . They show LREE enrichment, a negative slope in the HREE (average  $\text{Lu}_N/\text{Gd}_N = 0.15$ ) and a range in  $\text{Eu}/\text{Eu}^*$  between 0.63-1.12 (with average  $\text{Eu}/\text{Eu}^* = 0.92$ ). Temperatures of last equilibration for the low-Mg eclogites range between  $780$  and  $930^\circ\text{C}$  (calculated at 5 GPa; Krogh, 1988).

### High-Mg eclogites

Eight high-Mg eclogites have garnet with  $\text{MgO}$  between 11.6-18.4 wt%,  $\text{CaO}$  between 4.0-8.5 wt% and  $\text{FeO}$  between 13.3-17.9 wt%.  $\text{Cr}_2\text{O}_3$  varies between 0.05 and 0.18 wt%. Garnets are LREE depleted with  $\text{Ce}_N/\text{Sm}_N$  between 0.02-0.08 and have flat to slightly fractionated MREE to HREE ( $\text{Lu}_N/\text{Gd}_N = 0.5\text{-}3.7$ ). Samples have both slightly negative and slightly positive Eu anomalies, with  $\text{Eu}/\text{Eu}^*$  between 0.81 to 1.15 (Average  $\text{Eu}/\text{Eu}^* = 0.99$ ). Omphacitic clinopyroxenes have  $\text{Na}_2\text{O}$  between 2.7 and 4.7 wt%, LREE enrichment (average  $\text{La}_N/\text{Sm}_N = 2.69$ ) and a negative slope in the HREE (average  $\text{Lu}_N/\text{Gd}_N = 0.04$ ). Clinopyroxene has  $\text{Eu}/\text{Eu}^*$  between 0.9 and 1.1; with average  $\text{Eu}/\text{Eu}^* = 1.01$ . The high-Mg eclogites have temperatures of last equilibration between

835 and 975 °C (calculated at 5 GPa; Krogh, 1988).

### Pyroxenites

Sixteen pyroxenites have garnet with MgO = 15.0-20.9 wt%, CaO = 4.0-8.0 wt% and FeO = 8.2-14.1 wt%. Cr<sub>2</sub>O<sub>3</sub> ranges from ~ 0.1 to 0.9 wt%. Garnet is LREE depleted with La<sub>N</sub>/Sm<sub>N</sub> < 0.1 and has flat to slightly fractionated MREE to HREE, with Lu<sub>N</sub>/Gd<sub>N</sub> between 0.9 and 3.9. Eu/Eu\* range between 0.93 and 1.17. Diopsidic clinopyroxene has between 0.9-2.7 wt% Na<sub>2</sub>O and is LREE enriched (La<sub>N</sub>/Sm<sub>N</sub> between 2.3 and 20.8). It displays a negative slope in the HREE with average Lu<sub>N</sub>/Gd<sub>N</sub> = 0.07 and Eu/Eu\* between 0.9 and 1.2. Eight of the pyroxenites contain enstatite, with a range in Mg# from 90.4 to 93.6 and 0.6-0.9 wt% Al<sub>2</sub>O<sub>3</sub>. Orthopyroxene was not analysed for trace elements, as it is not considered to be a major host for trace elements in the SCLM (e.g., Pearson et al., 2003).

The orthopyroxene-free pyroxenites yield temperatures between 770 and 860 °C (calculated at 5 GPa; Krogh, 1988).. The eight orthopyroxene-bearing samples allowed for both pressure and temperature calculations. Temperatures for Fe-Mg exchange between orthopyroxene and clinopyroxene (Taylor, 1998) were calculated iteratively with Al-in-orthopyroxene pressures (Nickel and Green, 1985) - yielding temperatures between 610 and 1030 °C and pressures between 2.0 and 4.7 GPa.

### 3.3.2 Strontium isotopic compositions

Strontium isotopic compositions for clinopyroxene from 12 samples were determined (Table C.1). Six samples were analysed by TIMS and nine samples by *in situ* MC-ICP-MS. Three samples were analysed by both techniques.

The high-Ca eclogite has clinopyroxene with the lowest Sr concentration (~30 ppm) in the suite. Clinopyroxene in the three low-Mg eclogites have ~ 150 to 300 ppm Sr; whereas clinopyroxene in the three high-Mg eclogites have slightly higher Sr concentrations, ranging from ~ 130 to 600 ppm Sr (Table C.1). The pyroxenites have clinopyroxene with the highest average Sr concentrations - the orthopyroxene-free pyroxenites range between ~ 250 and 690 ppm Sr; and the orthopyroxene-bearing pyroxenites between ~550 and 900 ppm Sr (Ta-

ble C.1). Rb concentrations are low ( $< 5$  ppm) and are below detection in half the samples. The six samples measured by TIMS have  $^{87}\text{Rb}/^{86}\text{Sr} < 0.01924$ .

The  $^{87}\text{Sr}/^{86}\text{Sr}$  for clinopyroxene in the different eclogite groups is broadly similar and all are less radiogenic than the present-day bulk Earth composition ( $^{87}\text{Sr}/^{86}\text{Sr} = 0.7045$ ; DePaolo and Wasserburg, 1976). Clinopyroxene in the three low-Mg eclogites analysed have a measured, present-day  $^{87}\text{Sr}/^{86}\text{Sr}$  ranging between 0.7021 and 0.7031, the three high-Mg eclogites between 0.7020 and 0.7031, the three opx-free pyroxenites between 0.7020 and 0.7029 and the two opx-bearing pyroxenites between 0.7027 and 0.7039. The single high-Ca kyanite-bearing eclogite has clinopyroxene with  $^{87}\text{Sr}/^{86}\text{Sr}$  of 0.7019. Three samples that were analysed by both TIMS and MC-ICP-MS have measured present-day  $^{87}\text{Sr}/^{86}\text{Sr}$  ratios within error of each other (Table C.1). Due to low Rb contents, the calculated initial  $^{87}\text{Sr}/^{86}\text{Sr}$  (at the time of kimberlite eruption,  $\sim 180$  Ma; Januszczak et al., 2013) for all samples are within error of their measured present-day values (Table C.1).

### 3.3.3 Oxygen isotopic compositions

Oxygen isotopic composition in garnet from all 33 samples was collected by SIMS. The majority of garnets have  $\delta^{18}\text{O}$  values between  $\sim 5$  to  $6$  ‰, within error of the pristine mantle average ( $\delta^{18}\text{O} = 5.5 \pm 0.2$  ‰; Matthey et al., 1994), with  $\delta^{18}\text{O}$  in garnet  $\approx \delta^{18}\text{O}$  in the whole rock (Eiler, 2001, and references therein). Garnet in three of the low-Mg eclogites is more enriched in  $^{18}\text{O}$  and has  $\delta^{18}\text{O}$  values outside of error of the pristine mantle average ( $7.0 \pm 0.5$  ‰;  $6.3 \pm 0.4$  ‰ and  $6.3 \pm 0.4$  ‰) ( $2\sigma$ ). The results from the oxygen isotope analyses are given in Table C.2 and Figure 3.5.

### 3.3.4 Rhenium and osmium isotopic compositions

Whole rock Re-Os isotopic compositions were obtained for 10 samples, considered to be representative of the different sample groups. Results are given in Table C.3. Rhenium and Os concentrations are plotted together with MORB and peridotite samples world-wide in Figure 3.6.

The single high-Ca eclogite has Re = 0.08 ppb and Os = 0.08 ppb. The three low-Mg eclogites have Re concentrations ranging from 0.10 to 0.56 ppb

and Os from 0.10 to 0.14 ppb. The three high-Mg eclogites range between 0.03 and 0.16 ppb Re, with 0.17 to 0.21 ppb Os. The three pyroxenites have 0.03 to 1.53 ppb Re and 0.21 to 0.64 ppb Os.

The  $^{187}\text{Os}/^{188}\text{Os}$  for all samples, apart from one pyroxenite, are radiogenic relative to the composition for O-chondrites (0.1283; Walker et al., 2002). This is expressed in their  $\gamma_{\text{Os}}$ , which is defined as the percentage deviation from a specific reservoir (O-chondrite in this case) at a certain time (e.g., Walker et al., 1989). The high-Ca eclogite has present day  $\gamma_{\text{Os}} = 60$ , the three low-Mg eclogites range from 153 to 1737 and the three high-Mg eclogites from 188 to 852. The three pyroxenites have a wide range in  $\gamma_{\text{Os}}$ , with one unradiogenic sample ( $\gamma_{\text{Os}} = -9$ ) and two radiogenic samples ( $\gamma_{\text{Os}} = 152$  and 623). The pyroxenite with the unradiogenic  $\gamma_{\text{Os}}$  composition is also the sample with the highest Re concentration (1.53 ppb) and is orthopyroxene-free.

The  $\gamma_{\text{Os}}$  values are shown in Figure 3.7 in relation to other mantle lithologies, ocean island basalts, continental crust and Archaean komatiites and basalts. Initial  $\gamma_{\text{Os}}$ , calculated for the time of kimberlite eruption ( $\sim 180$  Ma), is within 1 to 3 % of the present day  $\gamma_{\text{Os}}$  values (Table C.3).

The Re and Os isotopic compositions do not show any isochronous relationships and their model ages ( $T_{MA}$ ), or mantle extraction ages, have a wide range between  $\sim 1$  Ga and 41 Ga. The majority of model ages are older than the age of the Earth - these unrealistic ages typically reflect Re/Os ratios too low to account for the high measured  $^{187}\text{Os}/^{188}\text{Os}$ .

## 3.4 Discussion

### 3.4.1 Reconstructed bulk rock chemistry

Due to kimberlite infiltration in eclogitic / pyroxenitic xenoliths, original bulk incompatible trace element compositions cannot be measured directly, but need to be reconstructed using the modal proportions and analyses of clean mineral separates. Meaningful mineral modes could not be determined for these samples due to their small size, and approximate bulk rocks were reconstructed using modes of garnet 50% and clinopyroxene 50%. For the

orthopyroxene-bearing pyroxenites, modes of garnet 45%, clinopyroxene 45% and orthopyroxene 10% were used. Previous studies have shown that the reconstructed trace element patterns for eclogites are relatively insensitive to the exact modes of constituent minerals (e.g., Jerde et al., 1993; Aulbach et al., 2007; Smart et al., 2009).

The bulk rock compositions of all eclogites and pyroxenites are shown in Figure 3.8, along with field for N-MORB (Sun and McDonough, 1989) and oceanic crust gabbro (Bach et al., 2001). The high-Ca eclogite has HREE abundances comparable to oceanic crust gabbro. The presence of the highly aluminous phase, kyanite, and a positive Eu anomaly ( $\text{Eu}/\text{Eu}^* = 1.45$ ) in the high-Ca eclogite, provide additional support for a gabbroic protolith. Positive Eu anomalies along with positive Sr anomalies (seen relative to Pr and Nd in Figure 3.8) are generally attributed to plagioclase accumulation and typical for cumulate gabbros of the lower oceanic crust. Strontium anomalies are generally considered to be more robust support for plagioclase accumulation since Eu anomalies may not be substantial if plagioclase crystallised together with a large proportion of clinopyroxene (Schmickler et al., 2004).

The low-Mg eclogites have flat to slightly negative slopes in whole rock  $\text{HREE}_N$  patterns, with higher HREE abundances than gabbro, more comparable to average N-MORB as well as basalts from the Superior craton (e.g., tholeiites from several greenstone belts). However, the low-Mg eclogites do show positive Sr anomalies (Figure 3.8). Basalts typically possess neither positive Eu or Sr anomalies (see for example, N-MORB of Sun and McDonough (1989) and Klein (2003)), both of which are attributed to plagioclase fractionation/accumulation and therefore expected in a gabbro.

The low-Mg eclogites may be considered to have an intermediate REE composition between MORB and gabbro, that is more representative of bulk oceanic crust. For example, Viljoen et al. (2010) calculated 50:50 mixtures between N-MORB (composition from Klein, 2003) and a gabbro sample (sample 92OG53 from Benoit et al., 1996). This intermediate trace element composition has strong positive Sr anomalies, no Eu anomalies and HREE abundances between the two end-members - very similar to the REE composition of the low-Mg eclogites.

### 3.4.2 Formation of low-Mg and high-Ca eclogites

Petrogenetic models for mantle eclogites include an origin as high pressure cumulates of mantle melts (e.g., O'Hara and Yoder, 1967; MacGregor and Carter, 1970; Hatton and Gurney, 1987; Smyth et al., 1989; Caporuscio and Smyth, 1990) and an origin as high pressure metamorphic products of oceanic crust, emplaced into the SCLM by subduction processes (Helmstaedt and Doig, 1975; Helmstaedt and Schulze, 1989; Jacob et al., 1994). An extension of the subduction model is that some eclogites may be residues after TTG (tonalite-trondhjemite-granodiorite) extraction from former oceanic crust in the garnet stability field (Ireland et al., 1994; Rollinson, 1997; Barth et al., 2001). These different models and their applicability to the formation of Victor eclogites are discussed below.

#### Origin as high pressure mantle melts

A high pressure origin for the low-Mg eclogites is considered unlikely due to a number of reasons. Reconstructed bulk rock compositions of the low-Mg eclogites do not overlap with the composition of experimental melts of peridotite at 3-7 GPa (Walter, 1998, Figure 3.9). High pressure melts are too high in MgO and too low in Al<sub>2</sub>O<sub>3</sub> to match these low-Mg eclogitic bulk compositions and, additionally, have olivine as a liquidus phase (e.g., O'Hara and Yoder, 1963), a phase not present in eclogites. Kyanite, found as an accessory phase in the single high-Ca eclogite, is not in equilibrium with a high pressure peridotite-derived melt composition. Additionally, clinopyroxenes in these low-Mg eclogites are jadeitic, whereas high pressure liquidus clinopyroxenes are predominantly Ca-Tschermaks (experimental compositions of Eggins, 1992).

We considered the possibility that the eclogites at Attawapiskat are Midcontinent Rift basalts that have crystallised at depth in the SCLM to form eclogites. The bulk compositions of the Mamainse Point basalts (Shirey et al., 1994) show some similarity to the low-Mg eclogites (Figure 3.9). However, if these eclogites were products of single-stage melting related to the Midcontinent Rift, coherent Re-Os isochron and model age relationships should be present, indicating extraction from the convecting mantle at  $\sim 1.1$  Ga. The lack of any Re-Os isochron or model age relationships in the eclogites, preclude a single-stage

melt model for their genesis, but rather require a more complex multi-stage model. Furthermore, the high  $\delta^{18}\text{O}$  in three low-Mg eclogites requires surficial alteration, as oxygen isotopes cannot be appreciably fractionated at high temperatures in the mantle (e.g., Clayton et al., 1975; Eiler, 2001).

### Origin as low pressure melts

Support for plagioclase-bearing protoliths comes from the presence of kyanite (not in equilibrium with high pressure peridotitic melt compositions), and the positive Eu ( $\text{Eu}/\text{Eu}^* = 1.45$  in the high-Ca, kyanite-bearing sample) and Sr anomalies (in all low-Mg and high-Ca samples) and the generally flat MREE to HREE patterns in the low-Mg eclogites (e.g., Green, 1994; Jacob et al., 2003b; Jacob, 2004). These flat REE patterns can be neither garnet-rich cumulates (which would have higher HREE abundances in garnet) nor melts with garnet in the residue and instead resemble the REE patterns of MORB / plagioclase, thereby suggesting a metamorphic origin for garnet from lower pressure protoliths.

Compared to Archaean tholeiites and komatiites, the whole rock compositions of the low-Mg eclogites are lower in  $\text{SiO}_2$  and higher in CaO and  $\text{Al}_2\text{O}_3$ . They do, however, show overlap with oceanic gabbros (Bach et al., 2001), apart from their slightly lower  $\text{SiO}_2$  content (Figure 3.10). The low-Mg eclogites (including the kyanite-bearing sample) are LREE depleted, which together with their lower bulk  $\text{SiO}_2$  content (relative to basalts and oceanic crust gabbro) indicate that they may be residues of a secondary partial melting event.

Also, their Re concentrations are low relative to MORB (Figure 3.6; Gannoun et al., 2007) - too low to account for the radiogenic Os isotopic compositions - consistent with Re loss during dehydration/partial melting of a subducting slab (e.g., Dale et al., 2007). This, along with their variation in model age and isochron systematics, provides further support that the low-Mg eclogites are residues after partial melting.

As has been proposed for other localities, TTG's and eclogites show a complementary melt-residue relationship (Ireland et al., 1994; Rollinson, 1997; Barth et al., 2001; Tappe et al., 2011), with the major element composition of greenstone-belt basalts lying on a broadly linear trend between the eclogites

and TTG's (Figure 3.10).

This complementary relationship between TTG and low-Mg eclogite is also seen in the rare earth elements (Figure 3.11a) - tonalites are LREE-enriched and HREE-depleted (e.g., Kemp and Hawkesworth, 2003), whereas the low-Mg eclogites studied here are LREE-depleted and HREE-enriched. As a further test of a possible melt-residue relationship between low-Mg eclogites and TTG's, compositions of residue and melt during batch melting of former pillow basalt were calculated. For these calculations, basalts from greenstone belts in the western Superior Province and partition co-efficients for eclogite in equilibrium with a tonalite melt (Barth et al., 2002c) were used. Residue and melt compositions at varying melt fractions are plotted in Figure 3.11b. The LREE-depleted composition of the low-Mg eclogites can be reproduced with  $\sim 25\text{-}40\%$  melt extraction, and the co-existing melt composition overlaps with that of tonalite. These results are consistent with experimental studies that produced TTG melts at  $\sim 25\text{-}40\%$  partial melting of metabasalt at high pressures (2.2 - 3.2 GPa) (Rapp et al., 1991; Rapp and Watson, 1995). The experimental residues at 3.2 GPa are eclogitic and contain garnet with  $\text{MgO} = 8.5 - 10.4 \text{ wt\%}$ ,  $\text{FeO} = 19.9 - 21.1 \text{ wt\%}$ ,  $\text{CaO} = 5.6 - 9.0 \text{ wt\%}$  and clinopyroxene with  $\text{MgO} = 8.7 \text{ wt\%}$ ,  $\text{CaO} = 11.3 \text{ wt\%}$ ,  $\text{Na}_2\text{O} = 6.6 \text{ wt\%}$  (Table 5 and 6 in Rapp and Watson, 1995). These major element compositions overlap with those of the Victor low-Mg eclogites (Table A.3 to Table A.10).

The tectonic setting for formation of TTG magmas, and by inference, emplacement of the low-Mg eclogites in the SCLM, is still debated. TTG's may be products of fluid-present melting of altered mafic rocks in a subducting slab (e.g., Rapp and Watson, 1995; Prouteau et al., 1999) or fluid-absent melting of mafic rocks in a thickened crust at higher temperatures (e.g., Rapp et al., 2003). To explain the HREE-depleted nature of TTG's, they are considered to be the melt products of mafic rocks with garnet in the residue - either garnet amphibolite or eclogite (e.g., Jahn et al., 1981; Rapp et al., 1991; Foley et al., 2002).

The  $\delta^{18}\text{O}$  values of the low-Mg eclogites constrains the tectonic setting for melt extraction. Their fractionated values cannot be produced at high temperatures in the mantle, but only at low temperatures due to seafloor weathering

(Muehlenbachs and Clayton, 1972a,b). A study of basaltic glasses at Macquarie Island by Bindeman et al. (2012), confirmed that the oxygen isotopic composition of the mantle stays within a narrow range, even under a wide range of melting conditions. Additionally, it has been shown that Archaean granitoids on the Superior craton that are derived from a mantle source have a narrow range in  $\delta^{18}\text{O}$  ( $5.5 \pm 0.4$  ‰), whereas those with crustal contributions to the source regions have a higher  $\delta^{18}\text{O}$  ( $6.4 \pm 0.2$  ‰), outside the pristine mantle range (King et al., 1998).  $\delta^{18}\text{O}$  in garnet of three low-Mg eclogites are higher than the typical mantle value, which is considered strong evidence that these eclogites had shallow oceanic crust precursors that were affected by low-temperature seafloor alteration processes and subsequently subducted and emplaced into the SCLM.

## Summary

We have argued that the low-Mg eclogites have a shallow origin as plagioclase-bearing protoliths that were subsequently subducted and emplaced into the SCLM. This is supported by their generally flat MREE to HREE compositions, the presence of kyanite and a positive Eu anomaly in the high-Ca sample, and  $\delta^{18}\text{O}$  in three low-Mg eclogites that are higher than the pristine mantle value. LREE depletion in the low-Mg eclogites, along with unradiogenic  $^{87}\text{Sr}/^{86}\text{Sr}$  (less than present-day bulk Earth  $^{87}\text{Sr}/^{86}\text{Sr} = 0.7045$ ; DePaolo and Wasserburg, 1976) indicate that they were not affected by widespread metasomatism after emplacement in the SCLM.

### 3.4.3 Formation of high-Mg eclogites and pyroxenites

The high-Mg eclogites and pyroxenites have several compositional characteristics that require a distinct origin to the low-Mg eclogites. These include 1.) bulk rock compositions which are broadly similar to  $< 3$  GPa peridotite-derived melts and massif pyroxenites (Baker and Stolper, 1994; Pearson et al., 1993), 2.) LREE-enriched compositions, 3.) mantle-like  $\delta^{18}\text{O}$  and 4.) a wide range in Os isotopic compositions from unradiogenic to radiogenic (relative to the  $^{187}\text{Os}/^{188}\text{Os}$  of O-chondrites = 0.1283; Walker et al., 2002).

The LREE's are not typically considered in petrogenetic models for eclogite xenolith suites, as any enrichment may be due to secondary processes

after emplacement in the SCLM. Metasomatism by kimberlitic/carbonatitic mantle melts with high Mg content and strong LREE enrichment (le Roex et al., 2003) has previously been suggested for some eclogite suites. For example, the Udachnaya eclogites show an increase in MgO and incompatible trace elements compared to inclusions in diamonds (e.g., Ireland et al., 1994; Snyder et al., 1997).

The LREE enrichment in the Victor high-Mg eclogites and pyroxenites could support this carbonatite/kimberlite metasomatism model, for example, if 5% average carbonatite (from Tappe et al., 2006) is mixed with the low-Mg eclogites, the REE compositions of the high-Mg eclogites can be reproduced (Figure 3.12). However, 5% addition of kimberlite or carbonatite does not significantly alter the major element compositions and even higher degrees of metasomatism do not provide sufficient enrichment in SiO<sub>2</sub> or MgO to match the compositions of the high-Mg eclogites and pyroxenites. Additionally, these samples all have unradiogenic <sup>87</sup>Sr/<sup>86</sup>Sr, uncharacteristic for samples that have undergone metasomatism by fluids/melts originating in an ancient enriched SCLM, which would typically impose radiogenic <sup>87</sup>Sr/<sup>86</sup>Sr and unradiogenic <sup>143</sup>Nd/<sup>144</sup>Nd (e.g., Richardson et al., 1984).

The metasomatic model is therefore not suitable for the Victor high-Mg eclogites and pyroxenites. The LREE enrichment observed in these samples is not considered to be a secondary feature in these rocks, but rather a primary characteristic that needs to be accounted for in any model that satisfactorily explains their genesis.

Several other models for pyroxenite (and high Mg eclogites) petrogenesis have been proposed. These include 1.) the *in situ* crystallisation of partial melts of peridotite (e.g., Dick and Sinton, 1979; Sinigoi et al., 1983; Voshage et al., 1988); 2.) mafic to intermediate melts infiltrating depleted peridotite and forming a mixing product (e.g., Kelemen et al., 1993; Yaxley and Green, 1998; Garrido and Bodinier, 1999; Rapp et al., 1999; Aulbach et al., 2002; Taylor et al., 2003; Smart et al., 2009) and 3.) similar to the model proposed for eclogites, residues of melting of oceanic crust in the mantle (e.g., Dick and Sinton, 1979; Polvé and Allègre, 1980; Loubet and Allègre, 1982; Allègre and Turcotte, 1986; Blichert-Toft et al., 1999). The applicability of these models

to the high Mg eclogites and pyroxenites at Victor is discussed below.

### **Origin as residues of melting of oceanic crust**

The high-Mg eclogites and pyroxenites have only slight negative / positive Eu and Sr anomalies (Figures 3.4 and 3.8). Although eclogite protoliths with significant plagioclase crystallisation may not necessarily show large Eu anomalies, the lack of strong positive Sr anomalies does not support plagioclase accumulation in the protoliths (e.g., Schmickler et al., 2004). Additionally, their LREE enrichment relative to chondrite/NMORB argues against a residual origin (e.g., after partial melting during subduction) (Figure 3.8).

### **Origin as high pressure mantle melts**

Calculated pressures for the orthopyroxene-bearing assemblages indicate they originated between 2 and 5 GPa. At these pressures, melts generated from peridotite would be basaltic-picritic (e.g Takahashi, 1986; Takahashi et al., 1993), which does not correspond with the bulk compositions of these eclogites and pyroxenites in terms of their MgO content.

Higher MgO melts, such as komatiites typically originate from higher pressures (5-7 GPa; Takahashi, 1986; Takahashi et al., 1993). However, the bulk compositions of the Victor high-Mg eclogites and pyroxenites are not similar to either high pressure peridotite melts (3-7 GPa experimental melts of Walter, 1998) or natural komatiites from greenstone belts on the Superior (Figure 3.10). The high-Mg eclogites and pyroxenites are also more strongly LREE-enriched (up to 100 times chondrite) and have higher HREE abundances than komatiites from greenstone belts in the Superior, which have flat REE patterns at < 10 times chondritic abundance (Hollings et al., 1999).

The whole rock compositions of the high-Mg eclogites and pyroxenites are similar to peridotite melts at intermediate pressure - they fall between  $\sim 1$  GPa peridotite melts (experimental melts of Baker and Stolper, 1994) and  $\sim 3-7$  GPa peridotite melts (experimental melts of Walter, 1998, Figure 3.9) - suggesting that they may have an origin as deeper portions of oceanic lithosphere, that were subsequently displaced to slightly greater depths. Additionally, these compositions overlap with Beni Bousera pyroxenites (Pearson et al., 1993) and

high-Mg eclogites from Koidu. For the latter, Barth et al. (2002a) suggested an origin as deeper portions of oceanic lithosphere, as gabbroic cumulates or pyroxenitic veins. Pyroxenitic veins in the deeper oceanic lithosphere have also been suggested as protoliths for eclogitic diamond inclusions at Jericho (Smart et al., 2012).

An origin as melts emplaced in the deeper portions of the oceanic lithosphere, however, does not account for the unradiogenic Os isotopic composition in pyroxenite - unless the melt had interacted / equilibrated with a depleted component (e.g., peridotitic wall rock), as discussed in the next section.

### **Origin as reaction products between melt and peridotite**

Formation of pyroxenite and Mg/Si-rich eclogites by mixing/reaction between peridotite and siliceous melts has been proposed by various authors since the 1970's (e.g., Ringwood, 1974; Sekine and Wyllie, 1982; Kelemen, 1986) and supported by the experimental studies of Yaxley and Green (1998), Rapp et al. (1999) and Mallik and Dasgupta (2012). Siliceous melts generated from eclogite will react with surrounding peridotite and therefore cannot percolate upwards (Yaxley and Green, 1998, and references therein). This reaction is at the expense of olivine.

This mode of origin has been proposed for several eclogite/pyroxenite massifs and xenolith localities. For example, formation of websterites in the Ronda massif has been related to melt-rock reactions, whereby upwelling asthenospheric melts infiltrate the lithosphere and react with peridotite (Garrido and Bodinier, 1999). Formation of the LREE-enriched pyroxenites in the Cabo Ortegal massif (Santos et al., 2002) has been linked to the introduction of melts from a subducting slab. The involvement of slab melts was also suggested for the genesis of websteritic inclusions in Venetia diamonds (Aulbach et al., 2002) and the petrogenesis of high-Mg eclogites and pyroxenites in Yakutia (Taylor et al., 2003). Origin of the high-Mg eclogites at Jericho has been attributed to similar processes involving partial melting of low-Mg eclogites and the surrounding peridotite which facilitates elemental exchange and equilibration between the two rock types (Smart et al., 2009).

There are several compositional characteristics of the high-Mg eclogites and

pyroxenites that are consistent with this origin:

- The LREE enrichment in the high-Mg eclogites and pyroxenites is consistent with the involvement of a low degree partial melt in their genesis. This is similar to the suggested formation mode for LREE-enriched spinel pyroxenites as crystal cumulates of mafic magmas within the lithospheric mantle. These are not necessarily cumulates by gravitational settling, but by crystal plating onto the side of a flowing magma conduit (e.g., Frey, 1980; Vaselli et al., 1995; Witt-Eickschen and Kramm, 1998; Dobosi et al., 1998). This scenario is consistent with low-degree melts from a subducting slab infiltrating the overlying peridotitic mantle wedge, with the crystals plating onto the side of the conduit forming hybridised reaction products between melt and wall rock.

- Reconstructed whole rock compositions of the high-Mg eclogites and pyroxenites are intermediate between eclogite-derived melts and an average fertile peridotitic composition (pyrolite) (Figure 3.9), suggesting that they may be the result of mixing between these two end-members. In addition, their compositions are broadly similar to experimentally produced mixtures of partial melts of MORB-eclogite and fertile peridotite at 3 GPa (Mallik and Dasgupta, 2012) and 3.5 GPa (Yaxley and Green, 1998).

- Higher Cr contents in garnet from the high-Mg eclogites and pyroxenites than in the low-Mg eclogites indicate equilibration with surrounding peridotite (Figure 3.3). Chromium is present in higher concentrations in peridotites than pyroxenites and eclogites (e.g., Gurney and Switzer, 1973; Pearson et al., 2003). High Cr/Al in peridotites is attributed to a protolith that experienced melt depletion in the spinel stability field (Bulatov et al., 1991; Trønnes et al., 1992; Canil and Wei, 1992; Stachel et al., 1998). Therefore reaction of depleted peridotite with a melt can explain the elevated Cr contents in garnet from the high-Mg eclogites and pyroxenites compared to low-Mg eclogites.

- The Osmium isotopic compositions of the high-Mg eclogites and pyroxenites range from unradiogenic ( $\gamma_{Os} = -10$ ) to radiogenic (Figure 3.7). The unradiogenic  $^{187}Os/^{188}Os$  requires the involvement of a depleted component during formation. During melting Re is moderately compatible and Os is incompatible, in time leading to highly radiogenic  $^{187}Os/^{188}Os$  in the former melt (e.g.,

MORB) and unradiogenic  $^{187}\text{Os}/^{188}\text{Os}$  in the depleted residue. Therefore, the most likely scenario for mixing between radiogenic and unradiogenic components involves melts from oceanic crust and depleted SCLM.

Experimental reaction products between eclogite-derived melts with intermediate compositions and peridotite are similar to those of the Victor eclogites. Layered run 9117 of Yaxley and Green (1998) sandwiched equal proportions of coesite-eclogite and pyrolite as starting materials. The reaction products at 1300 °C and 3.5 GPa were in four distinct zones, with the mineral compositions in each analogous to the compositions of certain Victor samples: Zone 1.) The products of the former coesite eclogite layer are almandine-rich garnet, omphacite and a dacitic melt. The mineral compositions of garnet and omphacite in this layer overlap with the Victor low-Mg eclogites (garnet with 12 wt% MgO, 17 wt% FeO and 6.6 wt% CaO; omphacite with 3.8 wt% Na<sub>2</sub>O and 9 wt% MgO). Zone 2.) Layer of biminerally eclogite. Garnet with 19.9 wt% MgO and 0.4 wt% Cr<sub>2</sub>O<sub>3</sub>, indicating increasing equilibration with peridotite. Clinopyroxene is diopsidic with 1.3 wt% Na<sub>2</sub>O and 19.1 wt% MgO. These mineral compositions are similar to those of the high-Mg eclogites and pyroxenites. Zone 3.) Layer with a high proportion of orthopyroxene and minor olivine, clinopyroxene and garnet. This layer could be the equivalent to the orthopyroxene-bearing pyroxenites, although orthopyroxene is not a major phase in Victor samples. Zone 4.) Layer of enriched former pyrolite (garnet lherzolite). Garnet has 20 wt% MgO and 1.3 wt% Cr<sub>2</sub>O<sub>3</sub> and the diopside has 1.2 wt% Na<sub>2</sub>O and 19.2 wt% MgO.

The similarity of these experimental products to our samples is strong support for a model whereby the low-Mg eclogites are residues after partial melt extraction from former MORB, and the high-Mg eclogites and pyroxenites are reaction products between such melts and peridotitic wall rock.

## Summary

The high-Mg eclogites and pyroxenites have compositional characteristics that require a distinct origin to the low-Mg eclogites. Their bulk compositions, LREE<sub>N</sub>-enriched trace element patterns and in particular, occurrence of unradiogenic  $^{187}\text{Os}/^{188}\text{Os}$  (less than the  $^{187}\text{Os}/^{188}\text{Os}$  of O-chondrites = 0.1283; Walker et al., 2002), is consistent with formation by reaction of broadly

siliceous melts (generated from the melting of low-Mg eclogites) with depleted peridotite.

### 3.4.4 Relative age constraints

The timing of eclogite and pyroxenite formation could not be constrained, as the Re-Os isotopic compositions of the eclogites and pyroxenites do not have any coherent isochron or model age relationships. The radiogenic  $^{187}\text{Os}/^{188}\text{Os}$  of the majority of the samples - similar to Archaean komatiites and basalts (Figure 3.7) - do, however, require long term isolation of a high Re/Os component from the convecting mantle after melt extraction. Therefore a Neoproterozoic age for the formation of these eclogites is likely, consistent with  $\sim 2.8\text{-}2.6$  Ga U-Pb crystallisation ages for lower crustal granulite xenoliths from Attawapiskat (Moser et al., 1997), which may be the lower grade metamorphic equivalent to the eclogites discussed here.

### 3.4.5 Implications for Superior craton assembly

Models for the formation of cratonic roots include: 1.) subcretion of mantle plumes (e.g., Wyman and Kerrich, 2002; Griffin et al., 2003), 2.) stacking of oceanic lithosphere (Helmstaedt and Schulze, 1989; Helmstaedt and Gurney, 1995) with possible additional fluid-fluxed melting of residual peridotite in the mantle wedge to produce highly depleted dunitic residues (e.g., Hirschmann et al., 1999; Bernstein et al., 2006; Pearson and Wittig, 2008), 3.) melting at the base of oceanic plateaus to form TTG's with delamination of the high density resititic eclogite (Bédard, 2006) and 4.) diapiric ascent of foundered shallow melting residues (Herzberg and Rudnick, 2012).

The low-Mg eclogites have been shown in this paper to require low pressure protoliths, which is consistent with emplacement into the SCLM by subduction, as is now the preferred model for Superior craton formation (see references above). This precludes the viability of plume models for craton assembly. The three remaining models all predict shallow basaltic precursors for mantle eclogites. Consistent with a low pressure origin, the high  $\delta^{18}\text{O}$  values in the low-Mg eclogites require an origin as seafloor-altered oceanic crust.

A subduction origin of the eclogites studied here is consistent with numer-

ous terranes in the western Superior which have submarine basalt sequences (i.e. ocean floor) (e.g., Hollings et al., 1999; Rogers, 2002) and magmatic arc assemblages (i.e. melting in the mantle-wedge above a subducting slab) (e.g., Corfu and Stone, 1998). Various field-based studies have reported terrane accretion by successive subduction of the west-east orientated terranes in the western Superior Province (e.g., Corfu and Stott, 1986; Stott and Corfu, 1988; Corkery et al., 2000; Skulski et al., 2000). This is supported by seismic profiles in the Abitibi-Grenville (Calvert et al., 1995) and western Superior (White et al., 2003) that have dipping structures interpreted to represent Neoproterozoic subduction zones. These are seen to depths of at least 30 km, corresponding to a pressure of 1 GPa, the minimum for eclogite stability (e.g., Green and Ringwood, 1972).

### 3.5 Conclusions

Eclogites and pyroxenites sampled by the Victor kimberlite have large compositional variability. Distinct origins are required for low-Mg eclogites and high-Mg eclogites (and pyroxenites). The low-Mg eclogites have oceanic crust precursors that were emplaced into the SCLM by subduction and are residues after extraction of a broadly siliceous melt (TTG?). The high-Mg eclogites and pyroxenites are shown to likely result from interaction between a siliceous melt and surrounding peridotite.

These two processes, i.e., partial melting leaving low-Mg eclogitic residues and subsequent reaction of these melts with peridotite to form high-Mg eclogites and pyroxenites, may be temporally related. We consider two plausible scenarios:

Scenario 1 involves the melting of meta-basalt (former oceanic crust) in a downgoing subducting slab. Slab melting is possible due to higher heat flow in the Archaean (e.g., Sleep and Windley, 1982; Martin, 1986). Melt extraction leaves the low-Mg eclogites as residues. The broadly tonalitic melt reacts with the overlying peridotitic mantle to form eclogites with elevated Mg# and orthopyroxene-bearing layers.

Scenario 2 involves the emplacement of undepleted low-Mg eclogites into the

SCLM by subduction, without significant slab-melting. A later heating event (perhaps upwelling of asthenospheric mantle, e.g., during the Midcontinent Rift at 1.1 Ga (Paces and Miller, 1993)) causes the eclogites to melt, due to the lower hydrous solidus of eclogite compared to peridotite (Yasuda et al., 1994). This eclogite-derived melt, which is broadly tonalitic to granodioritic in composition, then reacts with the surrounding peridotite to form Mg- and Cr-rich eclogite as well as orthopyroxene-bearing layers, similar to experimental products in Yaxley and Green (1998).

Figure 3.1: Representative samples in thin section (plane-polarised light). a.) Bimineralic low-Mg eclogite with omphacite and garnet. b.) Pyroxenite with diopside, garnet and enstatite.

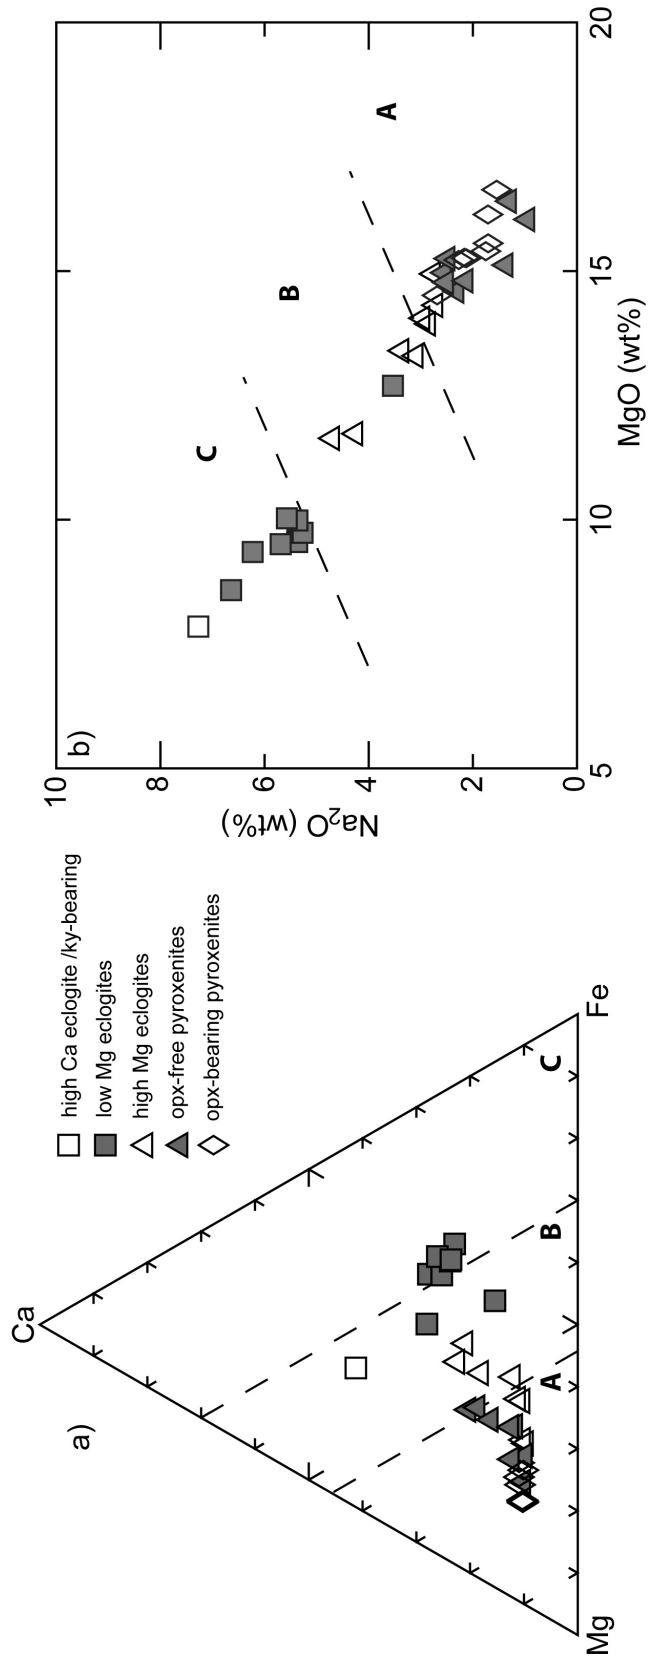

Figure 3.2: a.) Ca-Mg-Fe compositions of garnet in eclogite and pyroxenite xenoliths. b.) Clinopyroxene compositions. Both figures show the A-B-C eclogite classification scheme of Coleman et al. (1965). Garnet and clinopyroxene may lead to different classifications; for example, the high-Ca eclogite falls in the group B field according to garnet compositions and in group C according to clinopyroxene.

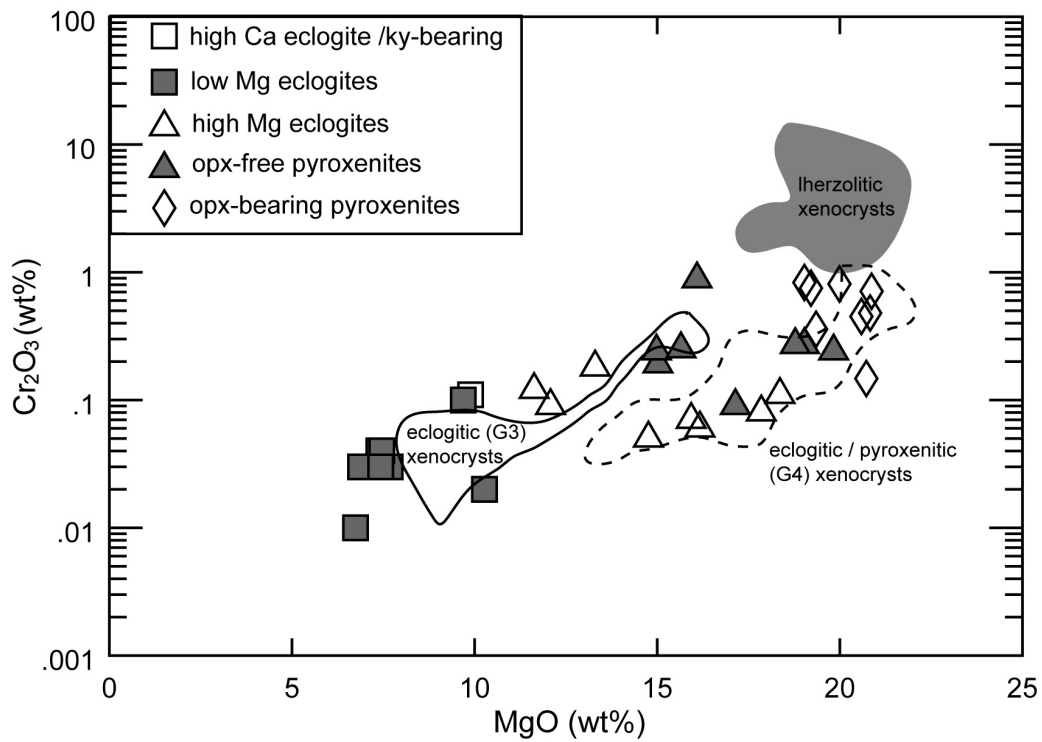

Figure 3.3: Garnet MgO and  $\text{Cr}_2\text{O}_3$  in eclogite and pyroxenite xenoliths compared to xenocryst compositions from Victor (Chapter 5). G3 / G4 classification for eclogitic and pyroxenitic xenocrysts after Grütter et al. (2004). Garnet from pyroxenitic xenoliths and xenocrysts have similar MgO but lower  $\text{Cr}_2\text{O}_3$  content compared to Victor lherzolitic xenocrysts.

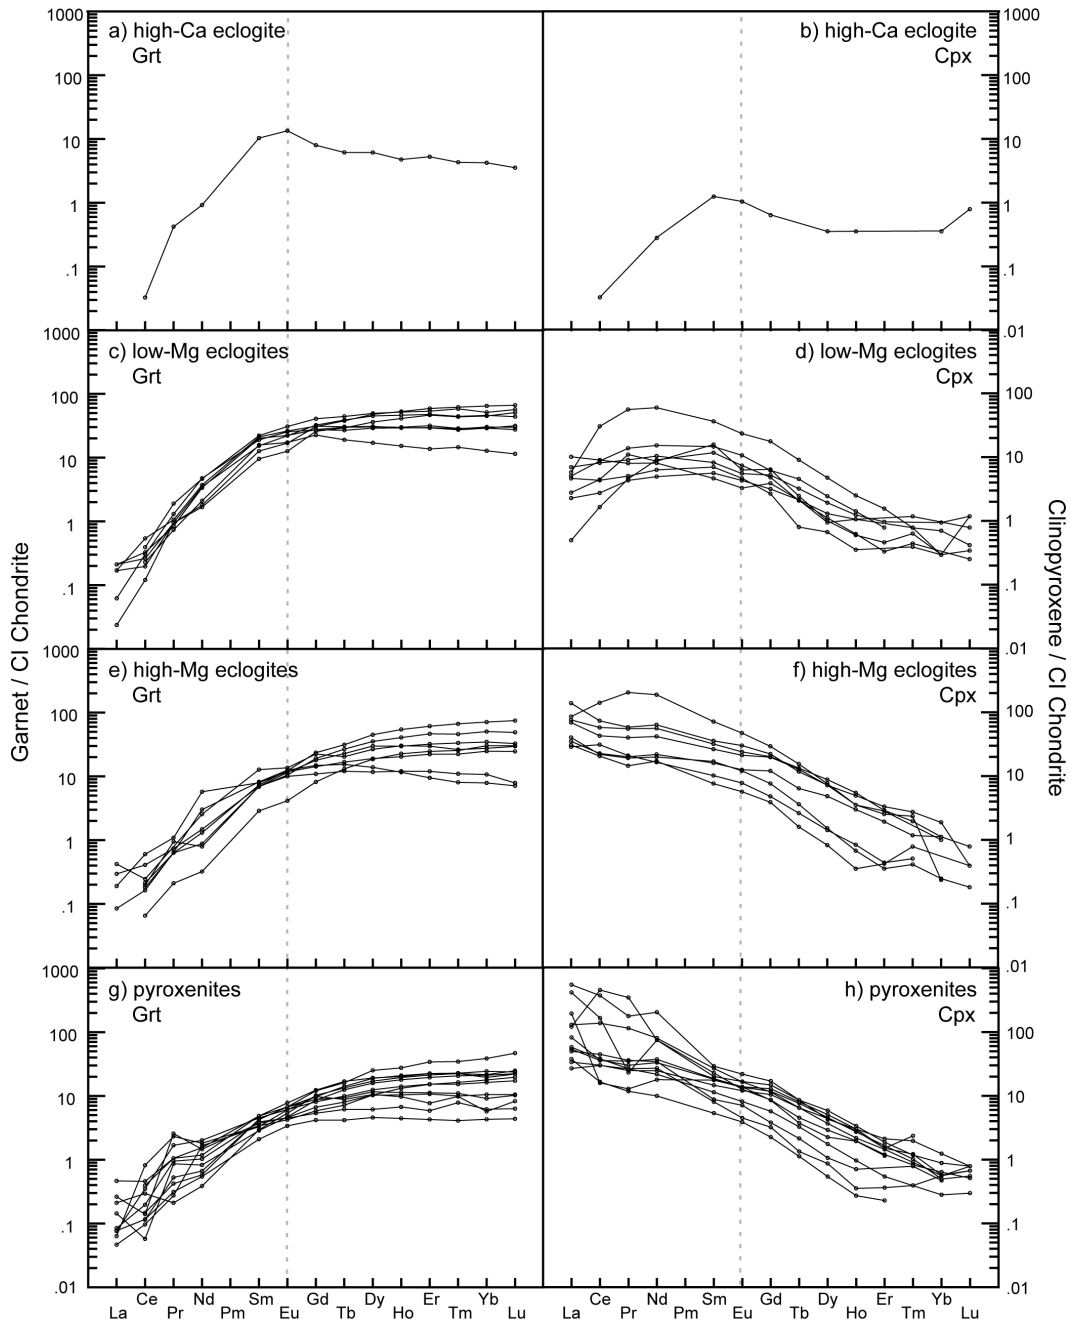

Figure 3.4: Garnet and clinopyroxene REE compositions, for the different compositional groups, normalised to CI chondrite (Sun and McDonough, 1989).

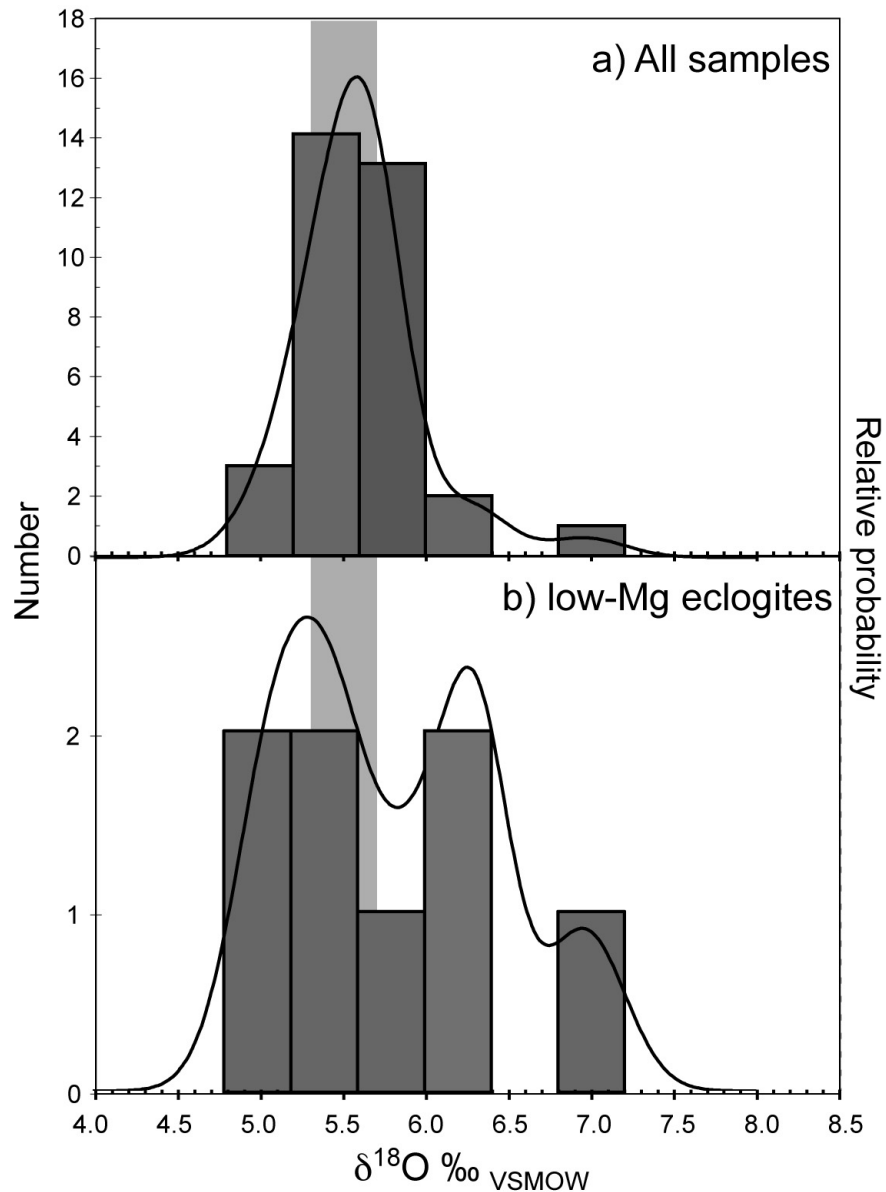

Figure 3.5: a) Oxygen isotope data for all samples in the study, showing a normal distribution around the mantle average (grey field;  $\delta^{18}\text{O} = 5.5 \pm 0.2 \text{‰}$ ; Matthey et al., 1994). b) low-Mg eclogites with 3 samples that have values higher than pristine mantle. Bin sizes for the histograms are  $0.4 \text{‰}$ , equivalent to the average error on the analyses. The probability distributions were plotted in Isoplot (Ludwig, 1991).

Figure 3.6: Rhenium and Os concentrations of the samples in this study compared to MORB (Gannoun et al., 2007) and worldwide mantle xenoliths (Pearson et al., 1995a,b; Graham et al., 1999; Barth et al., 2002b; Irvine et al., 2003; Menzies et al., 2003; Westerlund, 2005; Aulbach et al., 2009; Luguet et al., 2009; Wittig et al., 2010). "Common Os" - the Os concentration after in-grown  $^{187}\text{Os}$  is subtracted - is plotted for eclogites and MORB. The low-Mg eclogites have lower Re contents than MORB (at the same Os concentration), in agreement with the interpretation that they are residues of melting of subducted oceanic crust. In such a scenario, Re would have been lost (along with the other incompatible elements) during dehydration and partial melting of the subducting slab (e.g., Becker, 2000; Dale et al., 2007).

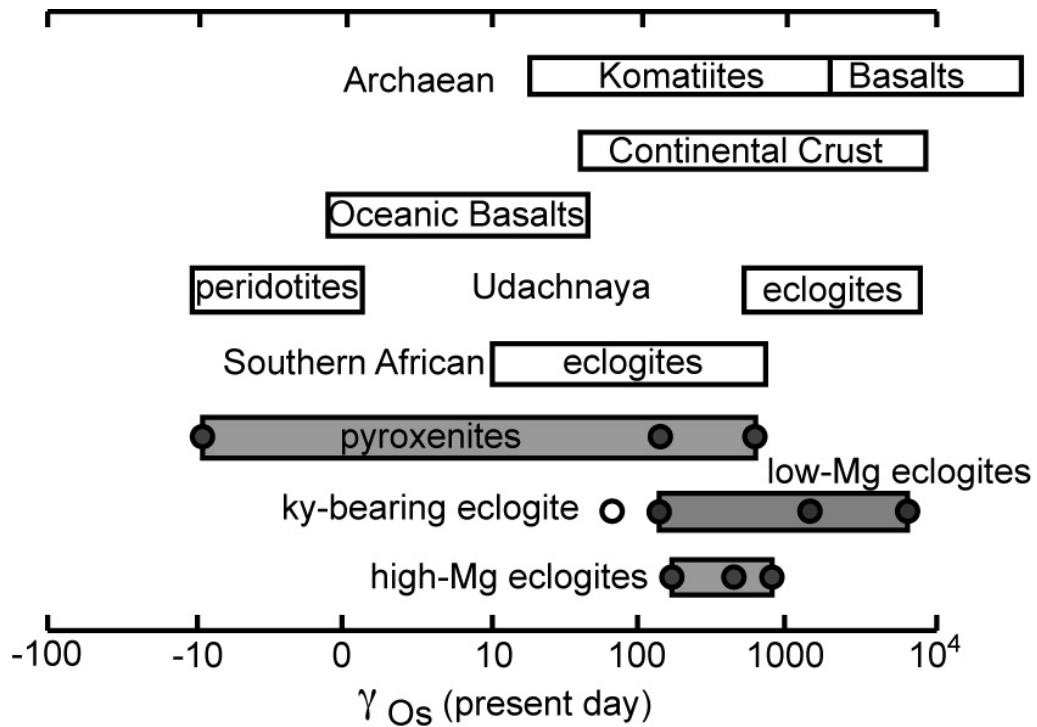

Figure 3.7: Comparison of present day  $\gamma_{O_s}$  for Victor eclogites and pyroxenites (shaded) with other eclogite suites and a variety of mafic magmas.  $\gamma_{O_s}$  was calculated as the percentage deviation from O-chondrite (Walker et al., 2002). Literature data from Pearson et al. (2003, and references therein).

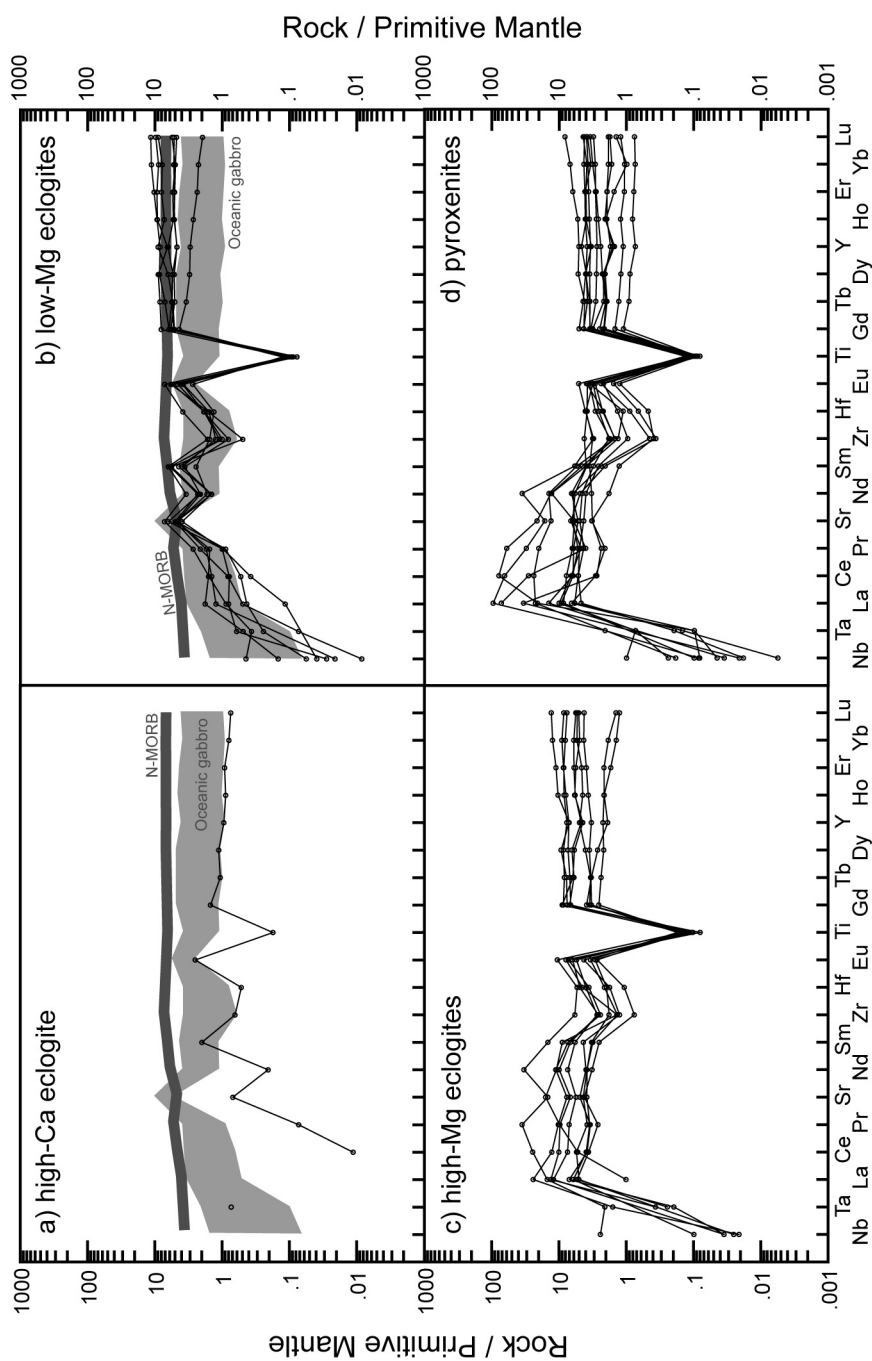

Figure 3.8: a) and b) Reconstructed whole rock extended trace element compositions of the Victor high-Ca and low-Mg eclogites, compared to oceanic gabbro (Bach et al., 2001) and N-MORB (Sun and McDonough, 1989). c) and d) Reconstructed whole rock extended trace element compositions of the Victor high-Mg eclogites and pyroxenites. Whole rock compositions were reconstructed using modes of 50% garnet and 50% clinopyroxene. Normalised to primitive mantle (Sun and McDonough, 1989).

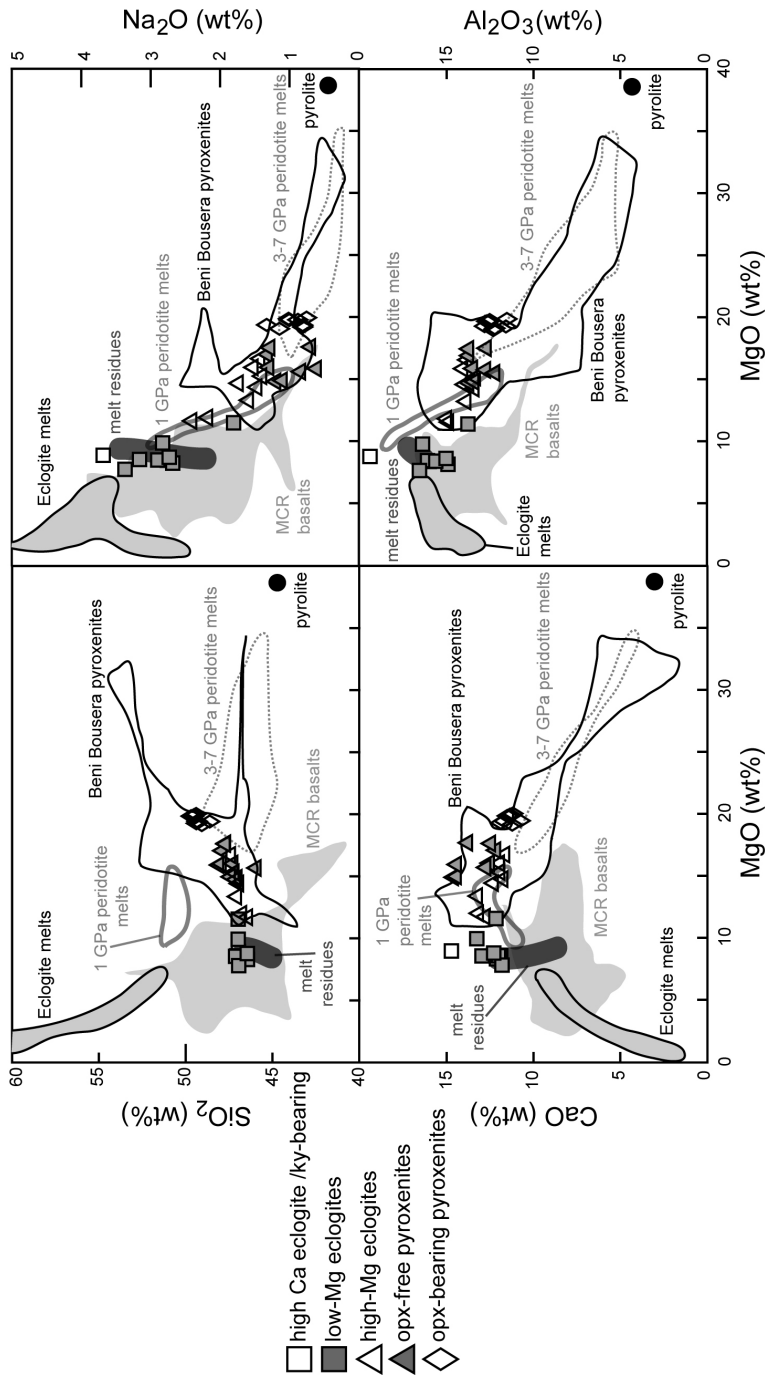

Figure 3.9: Reconstructed xenolith whole rock compositions compared to experimental mantle melts, massif pyroxenites (Beni Bousera; Pearson et al., 1993) and Midcontinent Rift basalts (Shirey et al., 1994). Eclogite-derived melts from Rapp and Watson (1995) and Spandler et al. (2008), 1 GPa peridotite-derived melts from Baker and Stolper (1994) and 3-7 GPa peridotite-derived melts from Walter (1998). Pyrolite (MPY90) from Green et al. (1979). The composition of the low-Mg eclogites overlaps with residues of melting of metabasalt at 3.2 GPa from Rapp and Watson (1995). The high-Mg eclogites and pyroxenites have compositions intermediate between eclogite-derived melts and pyrolite - supporting the interpretation that they may be reaction products between these two end-members. See text for discussion.

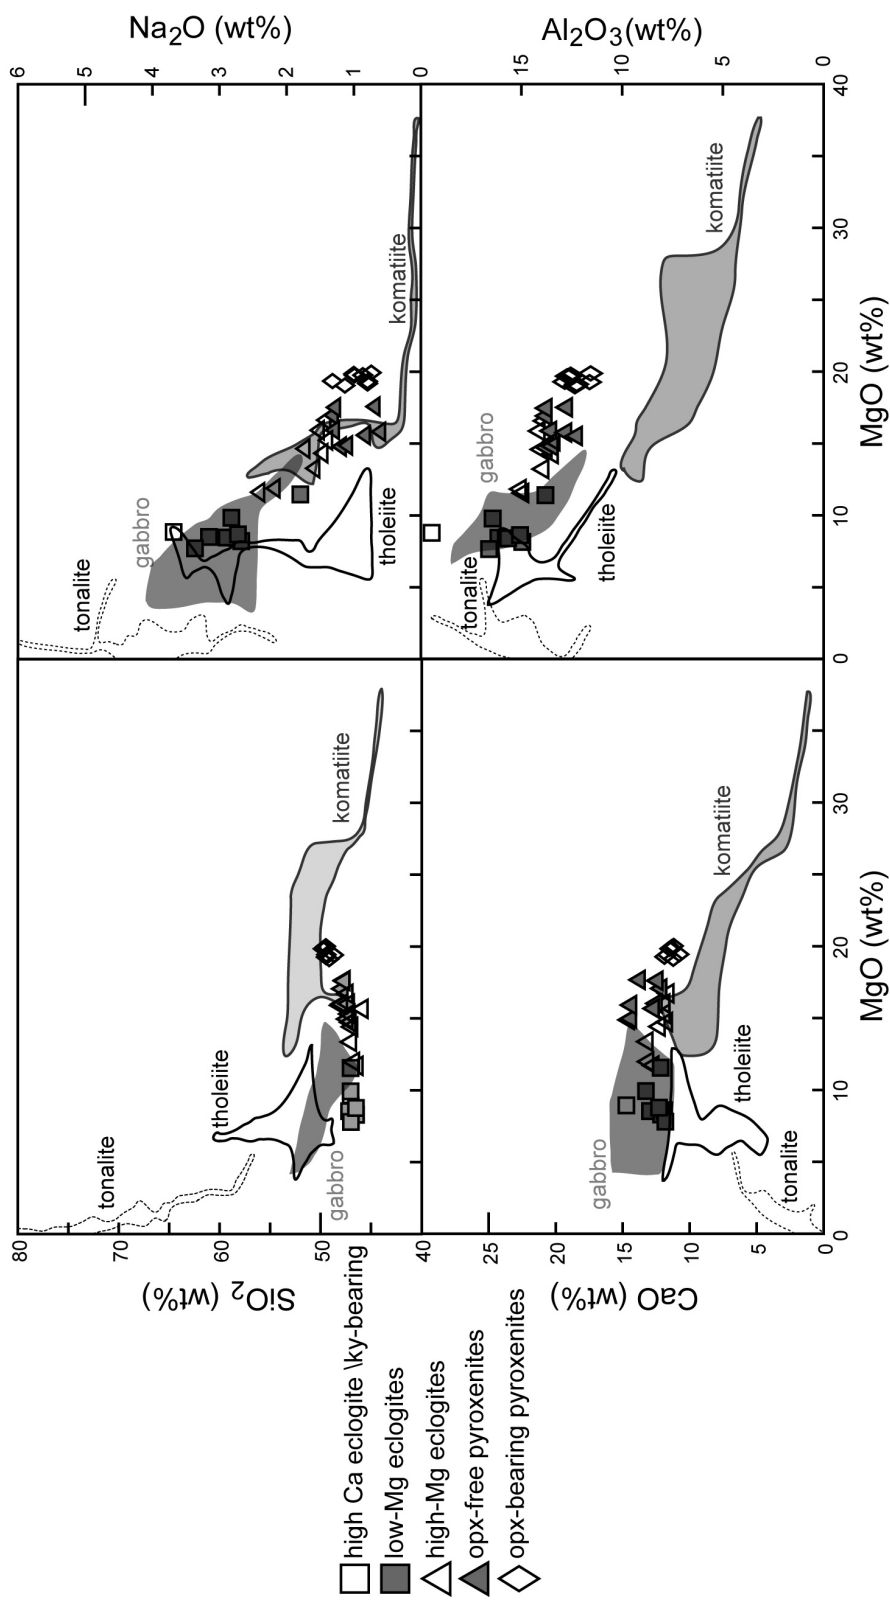

Figure 3.10: Reconstructed xenolith whole rock compositions compared to various rock types in greenstone belts from the Superior craton and oceanic crust gabbro (Bach et al., 2001). Tonalite compositions are from the Birch-Uchi and North Caribou greenstone belts (Rogers, 2002; Wyman et al., 2011). Tholeiite and komatiite compositions are from the Lumby Lake, Red Lake, Rice Lake and North Caribou greenstone belts (Hollings et al., 1999).

Figure 3.11: a) Complementary REE compositions of low-Mg eclogite and tonalite (North Caribou greenstone belt; Wyman et al., 2011). b) Batch melting calculations for average basalt (bold line) (Lumby Lake, Red Lake, Rice Lake and North Caribou greenstone belts; Hollings et al., 1999). Solid lines are residual compositions for 1-50% partial melting, with the dashed lines indicating the co-existing melt compositions. Partition coefficients from Barth et al. (2002c). The compositions of Victor low-Mg eclogite xenoliths and tonalites from the North Caribou greenstone belt can be reproduced with  $\sim 30\%$  melting.

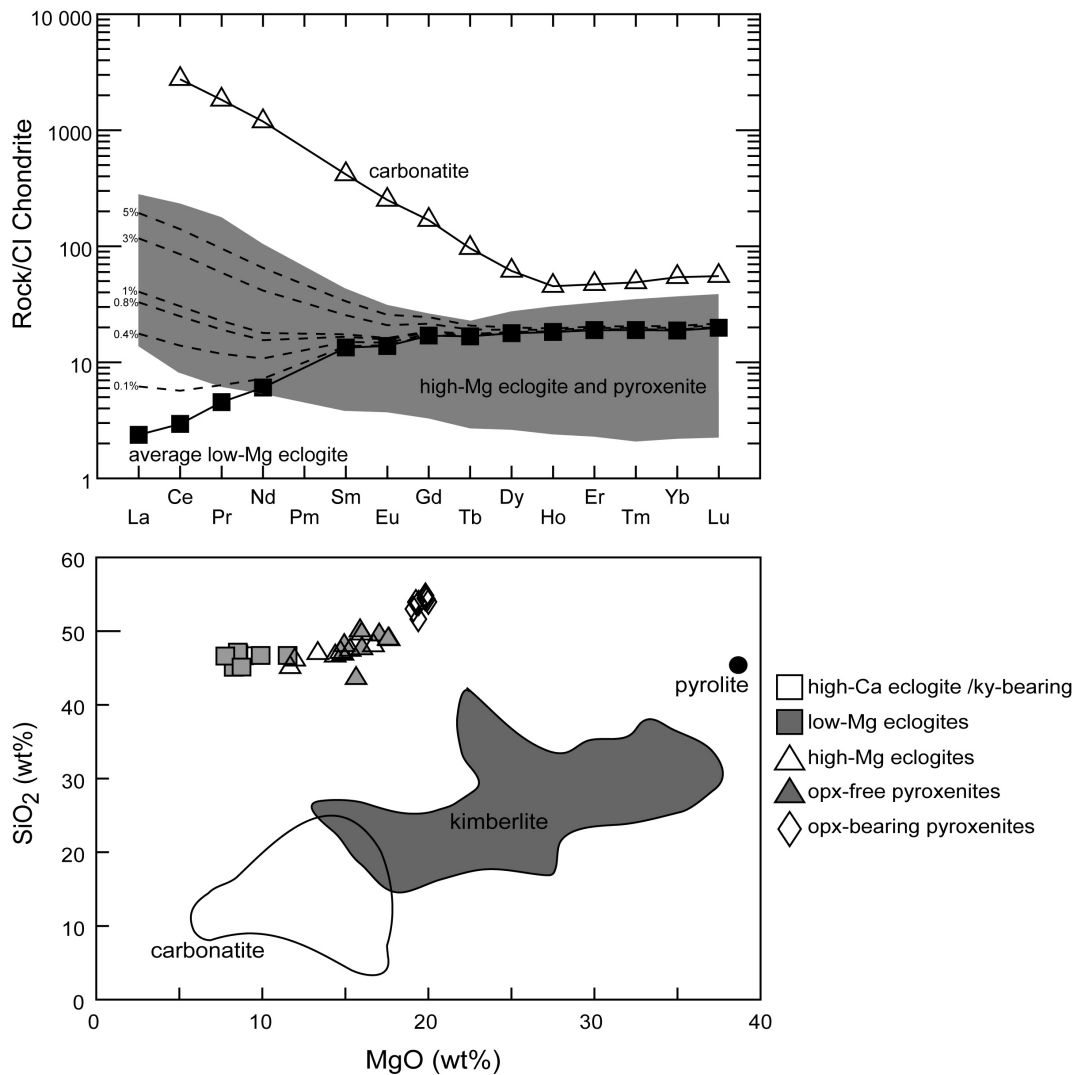

Figure 3.12: a) The REE compositions of the high-Mg eclogites can be reproduced by adding a low volume melt, e.g., 5% average carbonatite from Tappe et al. (2006), to the low-Mg eclogites. Dashed lines indicate mixing of low-Mg eclogite with 0.1%, 0.4%, 0.8%, 1%, 3% and 5% carbonatite. b) Addition of kimberlite or carbonatite would not provide sufficient enrichment in SiO<sub>2</sub> to account for the major element compositions of the high-Mg eclogites and pyroxenites. Carbonatite compositions from Wallace and Green (1988); Tappe et al. (2006); kimberlite compositions from Kaminsky et al. (2002); le Roex et al. (2003); Birkett et al. (2004); Nielsen et al. (2009); Patterson et al. (2009); pyrolite composition (MPY90) from Green et al. (1979).

## Chapter 4

# Multiple generations of diamond in the Attawapiskat area

### 4.1 Introduction

The Attawapiskat diamondiferous kimberlites on the Superior craton, Canada, provide an opportunity to study the association of a primary diamond deposit with a post-Archaean rift system. The southern margin of the Superior craton was affected by the Midcontinent Rift at  $\sim 1.1$  Ga (e.g. White, 1972; van Schmus and Hinze, 1985) and kimberlites that erupted syn- and post- rift sample distinctive lithosphere compositions.

The Kyle Lake kimberlites, which are coeval with the Midcontinent Rift, sample predominantly harzburgitic lithosphere with an elevated geothermal gradient and a resulting small diamond window (Sage, 2000; Grütter, 2009). The nearby kimberlites at Attawapiskat, including Victor - the first diamond mine on the Superior craton - were emplaced during the Jurassic, subsequent to the Rift. These kimberlites sample a lithosphere with a cooler geotherm and a larger diamond window. Garnet xenocrysts at Victor have refertilised lherzolitic compositions - perhaps related in origin to the Midcontinent Rift - depleted domains are, however, still preserved (Sage, 2000, and Chapter 5 of this thesis).

Here we study diamonds from the T1 and U2 diamondiferous kimberlites in the Attawapiskat area, in order to gain a better understanding of the diamond growth events in the lithosphere. These kimberlites are of similar age to Kyle Lake and Victor, respectively, and will allow us to investigate the timing of

diamond formation relative to the Midcontinent Rift. Through comparison of nitrogen aggregation characteristics and carbon isotopic compositions in T1 and U2 diamonds, we aim to answer the following questions: Are the diamonds sampled by post-rift kimberlites (e.g., Victor / U2) an older generation of harzburgitic / lherzolitic diamonds which survived any melt metasomatic impact of the Midcontinent Rift? Or are they a younger generation (<1.1 Ga) of lherzolitic or eclogitic / pyroxenitic diamonds?

## 4.2 Analytical Techniques

### 4.2.1 Nitrogen concentration and aggregation state by FTIR

One hundred microdiamonds each from the T1 and the U2 kimberlite were analysed. All 100 diamonds from T1 were in the size range 0.425 to 0.600 mm; 49 diamonds from U2 ranged between 0.425 and 0.600 mm, with 51 diamonds between 0.600 and 0.850 mm. Diamonds were mounted along the side of a glass slide with double-sided tape. Absorption spectra were measured with a Thermo-Nicolet Nexus 470 Fourier Transform Infrared (FTIR) spectrometer coupled with a Nicolet Continuum infrared microscope and attached to a KBr beam splitter and a MCT detector that was cooled with liquid nitrogen.

The sample stage was purged continuously with dry nitrogen-oxygen. All spectra were recorded for 200 seconds over the mid-infrared range (650 to 4000  $\text{cm}^{-1}$ ), with resolution set at 4  $\text{cm}^{-1}$  and a square aperture of 50  $\mu\text{m}$ . Background spectra were recorded repeatedly (every 2 hours) during the analytical session and subtracted from the diamond spectra to correct for non-sample contributions. The OMNIC software was used for baseline correction and the subtraction and normalisation to a pure Type II diamond spectrum. The Type II diamond spectrum was normalised to 11.94  $\text{cm}^{-1}$  at 1995  $\text{cm}^{-1}$  prior to subtraction from sample spectra. After sample spectra were baselined, the peak area tool in the OMNIC software was used to measure the intensities of the platelet peak (1350 to 1380  $\text{cm}^{-1}$ ) and a hydrogen-related peak at 3107  $\text{cm}^{-1}$ .

Spectral decomposition to quantify nitrogen content and aggregation state

was done on a spreadsheet provided by David Fisher of the DTC Research Centre in Maidenhead, UK. Nitrogen concentration is calculated from absorption co-efficients at  $1282\text{ cm}^{-1}$ :  $[N_A] = 16.5 \times \mu\text{A}$  (Boyd et al., 1994) and  $[N_B] = 79.4 \times \mu\text{B}$  (Boyd et al., 1995). Typically, two analyses per diamond were performed. As the nitrogen characteristics of these two analyses may be significantly different due to the heterogeneous nature of diamond, they were not averaged.

### 4.2.2 Carbon isotopes and nitrogen content by SIMS

A subset of diamonds from the T1 and U2 kimberlites (44 diamonds from T1 / 46 diamonds from U2) were sectioned for cathodoluminescence (CL) imaging of growth zones and multi-collector secondary ion mass spectrometry (MC-SIMS) analyses of  $\delta^{13}\text{C}$  and N content. Whole diamonds were mounted in epoxy, at random orientations, and polished with a series of diamond-embedded metal plates. The final polish used a plate with  $3\ \mu\text{m}$  embedded diamonds. The epoxy mounts were coated with 5 nm of gold for backscatter electron (BSE) and CL imaging, using a Zeiss EVO 15 Scanning Electron Microscope (SEM) equipped with a CL detector from ETP Semra, Pty. Ltd. Epoxy mounts were subsequently embedded in indium along with two reference materials - synthetic carbon (S00233a) and synthetic diamond (S0011Bd and S0011Cd) - and coated with 25 nm gold, prior to SIMS analyses.

#### Carbon isotopic ratios

$^{13}\text{C}/^{12}\text{C}$  ratios were measured using a Cameca IMS1280 ion microprobe. A  $^{133}\text{Cs}^+$  primary ion beam with  $\sim 3.5$  to  $4.0\ \text{nA}$  current was used for carbon isotopic analyses, with a mass resolution of 2950, sufficient to remove any hydride interferences. Samples were pre-sputtered for 30 seconds to remove surface contaminants and for automated tuning of the secondary ion beam. Carbon isotopes were measured with a  $10\ \mu\text{m}$  raster, with collection of secondary  $\text{C}^-$  ions on dual Faraday cups, and counting of 15 ratios at 5 seconds per ratio.

Analyses of S0011Bd and S0011Cd diamond were performed after every three to four unknowns in order to correct for instrumental mass fractionation and for error analysis. For each analytical session a polynomial fit was applied to

the analyses of S0011Bd and S0011Cd in order to correct for instrumental mass fractionation. The reference material used in this study has  $\delta^{13}\text{C} = -22.78 \pm 0.05 \text{ ‰}$ , established through conventional bulk analysis. Uncertainties on the unknowns vary between  $\pm 0.1$  to  $\pm 0.2 \text{ ‰}$  ( $2\sigma$ ) and include in-run precision (internal error), between spot error and uncertainty related to instrumental mass fractionation and reference material composition (external error). All results are reported relative to the international Vienna Pee-Dee Belemnite standard (V-PDB).

### Nitrogen abundances

Nitrogen abundances were determined as  $^{12}\text{C}^{14}\text{N}^- / ^{12}\text{C}_2^-$  on the same analytical spots as the carbon isotope analyses, however only a subset of the spots were analysed for their nitrogen content. Spots were pre-rastered for 60 to 120 seconds to remove surficial contamination. High mass resolution (7000) was needed in order to resolve  $^{13}\text{C}_2^-$ ,  $^{12}\text{C}^{13}\text{C}^1\text{H}^-$  and  $^{12}\text{C}^{14}\text{N}^-$  interferences.  $^{12}\text{C}_2^-$  and  $^{12}\text{C}^{14}\text{N}^-$  were measured on dual Faraday cups or a Faraday cup / Electron Multiplier combination, depending on nitrogen concentration. Ten ratios were collected with a counting time of 5 seconds per ratio.

Nitrogen concentrations from the unknowns were referenced back to diamond (S0011G) for which FTIR nitrogen abundance is known. Uncertainties reported in the tables include the within-spot counting statistics and the error in the nitrogen abundance calibration. An additional error of  $\sim 10\%$  ( $2\sigma$ ) is associated with uncertainty in the FTIR-determined nitrogen abundance, and should be used when comparing data with nitrogen concentrations determined elsewhere (i.e., this error does not apply to relative differences between analytical spots).

## 4.3 Nitrogen aggregation characteristics of whole diamonds

Nitrogen is the main impurity in diamond, and its principal significance in diamond studies is the temperature-time dependence of the conversion of nitrogen from A centres (pairs of N atoms) to B centres (4 N atoms distributed around a vacancy) (Bursill and Glaisher, 1985). This conversion allows deriva-

tion of time-averaged mantle residence temperatures for given mantle residence times (Evans and Qi, 1982; Taylor et al., 1990). Any temperatures calculated from nitrogen aggregation are time-averaged temperatures and therefore may not necessarily correlate with those calculated from silicate inclusions, as ambient mantle temperatures may fluctuate over a billion year timescale.

During formation of B nitrogen aggregates, carbon atoms are expelled from the diamond lattice and form platelets (Humble, 1982; Woods, 1986). In diamond zones with low nitrogen content, platelet nucleation and growth are slow, whereas the opposite is true for higher nitrogen zones (Woods, 1986). In 'regular' diamonds the amount of nitrogen in B aggregates is strictly proportional to the platelet peak strength. However, platelet degradation may occur due to transient thermal events and/or deformation, with the result that this proportional relationship breaks down - leading to 'irregular' diamonds (Woods, 1986; Evans et al., 1995; Kiflawi and Bruley, 2000). For cuboid growth sectors the linear relationship between B aggregates and platelet peak area does not hold (Howell et al., 2012), implying that apparent platelet degradation may relate to the presence of cuboid growth sectors not necessarily recognisable from external morphology. For diamonds where no CL images are available to investigate internal growth zoning, high hydrogen content could be an indication for cuboid growth, where diamonds with  $\geq 20 \text{ cm}^{-2}$  hydrogen at  $3107 \text{ cm}^{-1}$  may have cuboid sectors (Howell et al., 2012).

### 4.3.1 T1

A high proportion (93 %) of the T1 diamonds analysed with FTIR are Type II, with no measurable nitrogen. The 7 % of diamonds that contain nitrogen, have nitrogen contents between 23 and 920 at. ppm, with a median of 50 at. ppm (average = 145 at. ppm; Table D.1). T1 diamonds are highly aggregated, with all N-bearing diamonds showing >70 % B aggregates. The majority of N-bearing diamonds from T1 show an irregular relationship between %B aggregates and platelet peak area (Figure 4.2a,b).

### 4.3.2 U2

U2 has a greater percentage (25 %) of nitrogen-bearing diamonds than T1. Nitrogen contents are also significantly higher than in T1 diamonds, varying

between 24 at. ppm and 1740 at. ppm, with a median of 266 at. ppm (average of 512 at. ppm; Table D.2). The nitrogen aggregation state in U2 diamonds varies from 0 to 100 % B. In general, the diamonds from U2 are characterised by lower aggregation states (Type IaA, with <10 % B aggregation) at higher average nitrogen contents than the diamonds from T1 (Figure 4.1). 29 % of U2 diamonds show a hydrogen peak at  $3107\text{ cm}^{-1}$ . Unlike the samples from T1, the greatest hydrogen peak area, is not found in the diamonds with the highest nitrogen content (Table D.2).

## 4.4 Carbon isotopes and nitrogen content by SIMS

### 4.4.1 T1

The 44 analysed diamonds (158 point analyses) from T1 have a narrow distribution in  $\delta^{13}\text{C}$  from -4.0 to -0.9 ‰, with a sharply defined mode at -3.4 ‰ (Figure 4.3 and Figure 4.4). Nitrogen content in the 44 diamonds (104 analyses) varies from 0.3 at. ppm to 121 at. ppm, with a median of 5.4 at. ppm (Table D.3). This is significantly lower than the median determined from FTIR analyses ( $\sim 50$  at. ppm).

Zoning in some T1 diamonds reveals that earlier growth is associated with less negative  $\delta^{13}\text{C}$  (-2.0 to -0.9 ‰) followed by later growth with more negative  $\delta^{13}\text{C}$  values (-4.0 to -2.5 ‰) (Figure 4.5). No systematic co-variations in  $\delta^{13}\text{C}$  and nitrogen content could be established within individual growth zones or within the individual diamonds as diamond growth is interrupted by numerous resorption surfaces.

### 4.4.2 U2

The 46 analysed diamonds (203 point analyses) from U2 have a wide variation of  $\delta^{13}\text{C}$  from -17.7 to 0.6 ‰, with a mode at -5.7 ‰ (Figure 4.3). Nitrogen content (103 analyses) ranges between 1.15 at. ppm and 1593 at. ppm, with a median of 5.4 at. ppm (Table D.4). This is lower than the median nitrogen from FTIR analyses (266 at. ppm). Overall, U2 diamonds have significantly higher nitrogen than the diamonds from T1.

The  $\delta^{13}\text{C}$  distribution for U2 diamonds is represented by 3 different popu-

lations: 1.) One diamond has lighter carbon isotopic compositions than the rest of the U2 population. The central portion of this diamond has  $\delta^{13}\text{C}$  from -15.8 to -17.7 ‰ and low nitrogen contents (105 to 220 at. ppm; n=4), surrounded by diamond growth more enriched in  $^{13}\text{C}$ , with  $\delta^{13}\text{C}$  from -6.7 to -9.4 ‰ and higher nitrogen (720 to 780 at. ppm) (Figure 4.4 and Figure 4.6f). 2.) Five diamonds have compositions that are more  $^{13}\text{C}$ -enriched than average mantle, with  $\delta^{13}\text{C} > -4$  ‰ (Figure 4.4 and CL images in Figure 4.6). 3.) The remaining diamonds from U2 have  $\delta^{13}\text{C}$  ranging from -7.8 to -4.2 ‰ with a mean of -6.0 ‰. This population has two distinct peaks - with modes of -6.7 ‰ and -5.3 ‰ - which could potentially represent sub-populations of diamonds.

Diamonds from U2 show both more negative  $\delta^{13}\text{C}$  and more positive  $\delta^{13}\text{C}$  compositions towards the rim (Figure 4.6c and 4.7). However, as with T1 diamonds, no correlation between  $\delta^{13}\text{C}$  and nitrogen content could be established for individual growth zones, or across zones with apparently uninterrupted diamond growth.

## 4.5 Discussion

### 4.5.1 Nitrogen aggregation state and relative timing of diamond formation

#### T1

For T1 diamonds, isotherms for a mantle residence time of 2.1 billion years were constructed, assuming Mesoarchean diamond formation and Mesoproterozoic kimberlite eruption (Figure 4.1). T1 diamonds experienced high temperatures during their mantle residency ( $>1200^\circ\text{C}$ ) (Figure 4.1) and also show high levels of platelet degradation (Figure 4.2). These diamonds were evaluated for possible cuboid growth sectors, for which the linear relationship between platelet peak area and B aggregation may not hold (Howell et al., 2012). The three nitrogen-bearing diamonds that underwent SIMS analyses, have no cuboid growth zones evident in their CL images. The sample with the highest nitrogen concentration in the T1 suite (average 656 at. ppm, with two analyses at 391 to 920 at. ppm, no CL image available) (Table D.1), also has the highest hydrogen contents. The two FTIR spectra for this sample exhibit hydrogen peak areas at  $3107\text{ cm}^{-1}$  of 70 and  $82\text{ cm}^{-2}$ . One of these analyses

plots along the 'regular' trend, whereas the other is 'irregular' (Figure 4.2a), suggesting this diamond may have some cuboid growth sectors and should be excluded during platelet evaluation. The remainder of the N-bearing diamonds (all irregular), have  $3107 \text{ cm}^{-1}$  peak areas  $<10 \text{ cm}^{-2}$ , which suggests absence of cuboid growth sectors. Therefore, with one exception, the irregular relationship between B centre concentration and platelet peak strength (Figure 4.2a,b) is interpreted to reflect platelet degradation during mantle residence (after Woods, 1986).

Platelet degradation typically occurs in response to thermal pulses and/or deformation events in the lithospheric mantle. Platelet degradation in T1 diamonds may relate to the Midcontinent Rift event, which affected the Superior craton around 1.1 Ga close to the time of kimberlite eruption. Elevated temperatures associated with the Midcontinent Rift are evident in the higher geotherm determined from clinopyroxene xenocrysts from the Proterozoic Kyle Lake kimberlites. This is not a perturbed geotherm and indicates that the heating event has already been conducted through the sampled SCLM (Figure 4.8). This elevated geotherm results in a narrow 'diamond window' of only about 25 km thickness, where diamonds are only stable above  $\sim 1060 \text{ }^\circ\text{C}$ . Any previously existing diamonds at depths less than 140 km must have been graphitised due to this thermal effect of the Midcontinent Rift.

## U2

For U2 diamonds, isotherms reflect possible mantle residence times of both 3.0 billion years (assuming Archaean diamond formation and kimberlite eruption at 180 Ma) and 0.9 billion years (assuming diamond formation after the Midcontinent Rift) (Figure 4.1). Calculated residence temperatures for U2 diamonds are between  $1050 \text{ }^\circ\text{C}$  and  $1300 \text{ }^\circ\text{C}$ .

The relationship between %B aggregates and platelet peak area for U2 diamonds is shown in Figure 4.2c. In this plot, diamonds that have low aggregation states ( $< 1\%$ ) were excluded, as platelet development is associated with B centre formation. The one diamond with the highest aggregation state (100 % B aggregation) was also excluded as platelets disappear over time once nitrogen aggregation is completed. The remaining diamonds were grouped according to their nitrogen aggregation and temperature.

Seven analyses plot along or above the 'regular' trend (after Woods, 1986), whereas the remaining diamonds all display an irregular relationship between %B aggregates and platelet peak area (Figure 4.2c). None of the irregular diamonds have high hydrogen contents indicative of cuboid growth zoning (Howell et al., 2012). Three analyses that plot along and above the 'regular' trend have high hydrogen contents, with 3107 cm<sup>-1</sup> hydrogen peak areas between 10.4 and 17.6 cm<sup>-2</sup>; however these values are below the cutoff for cuboid growth sectors ( $\geq 20$  cm<sup>-2</sup>) suggested by Howell et al. (2012).

A subgroup of U2 diamonds have low levels of nitrogen aggregation, with some diamonds showing 0 % B, which indicate that these diamonds resided at low mantle temperatures ( $< 1050$  °C) and/or that these diamonds had an even shorter mantle residency time than 0.9 Ga (Figure 4.1). The lack of pervasive B aggregation compared to T1 indicates that these U2 diamonds never experienced the thermal conditions that are reflected by the high time average mantle residence temperatures for T1 diamonds. Therefore U2 diamonds must have formed after T1 diamonds acquired their high nitrogen aggregation states and likely postdate the Midcontinent Rift.

IaAB diamonds (1100 - 1200 °C) from U2 are platelet degraded (Figure 4.2), indicating that a minor population of U2 diamonds may have survived the impact of the Midcontinent Rift. Five diamonds from U2 have less negative  $\delta^{13}\text{C}$  ( $> -3.7$  ‰) similar to T1 (Figures 4.3 and 4.4). Only one of these diamonds has sufficient nitrogen for FTIR analyses. While  $\delta^{13}\text{C}$  of this diamond is -2.83 to -1.95 ‰ overlapping with T1; it has much lower nitrogen aggregation around 55 %, suggesting mantle storage at lower average temperatures than the diamonds from T1 ( $>70$  % B aggregation; temperatures  $>1200$  °C). This does not exclude the possibility that the other 4 Type II diamonds from U2 with less negative  $\delta^{13}\text{C}$  compositions may be inherited from the pre-rift lithosphere (sampled at T1).

The majority of U2 diamonds are Type IaA though and have more negative  $\delta^{13}\text{C}$  compositions than T1 diamonds, indicating they are clearly younger and unrelated to T1 diamonds. Under a normal cratonic geotherm, the range in residence temperatures for U2 diamonds indicates diamond derivation from

a wide depth range, similar to that seen in xenoliths and xenocrysts from Attawapiskat (Figure 4.8).

## 4.5.2 Carbon isotopic composition and diamond paragenesis

### Background

Diamonds worldwide display a large range in  $\delta^{13}\text{C}$  ( $\sim -41$  to  $\sim +5$  ‰), with the lowest  $\delta^{13}\text{C}$  values dominated by diamonds from Jericho in the northern Slave craton (Deines, 1980; Kirkley et al., 1991; Stachel et al., 2009; de Stefano et al., 2009; Smart et al., 2011). Eclogitic paragenesis diamonds are typically associated with  $\delta^{13}\text{C}$  distributions skewed towards light values ( $\delta^{13}\text{C} < -10$  ‰), whereas peridotitic diamonds have  $\delta^{13}\text{C}$  distributions between -10 and 0 ‰. This overlaps with the pristine mantle value, which has a similar range and a mean around -5 ‰, as determined from analyses of MORB, kimberlites and carbonatites (e.g., Deines and Gold, 1973; Pineau et al., 1973; Sheppard and Dawson, 1975; Marais and Moore, 1984; Matthey et al., 1984; Exley et al., 1986; Marty and Zimmermann, 1999).

However, diamonds with  $\delta^{13}\text{C}$  that overlap with mantle derived  $\delta^{13}\text{C}$  should not be used as firm evidence for a peridotitic source parageneses, as some eclogitic diamond populations also have narrow  $\delta^{13}\text{C}$  around  $\sim -5$  ‰, without a tail to  $^{13}\text{C}$ -depleted values. For example, diamonds in Siberian eclogite xenoliths have  $\delta^{13}\text{C}$  from -7 to -1 ‰ (Sobolev et al., 1994; Snyder et al., 1995), Premier diamonds with eclogitic inclusions have  $\delta^{13}\text{C}$  with a narrow range from -6.0 to -2.5 ‰ (database of Stachel and Harris, 2008) and diamonds hosted in low-Mg eclogites from Jericho have  $\delta^{13}\text{C}$  from -6.0 to -2.7 ‰ (Smart et al., 2011).

The full range in  $\delta^{13}\text{C}$  values observed for eclogitic diamonds can be reconciled with carbon input from several sources, including unaltered MORB ( $\sim -5$  ‰) and subducted sedimentary carbon which comprise both carbonates and organic carbon. Carbonates are  $^{13}\text{C}$ -enriched relative to MORB and precipitate from reaction of  $\text{CO}_2$ -bearing seawater and basaltic crust. They have an average  $\delta^{13}\text{C}$  around 0 ‰ (e.g., Coggon et al., 2006). Organic carbon has  $^{13}\text{C}$ -depleted compositions with  $\delta^{13}\text{C} < -15$  ‰ and can be produced through

reduction of magmatic CO<sub>2</sub> by both biogenic and abiogenic processes (e.g., Blank et al., 1993; Lilley et al., 1993; Nisbet et al., 1994; McCandless and Gurney, 1997; Delacour et al., 2008; Shilobreeva et al., 2011).

Extreme isotopic signatures of organic carbon are not always retained during high pressure metamorphism and subduction (e.g., McKirdy and Powell, 1974; Hoefs and Frey, 1976). The carbon isotopic composition of carbonate and organic carbon equilibrates with increasing temperature causing homogenisation after subduction into the mantle (e.g., Deines, 2002; Satish-Kumar et al., 2002; Cartigny, 2005). Therefore, if extremely <sup>13</sup>C-depleted domains are to be preserved after subduction, they need to be essentially free of carbonate. One example is eclogite in the Monviso ophiolite (Italy) that contains reduced carbon with an average  $\delta^{13}\text{C}$  of  $-24.2 \pm 1.2$  ‰ and negligible carbonates in the overall carbon budget of the rocks (Nadeau et al., 1993).

### **T1/U2 diamond parageneses**

Less than 1 % of worldwide peridotitic diamonds have  $\delta^{13}\text{C} < -10$  ‰ (Stachel and Harris, 2008). Therefore, the <sup>13</sup>C-depleted composition for one diamond from U2 (with  $\delta^{13}\text{C}$  ranging from -18 to -7 ‰) strongly indicates an eclogitic / pyroxenitic paragenesis for this sample. The strong mode around -5.7 ‰ for the main population at U2, however, resembles  $\delta^{13}\text{C}$  distributions for peridotitic diamond productions world-wide. As some eclogite productions (see above) show mantle-like values around -5 ‰ (suggesting input from mantle carbon or unaltered homogenised basaltic oceanic crust), a clear distinction between parageneses can, however, not be made without evidence from inclusions.

The predominantly lherzolitic compositions of garnet xenocrysts at Victor (Sage, 2000, and Chapter 5 in this thesis), suggest that, if peridotitic, the U2 diamonds are likely to be lherzolitic. Some lherzolitic garnets from Victor have sinusoidal REE<sub>N</sub> patterns (Section 5.12.3), typical for both harzburgitic and lherzolitic garnet inclusions in diamonds worldwide (e.g., Stachel et al., 2004).

The restricted range in carbon isotopic compositions and a lack of light  $\delta^{13}\text{C}$  values in T1 diamonds suggest that they represent one paragenesis, likely peri-

dotitic. This is supported by xenocrystic garnets from the Kyle Lake kimberlite ( $\sim$  coeval to T1) that are both harzburgitic and lherzolitic, and lack abundant eclogitic compositions (Sage, 2000).

### 4.5.3 Diamond growth processes inferred from internal variations in $\delta^{13}\text{C}$

*T1 diamonds* have a narrow range in  $\delta^{13}\text{C}$  with a mode at  $-3.4\text{‰}$ . This is more enriched in  $^{13}\text{C}$  than average mantle ( $\sim -5\text{‰}$ ) but corresponds well to the ranges in carbon isotopic composition of other diamond localities on the Superior craton. Peridotitic diamonds from Renard in the eastern Superior have  $\delta^{13}\text{C}$  between  $-5.4$  to  $-1.2\text{‰}$  (Hunt et al., 2012b) and Wawa harzburgitic diamonds have  $\delta^{13}\text{C}$  from  $-5.5$  to  $-1.1\text{‰}$  (Stachel et al., 2006; Miller et al., 2012).

The positive skewness of the probability density plot for T1 diamonds may look compatible with closed system Rayleigh fractionation from an oxidised source, where  $\delta^{13}\text{C}$  becomes more positive with progressive diamond crystallisation (Deines, 1980) (Figure 4.4). However, diamond growth zones revealed through CL imaging, show the opposite. Early growth in the core of diamond crystals is characterised by slightly less negative  $\delta^{13}\text{C}$  ( $-2.0$  to  $-0.9\text{‰}$ ) and later growth zones have more negative  $\delta^{13}\text{C}$  ( $-4.0$  to  $-2.5\text{‰}$ ) (Figure 4.5). Additionally, no systematic co-variations in  $\delta^{13}\text{C}$  and nitrogen content were observed within individual diamonds and multiple stages of resorption and growth are evident in CL images (Figure 4.5). This suggests that T1 diamond growth did not occur in one continuous event (involving Rayleigh fractionation of a single diamond forming fluid/melt), but rather during multiple growth events (e.g., Boyd et al., 1987; Harte et al., 1999; WiggersdeVries et al., 2013; Palot et al., 2013).

*U2 diamonds* have several characteristics that suggest diamond growth occurred during multiple stages, likely from multiple melts/fluids. U2 diamonds display core to rim  $\delta^{13}\text{C}$  trends that become both less negative (Figure 4.6c; Figure 4.7a,b) and more negative (Figure 4.7c), which may suggest diamond growth from both oxidised and reduced sources (e.g. Deines, 1980). However, no systematic internal compositional co-variations were observed, and due to the presence of numerous resorption surfaces, diamond growth must not be

modelled through a single Rayleigh fractionation process.

Additionally, the diamonds in Figure 4.7a-c have different core compositions of -6.9, -7.3 and -4.9 ‰, respectively, suggesting that diamonds at U2 grew from multiple melts/fluids, with substantially different  $\delta^{13}\text{C}$  compositions. This is consistent with the overall  $\delta^{13}\text{C}$  distribution in the main population of U2 diamonds (excluding the one diamond with light  $\delta^{13}\text{C}$ ) that can be unmixed into at least three distinct populations (Figure 4.4).

#### 4.5.4 Origin of carbon isotopic compositions in T1 and U2 diamonds

##### Low $\delta^{13}\text{C}$ values at U2

One diamond from U2 has lower  $\delta^{13}\text{C}$  than the rest of the population (-17.7 to -8.1 ‰). Possible explanations for the origin of such low carbon isotopic values include open system fractionation, by  $\text{CO}_2$  escape from a carbonate melt (Cartigny et al., 2001) and subduction of oceanic crust containing  $^{13}\text{C}$  depleted material (McCandless and Gurney, 1997).

The  $\text{CO}_2$  escape model can explain  $\delta^{13}\text{C}$  values down to -14 ‰, if fractionated from a mantle source with average carbon around -5 ‰ (Cartigny et al., 2001). If the starting composition is -9 ‰ (lower range of mantle carbonatites), modelling indicates that diamonds with  $\delta^{13}\text{C}$  as low as -18 ‰ could be precipitated, but only after >99 %  $\text{CO}_2$  separation from the carbonatite fluid/melt (e.g., Smart et al., 2011). However, this single diamond's growth zones do not seem to represent one continuously fractionating melt, but rather distinct growth events (Figure 4.6f). Therefore the role of subducted sediments and oceanic crust needs to be considered in order to explain the low  $\delta^{13}\text{C}$  of  $\sim$ -18 ‰ in this diamond.

The carbon isotopic composition of average altered oceanic crust is  $\sim$ -4.7 ‰ (Shilobreeva et al., 2011) and is due to mixing between organic ( $\delta^{13}\text{C} > -27$  ‰; Javoy et al., 1986; Strauss, 1986) and carbonate components ( $\delta^{13}\text{C} \approx 0$  ‰; Javoy et al., 1986; Schidlowski and Aharon, 1992). Subducted oceanic crust with varying proportions of oceanic crust, organic matter and carbonates can, therefore, account for a wide range in  $\delta^{13}\text{C}$  values (e.g., McCandless and

Gurney, 1997; Westerlund, 2005).

### $\delta^{13}\text{C}$ values from -7.8 to 0.6 ‰ at T1 and U2

Source reservoirs for the generation of fluids/melts that could precipitate diamonds with  $\delta^{13}\text{C}$  compositions between -7.8 and 0.6 ‰ observed for T1 and U2, can be generated in three ways described below.

1.) Carbonates in the oceanic crust have an average  $\delta^{13}\text{C}$  value of 0 ‰ (Javoy et al., 1986; Schidlowski, 2001; Coggon et al., 2006). With progressive subduction (e.g., during  $\sim 2.7$  Ga amalgamation of the Superior; Langford and Morin, 1976) these carbonates would undergo devolatilisation and consequent isotopic fractionation leading to more negative  $\delta^{13}\text{C}$  compositions (Kirkley et al., 1991, and references therein).

For diamonds at U2 that are younger than the Midcontinent Rift ( $\sim 1.1$  Ga), a modified version of this subduction model is considered as there are no subduction events documented below the North Caribou superterrane after Superior craton amalgamation at  $\sim 2.7$  Ga (Langford and Morin, 1976) to directly account for fluids/melts generated from the subduction of carbonated oceanic crust. However,  $\text{CO}_2$ -rich fluids/melts from an Archaean (2.7 Ga) subducting slab would have reacted with olivine in overlying peridotite to form carbonates (e.g., Wyllie and Huang, 1976). Later thermal events (e.g., the Midcontinent Rift at 1.1 Ga) could raise the local geotherm and carbonated peridotites could melt to form  $\text{CO}_3$ -bearing melts (e.g., van Groos, 1975; Eggler, 1978; Wendlandt and Mysen, 1980; Brey et al., 2008) which then infiltrate more reduced portions of the lithosphere and precipitate diamond.

2.) A fractionated mantle carbon reservoir, that is more enriched in  $^{13}\text{C}$ , but still within the range of mantle values. For example, carbonatite melts have  $\delta^{13}\text{C}$  ranging from -9 to -1 ‰ (Deines and Gold, 1973; Pineau et al., 1973; Sheppard and Dawson, 1975). Carbonatite magmatism in the Superior lithosphere occurred at 1.8 Ga; around 1.1 Ga (related to the Midcontinent Rift) and between 570 - 550 Ma (related to break-up of Rodinia and opening of the Iapetus ocean) (Doig, 1970; Bell and Blenkinsop, 1987; Rukhlov and Bell, 2010, and references therein).

3.) CH<sub>4</sub>-bearing fluids remobilised in the lithosphere or originating from the underlying asthenosphere will have  $\delta^{13}\text{C}$  within the mantle range. Diamond formation from reduced fluids ascending along a typical cratonic P-T- $f\text{O}_2$  path was demonstrated by Huizenga et al. (2012). This process was also invoked by Thomassot et al. (2007) for  $\sim 1.9$  Ga Premier lherzolitic diamonds based on  $\delta^{13}\text{C}$ -N co-variations; and Stachel et al. (2009), who, based on  $\delta^{13}\text{C}$  frequency distributions, suggested that harzburgitic diamonds worldwide frequently precipitated during CH<sub>4</sub> oxidation.

However, a single carbon source is not considered likely for T1 and U2 diamonds, as their internal growth zoning suggests multiple growth events involving isotopically distinct melts/fluids (Section 4.5.3).

## 4.6 Summary

*T1 diamonds.* Pre-1.1 Ga diamonds sampled at T1 have a narrow range in  $\delta^{13}\text{C}$ , with a mode of -3.4 ‰, corresponding to other diamond localities on the Superior. T1 diamonds have highly aggregated nitrogen and exhibit platelet degradation, possibly due to the thermal effect of the Midcontinent Rift. The probability density curve for  $\delta^{13}\text{C}$  in T1 diamonds is skewed towards less negative values; however, this is not indicative of crystallisation from an oxidised source. CL imaging reveals that earlier core growth has higher  $\delta^{13}\text{C}$ , whereas later diamond growth towards the rims has lower  $\delta^{13}\text{C}$ .

*U2 diamonds.* A high proportion of diamonds sampled by the Jurassic U2 kimberlite - including a likely eclogitic diamond with low  $\delta^{13}\text{C}$  - are Type IaA. Their unaggregated nature - compared to the highly aggregated T1 diamonds - indicate that they formed after thermal impact of the Midcontinent Rift at 1.1 Ga. The overall  $\delta^{13}\text{C}$  distribution for U2 diamonds is distinct to T1 and other Superior diamonds, further suggesting that U2 diamonds are not related to the older pre-rift diamonds. Three distinct peaks in the U2  $\delta^{13}\text{C}$  distribution, varying  $\delta^{13}\text{C}$  in diamond cores and lack of consistent internal  $\delta^{13}\text{C}$  and nitrogen variations suggest that U2 diamonds likely crystallised from fluids/melts derived from multiple sources.

Figure 4.1: Nitrogen content plotted against the percentage of B aggregation ( $100B / [A + B]$ ) for diamonds from T1 and U2. Only 13 FTIR analyses of T1 diamonds, and 43 analyses of U2 diamonds had measurable nitrogen contents. T1 diamonds are characterised by high levels of B aggregation ( $>70\%$ ). U2 diamonds have a wide variation of aggregation states, including a high proportion of Type IaA and Type IaAB diamonds with  $<20\%$  B aggregation. Isotherms for mantle residence times of 3.0 billion years, 2.1 billion years and 0.9 billion years, were constructed after Leahy and Taylor (1997) (see Section 4.5.1 for details on mantle residence times for T1 and U2 diamonds).

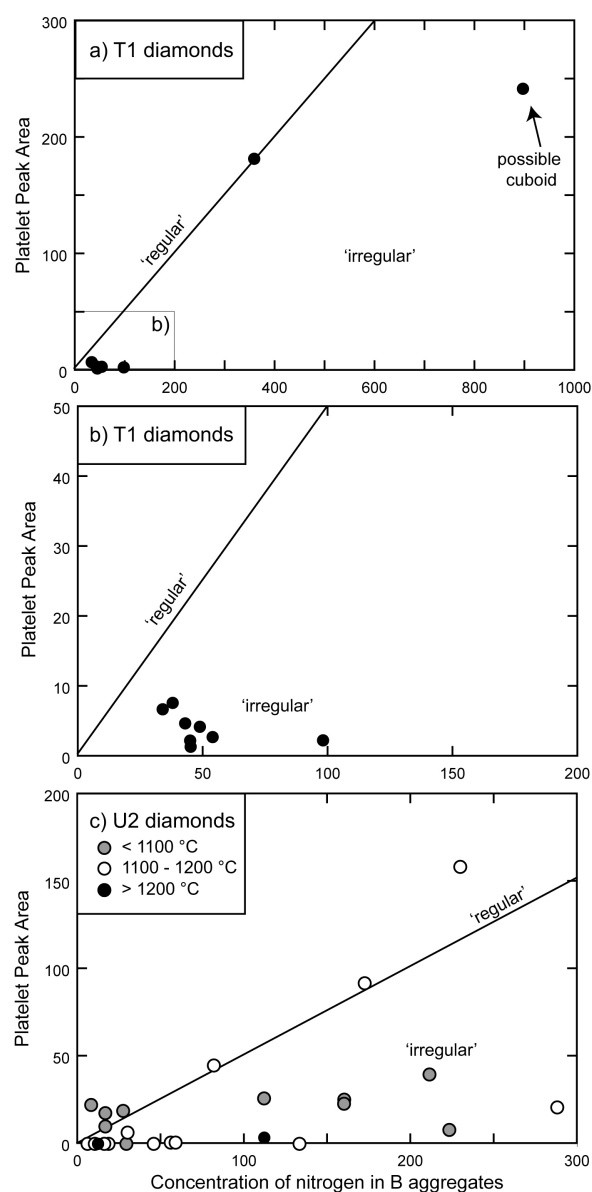

Figure 4.2: Platelet peak area vs B aggregation for Type IaAB diamonds from T1 and U2. Only diamonds with between 1 and 99 % B aggregation were plotted. Diamonds that have a proportional relationship between platelet peaks and %B aggregation fall along a 'regular' linear trend (after Woods, 1986). Platelet degradation may occur due to transient thermal events and/or deformation, with the result that this proportional relationship breaks down - leading to 'irregular' diamonds. For diamonds with cuboid growth, a linear relationship between B aggregates and platelet peak area may not exist (Howell et al., 2012).

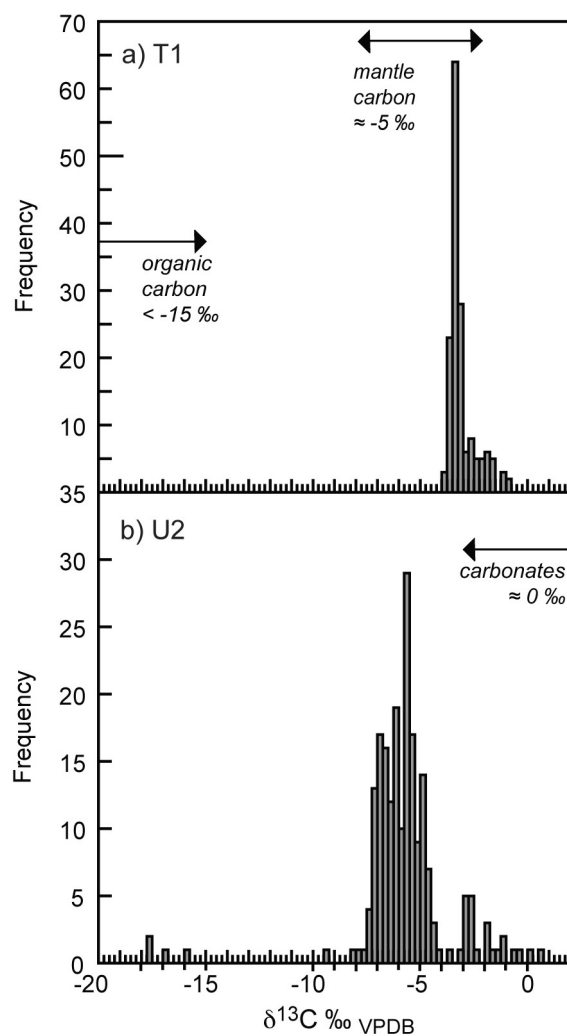

Figure 4.3: Histograms of SIMS analyses of  $\delta^{13}\text{C}$  for diamonds from T1 and U2. T1 diamonds (158 analyses, 44 diamonds) have a mode around -3.4 ‰, and 203 analyses from U2 (46 diamonds) have a mode around -5.7 ‰. Also shown are the carbon isotopic compositions of possible mantle and sedimentary carbon sources. Mantle carbon ranges from about -8 to -2 ‰, with a mean around -5 ‰; as determined from analyses of mid ocean ridge basalts, kimberlites and carbonatites. Organic carbon has < -15 ‰ and carbonates have a mean of  $\approx 0$  ‰. Refer to Section 4.5.2 for references.

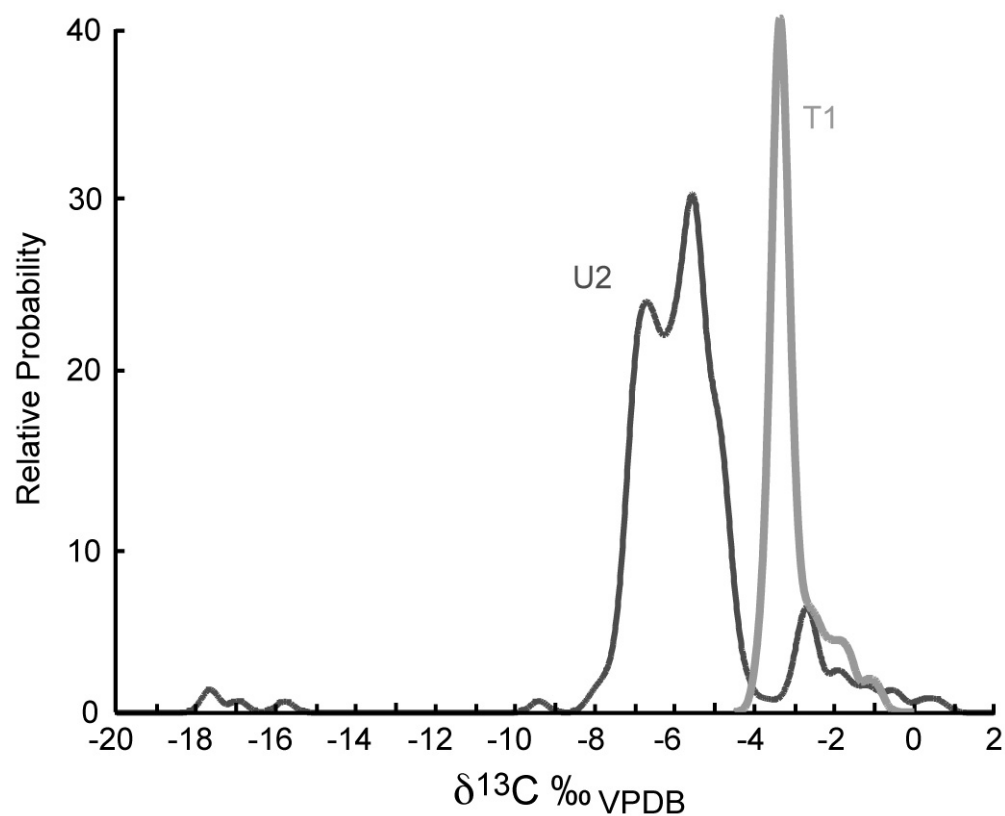

Figure 4.4: Probability density plots of  $\delta^{13}\text{C}$  for diamonds from T1 and U2. T1 diamonds have a narrow distribution that is skewed to more positive  $\delta^{13}\text{C}$ , resembling diamond growth by Rayleigh fractionation from oxidised sources (e.g., Deines, 1980). However, growth zoning in T1 diamonds suggest that early diamond growth was characterised by more positive  $\delta^{13}\text{C}$ , whereas later diamond growth had more negative  $\delta^{13}\text{C}$  (Figure 4.5). The distribution for U2 diamonds is represented by 3 to 4 different populations (see Section 4.4 for details).

Figure 4.5: Cathodoluminescence images for diamonds from T1. Spot analyses with  $\delta^{13}\text{C}$  and nitrogen content (at. ppm) are indicated. Earlier diamond growth has slightly less negative  $\delta^{13}\text{C}$  values (-2 to -0.9 ‰), followed by later overgrowths with more negative  $\delta^{13}\text{C}$  values (-4.0 to -2.5 ‰). These diamonds have multiple growth zones and resorption surfaces precluding a single diamond growth event with continuous Rayleigh fractionation.

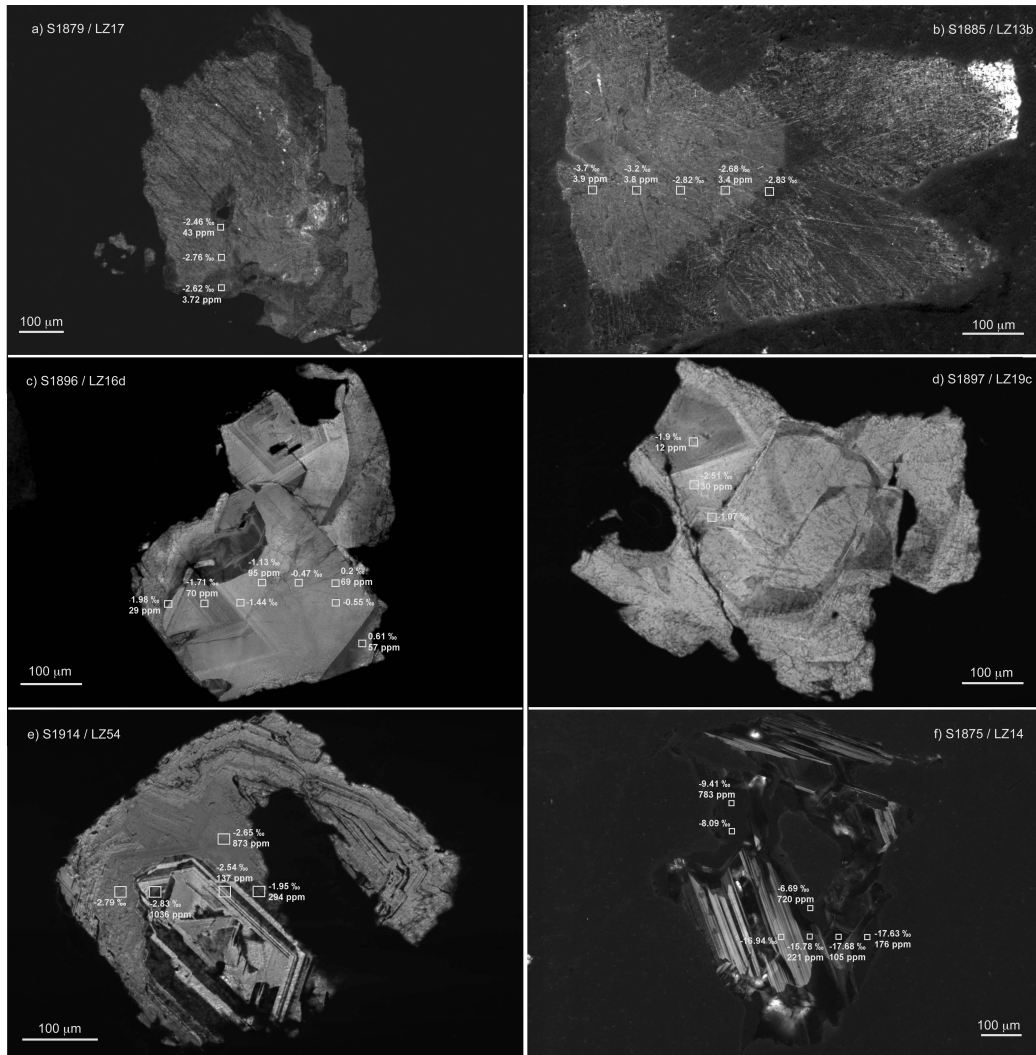

Figure 4.6: Cathodoluminescence images for U2 diamonds that have  $\delta^{13}\text{C}$  deviating from the main population in Figure 4.3. a-e.) five diamonds that have  $^{13}\text{C}$ -enriched carbon isotopic compositions ( $\delta^{13}\text{C} > -4$  ‰) and f.) the only diamond from U2 that has  $^{13}\text{C}$ -depleted carbon isotopic compositions ( $\delta^{13}\text{C} \approx -7$  to  $-18$  ‰). Spot analyses with  $\delta^{13}\text{C}$  and nitrogen content (at. ppm) are indicated.

Figure 4.7: Cathodoluminescence images for diamonds from U2 that have  $\delta^{13}\text{C}$  within the main population in Figure 4.3. Analytical spots with  $\delta^{13}\text{C}$  and nitrogen content (at. ppm) are indicated. a) and b) have increasing  $\delta^{13}\text{C}$  from core to rim; whereas in c)  $\delta^{13}\text{C}$  becomes more negative from core to rim, which may suggest diamond growth from oxidised and reduced sources, respectively. However, these diamonds have multiple resorption surfaces, which preclude modelling diamond growth through a continuous Rayleigh fractionation process.

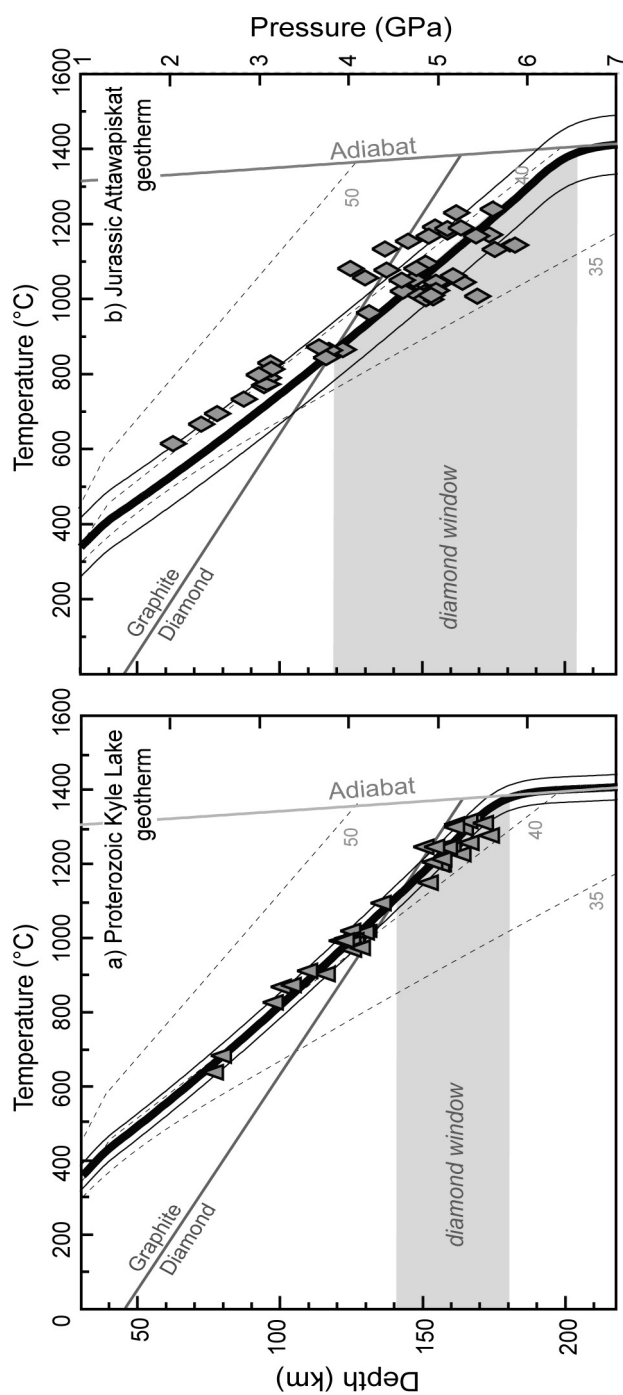

Figure 4.8: Fitplot (e.g., Mather et al., 2011) geotherms (and their error envelopes) for the lithosphere in the Attawapiskat area. Grey dashed lines are geotherms that correspond to 35, 40 and 50  $\text{mW/m}^2$  surface heat flow (Hasterok and Chapman, 2011). Graphite-diamond transition from Day (2012). Pressure (GPa) was converted to depth (km) using a constant density conversion of 0.0324. a.) PT calculations for Kyle Lake single clinopyroxene grains after Nimis and Taylor (2000) and data from Sage (2000). Lithosphere thickness, calculated as the intersection of the conducting geotherm and the mantle adiabat, is  $\sim 180$  km. Kyle Lake has a narrow "diamond window" of  $< 30$  km, with diamond stability above  $1060^\circ\text{C} / 140$  km. Nitrogen-based temperatures in T1 diamonds are all above  $1200^\circ\text{C}$ . b.) Victor single clinopyroxene xenocrysts combined with lherzolite, pyroxenite and harzburgite xenoliths from both Victor and Delta (Section 5.8.3). PT calculations after Nickel and Green (1985), Taylor (1998), Nimis and Taylor (2000) and Nimis and Grütter (2009). Lithosphere thickness is  $\sim 200$  km. Attawapiskat has a broad "diamond window" of  $\sim 70$  km, with diamond stability above  $860^\circ\text{C} / 120$  km. Nitrogen-based temperatures calculated for U2 diamonds are  $> 1050^\circ\text{C}$ .

## Chapter 5

# Mesoproterozoic reworking of Palaeoarchaeon lithospheric mantle beneath the Northern Superior superterrane

### 5.1 Introduction

Old continental crust is underlain by sub-continental lithospheric mantle (SCLM) that has undergone high degrees of melt depletion (removal of Ca, Al, Fe, H<sub>2</sub>O) leading to a residue with low density and high viscosity compared to the underlying asthenosphere (e.g., Jordan, 1975; Boyd and McCallister, 1976). Melt depletion is key for the long term survival of the lithospheric mantle root of a craton, however the process by which the lithosphere attained its highly depleted nature is still debated.

Melt depletion may have occurred at high pressures in a plume setting (e.g., Boyd, 1989; Arndt et al., 1998; Herzberg, 1999; Aulbach et al., 2007; Aulbach, 2012) or at lower pressures with initial melting at a mid-ocean ridge (e.g., Bulatov et al., 1991; Canil and Wei, 1992; Stachel et al., 1998; Canil, 2004; Bernstein et al., 2007; Herzberg and Rudnick, 2012). Regardless of the exact setting, the SCLM must have undergone high degrees of melting, in part to the point of orthopyroxene exhaustion and dunitic residues (Bernstein et al., 2006, 2007; Herzberg and Rudnick, 2012). This suggests that other minerals were introduced into the SCLM after the initial depletion event. Evidence for secondary addition of not only orthopyroxene, but also garnet, olivine and clinopyroxene, to the SCLM has been widely documented (e.g., Kelemen, 1990a; Kelemen et al., 1992; Shimizu et al., 1997; Grégoire et al., 2003; Simon et al., 2003; Bell et al., 2005; Rehfeldt et al., 2008; Hunt et al., 2012a).

Major tectonothermal events may result in lithosphere removal (e.g., the North China and Wyoming cratons Gao et al., 2002; Carlson et al., 2004; Yang et al., 2010; Liu et al., 2011, 2012), gradual melt metasomatism however may re-fertilise the SCLM. Melt metasomatism (and accompanying oxidation) may be detrimental to diamond preservation (e.g., McCammon et al., 2001) and may increase the water content in mantle minerals, thereby lowering the viscosity in the lithosphere (Peslier et al., 2010, 2012) which may contribute to the eventual demise of lithospheric roots. However, these enrichment events may also lead to lherzolitic diamond formation, for example Premier and Venetia on the Kaapvaal craton (Richardson et al., 1993, 2009), Ellendale on the Kimberley craton (Smit et al., 2010) and Udachnaya in Siberia (Richardson and Harris, 1997).

The Superior craton was affected by a major tectonothermal event, the Midcontinent Rift, at 1.1 Ga (White, 1972; Halls, 1978; Wold and Hinze, 1982; van Schmus and Hinze, 1985), which may have thinned the cratonic root in the southern Superior (Kopylova et al., 2011; Miller et al., 2012; Schaeffer and Lebedev, 2013; Zartman et al., 2013). Any effect of the Midcontinent Rift, or other thermal events on the SCLM in the Northern Superior province below Attawapiskat is not yet fully understood. Previous studies have suggested that the thermal effect of the Rift may be seen in the elevated geotherm at Kyle Lake (clinopyroxene xenocrysts; Sage, 2000; Grütter, 2009). Additionally, the lithosphere at 1.1 Ga, as sampled by Kyle Lake, is predominantly harzburgitic in composition; whereas the lithosphere sampled by younger kimberlites, including the Attawapiskat kimberlites (180 Ma) is predominantly lherzolitic (Sage, 2000). This may have been due to melt/fluid infiltration related to the Midcontinent Rift (Sage, 2000; Scully et al., 2004).

In this study, we analyse peridotitic xenocrysts and xenoliths from Attawapiskat on the Superior craton. We aim to answer the following questions: To what extent and in what setting did primary melt depletion occur during SCLM formation in the Archaean? What was the timing of initial depletion? How thick is the lithosphere and what are the diamond-stable lithologies? To what extent was the peridotitic lithosphere affected by the major Midcontinent Rift event?

In addition to major and trace element evidence, we present PGE analyses for sulphide / alloy inclusions in olivine from peridotite xenoliths. Due to fractionation of I-PGE's (Os, Ir, Ru; Barnes et al., 1985) and P-PGE's (Pt, Pd; Barnes et al., 1985) between residues and mantle melts (e.g., Bockrath et al., 2004), PGE analyses are a powerful tool for tracing depletion and enrichment processes in the lithosphere (Pearson et al., 2004; Wittig et al., 2010; Maier et al., 2012). Combining these PGE results with  $T_{RD}$  age determinations for these xenoliths - the first for the Superior craton - we aim to provide constraints on the timing of these processes.

## 5.2 Samples

### 5.2.1 Victor

Samples for this study include eclogite/pyroxenite xenoliths and mixed parageneses mineral concentrate from Victor Mine. We analysed a suite of 33 xenoliths - 17 biminerally eclogite xenoliths and 16 pyroxenite xenoliths, five of which are orthopyroxene-bearing. The formation of the eclogite and pyroxenite xenoliths from Victor has been fully described in Chapter 3, however their PT conditions of last equilibration and origin in either the graphite or diamond stability fields are discussed here in context with the peridotites. Garnet, clinopyroxene, orthopyroxene and olivine xenocrysts were picked from Victor mineral concentrate and analysed for their major and trace elements.

### 5.2.2 Delta

Samples analyses from Delta include seven harzburgites, five lherzolites, three dunites, three pyroxenites and one garnet dunite that were sawed out of kimberlite core. Due to the small size of most samples, they were not classified on mineral modal abundances but on the basis of their garnet chemistry, where garnet was present. Samples that contained that no clinopyroxene were classified as harzburgite and samples containing only olivine as dunite. The majority of the xenoliths show substantial modal metasomatism, with secondary amphibole, mica and clinopyroxene (summarised in Table E.1). Kimberlite infiltration and serpentinisation in olivine-bearing samples is common and kimberlite rims around the xenoliths are visible in thin section (Figure 5.1).

In this study, only the primary mantle mineralogy is discussed and xenoliths were analysed for their major elements and geothermobarometry. Olivine was picked from crushed peridotite xenoliths and analysed for its Re-Os isotopic composition and platinum group element (PGE) content.

## 5.3 Analytical techniques

### 5.3.1 Major elements

Major element compositions were measured using a JEOL8900R electron microprobe at the University of Alberta, operating at 20 kV accelerating voltage, 20 nA probe current and 1  $\mu\text{m}$  beam diameter. Peak count times varied between 30 and 60 seconds, and half that for background count times (Table A.1). Both natural and synthetic standards were used for calibration with matrix corrections following Armstrong (1995) (Table A.2). Multiple analyses for each mineral grain were averaged after those with low totals ( $< 98.5\%$ ) and poor stoichiometry were removed. Detection limits were below 100 ppm for all oxides, apart from 200 ppm for  $\text{Na}_2\text{O}$  and 250 ppm for  $\text{P}_2\text{O}_5$ .

### 5.3.2 Trace elements

In-situ trace element analyses were carried out using a Nd:YAG UP213 nm laser ablation system (New Wave Research) connected to a Perkin Elmer Elan 6000 Quadrupole ICP-MS. The NIST612 glass standard was used for calibration and optimisation of instrument parameters. Samples were typically ablated for 50 seconds, with a spot size of 150  $\mu\text{m}$  and the background analysed for 20 seconds prior to each analysis. Garnet grains (PN1 and PN2) that have been well characterised using several techniques (INAA, SIMS, LA-ICP-MS; Tappert et al., 2005) were analysed as secondary standards. Average concentration values obtained for these garnets overlap within error to the recommended values for these standards. Data reduction and concentration determinations, using EPMA-determined Ca concentrations in garnet as internal standard, were obtained using GLITTER laser ablation software (van Achterbergh et al., 2001).

### 5.3.3 Re-Os isotopic compositions and PGE content

Due to small sample size and the extensive nature of kimberlite infiltration in many xenoliths, olivine separates were analysed to ensure analyses of peridotite with the least contamination. Xenoliths were sawed out of kimberlite drill core using a low speed diamond saw, after which xenoliths were crushed (in a plastic bag to avoid metal contamination) and olivine picked under a binocular microscope. Olivine was rinsed three times and ultrasonically cleaned in milli-Q H<sub>2</sub>O for about 30 minutes. After dry down overnight on a hotplate, olivine was weighed and then attacked in 12N HCL at 80 °C overnight to start break down of the olivine lattice. Olivine was digested in reverse Aqua Regia for 16 hours at 290 °C and 120 bar in an Anton Paar high pressure Asher, sufficient to allow for equilibration with a mixed <sup>190</sup>Os-<sup>191</sup>Ir-<sup>99</sup>Ru-<sup>194</sup>Pt-<sup>106</sup>Pd-<sup>185</sup>Re spike.

#### Osmium isotopic composition and concentration

Osmium was separated by solvent extraction into either CHCl<sub>3</sub> (chloroform) or CCl<sub>4</sub> (carbon tetrachloride), with back extraction into HBr (following Cohen and Waters, 1996) and purification using micro distillation techniques (Roy-Barman and Allègre, 1994; Birck et al., 1997). For the distillation, 15 µl HBr was added to the tip of a conical beaker and 30 µl CrO<sub>3</sub>/H<sub>2</sub>SO<sub>4</sub> solution to the dried down Os fraction. The inverted beaker was placed on a hotplate for two hours at 85 °C. The HBr drop was partially dried down and loaded onto platinum ribbon filaments, along with Ba(OH)<sub>2</sub>. The osmium isotopic compositions were analysed by negative thermal ionisation mass spectrometry (N-TIMS) on a Thermo Scientific Triton Plus using an electron multiplier in peak jumping mode. Air was bled in during the sample run to ensure more efficient ionisation.

Mass spectrometer fractionation was corrected by normalising <sup>192</sup>Os/<sup>188</sup>Os to 3.08261 (Creaser et al., 1991). As Re and Os were run as negative oxides, data were corrected for interferences from three O isotopes, with <sup>17</sup>O/<sup>16</sup>O = 0.0003 and <sup>18</sup>O/<sup>16</sup>O = 0.0020. Analyses were corrected for procedural blanks of 0.2 ± 0.1 pg Os. <sup>187</sup>Os/<sup>188</sup>Os standard errors (SE) include the in-run precision, the uncertainty in the concentration and isotopic composition of the blank and the uncertainty in the spike calibration (Table I.3 and I.4). 2SE uncertainties in

$^{187}\text{Os}/^{188}\text{Os}$  are between  $\pm 0.3$  and  $3.7\%$ . Uncertainties in the Os concentration include the in-run precision, uncertainty in the blank concentration and error magnification due to overspiking.

### **Rhenium isotopic composition and PGE concentration**

Following Os extraction, the Re and PGE fractions were further separated by column chromatography, following methods similar to Pearson and Woodland (2000) and Becker et al. (2006). Aqua Regia fractions were dried down overnight, re-dissolved in 6N HCL overnight and dried down to remove all remaining  $\text{HNO}_3$ . Samples were dissolved in 1N HCL, centrifuged and loaded onto columns containing  $\sim 2$  ml pre-cleaned Biorad AG1X-8 anion exchange resin. After matrix elution in 10 ml 1N HCL and 6 ml 0.8N  $\text{HNO}_3$ , Re + Ru were collected in 12 ml 6N HCL, Pt + Ir in 15 ml concentrated  $\text{HNO}_3$  and Pd in 14 ml concentrated HCL. Following dry-down, Pt + Ir and Pd fractions were dried down in Aqua Regia to remove any organic material. All fractions were dissolved in 1 ml 0.8N  $\text{HNO}_3$  and centrifuged for ICP-MS analyses.

PGE and Re fractions were analysed on a Thermo Scientific Element 2 XR magnetic sector ICP-MS. Solutions were aspirated into the plasma at a flow rate of 0.05 ml/min and signals detected using an electron multiplier. Single element standards containing 1 ppb of the analyte in question were measured at the beginning, during and end of each analytical session to allow for mass fractionation correction. Standards were also prepared to measure oxide production rates in order to correct for possible isobaric interferences. For Pd analyses - ZrO/Zr was less than 4% and YO/Y less than 2.5%. For Pt+Ir analyses - HfO/Hf was less than 2.25% and LuO/Lu less than 0.35%. For Re analyses - YbO/Y was less than 0.06% and TmO/Tm less than 0.14%. For Ru analyses,  $^{95}\text{Mo}$  was monitored to correct for  $^{100}\text{Mo}$  on  $^{100}\text{Ru}$ .

Background signals were monitored before each analysis, with wash-out times between samples of about 2 minutes. PGE concentrations were corrected using procedural blanks of  $1 \pm 1$  pg Ir,  $0.49 \pm 0.48$  pg Pt,  $2 \pm 2$  pg Ru,  $0.45 \pm 0.25$  pg Pd and  $1 \pm 0.5$  pg Re.  $2\sigma$  uncertainties in the concentration of Re and PGE's include the in-run precision and the uncertainty in the blank

concentration.  $2\sigma$  uncertainties in  $^{187}\text{Re}/^{188}\text{Os}$  include in-run precision, the uncertainty in the concentration and isotopic compositions of the blanks.

## 5.4 Victor xenocryst major element chemistry

### 5.4.1 Garnet

According to the classification outlined in Grütter et al. (2004), 70% of the 375 Victor garnets analysed are lherzolitic (G9), 16% are eclogitic/pyroxenitic (G3/G4), 12% are megacrystic (G1), 2% classified as being derived from a high  $\text{TiO}_2$  peridotitic source (G11) and 1% are harzburgitic (G10) (Figure 5.2a,b; Table F.1 to Table F.6).

Lherzolitic (G9) garnets have  $\text{CaO} = 3.71 - 7.51$  wt% and  $\text{Cr}_2\text{O}_3 = 1.05 - 9.83$  wt%, with  $\text{TiO}_2 = 0 - 0.48$  wt% and Mg# between 70.6 and 84.9 with an average of 82.2. MnO content varies from 0.33 to 0.62 wt%. Eclogitic (G3) garnets have  $\text{CaO} = 6.03 - 13.1$  wt%,  $\text{Cr}_2\text{O}_3 = \leq 0.01 - 0.36$  wt% and Mg# between 39.1 and 73.0, with average of 57.1.  $\text{Na}_2\text{O}$  content varies from 0 to 0.22 wt%. Eclogitic / pyroxenitic (G4) garnets have  $\text{CaO} = 3.66 - 5.82$  wt%,  $\text{Cr}_2\text{O}_3 = 0.03 - 0.98$  wt% and Mg# between 54.95 and 85.24, with average of 70.84.  $\text{Na}_2\text{O}$  content varies from  $\leq 0.02$  to 0.36 wt%. Low-Cr megacrystic (G1) garnets have  $\text{CaO} = 4.09 - 4.91$  wt%,  $\text{Cr}_2\text{O}_3 = 0.98 - 3.59$  wt% and Mg# between 75.5 to 82.4, with an average of 80.3. High  $\text{TiO}_2$  peridotitic (G11) garnets have  $\text{CaO} = 3.99 - 5.23$  wt%,  $\text{Cr}_2\text{O}_3 = 3.02 - 5.39$  wt% and  $\text{TiO}_2 = 0.39 - 0.52$  wt%. Mg# range from 80.4 to 84.7, with an average of 83.5. Harzburgitic (G10) garnets are only marginally sub-calcic and plot near the boundary with lherzolitic garnets (Figure 5.2a). These garnets have  $\text{CaO} = 3.60 - 5.19$  wt%,  $\text{Cr}_2\text{O}_3 = 1.54 - 7.29$  wt% and Mg# from 78.6 to 85.6, with an average of 82.1.

### 5.4.2 Olivine

A total of 199 olivine grains were analysed, of which 171 remained after low analytical totals were removed. There are two populations of Victor olivine xenocrysts, differing in both colour and composition. 82 grains with a yellowish-green colour have more depleted compositions with Mg# ranging

between 90.0 to 93.6 (average and median of Mg# 92.7) (Table F.7). These compositions correspond to the worldwide average for olivine from harzburgite xenoliths (Mg# =  $92.8 \pm 0.9$ ; database of Stachel and Harris, 2008) (Figure 5.3).

Eighty-nine brownish-yellow grains have less depleted compositions. Mg# range from 88.1 to 91.7, with average and median of Mg# of 90.3 (Table F.8). These compositions are less depleted than the worldwide average for olivine from lherzolite xenoliths (Mg# =  $91.8 \pm 0.9$ ; database of Stachel and Harris, 2008) (Figure 5.3). NiO in all olivine ranges between between 0.21 and 0.38 wt%.

### 5.4.3 Clinopyroxene

Two hundred and four clinopyroxene grains were mounted for analysis. After low analytical totals were removed 157 grains remained. These are all chromian diopside, with Na<sub>2</sub>O = 0.86 to 4.03 wt%, MgO = 13.57 to 17.85 wt% and Cr<sub>2</sub>O<sub>3</sub> = 0.60 and 3.09 wt% (Table F.9). The criteria of Sobolev et al. (1992) and Grütter (2009) were used to distinguish clinopyroxene with Tschermak components (typical in the spinel stability field) from clinopyroxene where Al and Na are predominantly in the jadeite and kosmochlor components (typical in the garnet stability field) (Figure 5.4a,b).

### 5.4.4 Orthopyroxene

All 102 orthopyroxenes from the mineral concentrate that were analysed are enstatites and range in Mg# from 90.6 to 93.1, with a mean Mg# of 91.1 (Table F.10). They are likely sourced from lherzolites, as harzburgitic orthopyroxene generally will have much lower Ca content with Ca/(Ca+Mg+Fe) typically less than 0.006 (Brey et al., 1999; Grütter, 2009) (Figure 5.5). This is consistent with the predominance of lherzolithic garnets in the concentrate.

Grütter (2009) has shown that a coexisting equilibrium assemblage of clinopyroxene and orthopyroxene in garnet lherzolite may record mutually consistent compositional arrays and therefore, that the graphite-diamond transition Kennedy and Kennedy (1976) and the mantle adiabat ( $T = 1300 \text{ }^\circ\text{C}$ ) can be interpolated into orthopyroxene compositional space. These are shown for

reference on Figure 5.5, where it can be seen that orthopyroxene compositions straddle the graphite-diamond transition.

## 5.5 Xenoliths major element chemistry

### 5.5.1 Victor eclogite and pyroxenite xenoliths

The major element compositions of the 17 eclogite xenoliths and the 16 pyroxenite xenoliths are fully described in Chapter 3. They fall into four categories: 1.) High-Ca eclogite, 2.) Low-Mg eclogite, 3.) High-Mg eclogite and 4.) Pyroxenite  $\pm$  orthopyroxene. The distinction between eclogite and pyroxenite was made based on clinopyroxene compositions - eclogites contain omphacite, whereas pyroxenites contain diopside - consistent with commonly used definitions for eclogite (e.g., Coleman et al., 1965; Carswell, 1990; Pearson et al., 2003). Omphacite was distinguished from diopside by having  $0.2 \leq \text{Na}/(\text{Na}+\text{Ca})$ .

### 5.5.2 Delta pyroxenite xenoliths

Three orthopyroxene-bearing pyroxenite xenoliths from Delta were analysed. Garnet in these samples has CaO from 4.68 to 5.88 wt%, Cr<sub>2</sub>O<sub>3</sub> from 0.78 to 3.05 wt% and Na<sub>2</sub>O from 0.02 to 0.03 wt% (Table G.1). Only one pyroxenite has garnet with Cr<sub>2</sub>O<sub>3</sub> > 1 wt%, thereby classifying as G5 (after Grütter et al., 2004). Diopsides have 0.51 to 0.97 wt% Na<sub>2</sub>O and 16.3 to 17.1 wt% MgO (Table G.2). Enstatites have Mg# between 87.2 and 90.1 and Al<sub>2</sub>O<sub>3</sub> = 0.54 to 0.58 wt% (Tables G.5 and G.6) The pyroxenite with G5 garnet is also olivine-bearing (with Mg# = 85.32) (Table G.3).

### 5.5.3 Delta peridotite xenoliths

#### Dunites

Three dunite xenoliths contain only olivine, with Mg# ranging between 91.2 and 92.7 (average Mg# = 91.9; median Mg# of 92.1) (Table G.3 and G.4). One of these dunites contain metasomatic clinopyroxene (non-texturally equilibrated and associated with mica and amphibole) that has high Na<sub>2</sub>O and Cr<sub>2</sub>O<sub>3</sub> compositions, (Table G.2) distinct to clinopyroxene found in lherzolite xenoliths, discussed below.

## Lherzolites

Five xenoliths were classified as lherzolites based on their garnet CaO-Cr<sub>2</sub>O<sub>3</sub> compositions (CaO = 4.27 - 6.22 wt% and Cr<sub>2</sub>O<sub>3</sub> = 1.51 - 4.77 wt%; Table G.1). Four lherzolites contain olivine with Mg# between 90.1 and 92.5 (average Mg# = 91.3) (Table G.2) Enstatite occurs in four of the five lherzolites and has Mg# between 93.0 and 93.3 (average Mg# = 92.7; Table G.5 and G.6). Primary clinopyroxene in four lherzolites have diopsidic compositions with Na<sub>2</sub>O = 1.25 to 2.18 wt% (Table G.2).

## Harzburgites

Seven harzburgite xenoliths contain olivine ± enstatite ± garnet. Two of these harzburgites contain G10 garnets (CaO = 2.85 - 3.45 wt% and Cr<sub>2</sub>O<sub>3</sub> = 3.04 - 3.41 wt%; Table G.1). Olivine in the harzburgite xenoliths have Mg# between 91.4 to 92.7 (average Mg# = 92.2; Table G.3 and G.4). Six of the seven samples contain enstatite with Mg# ranging from 92.5 to 93.5 (average Mg# = 93.1; Table G.5 and G.6). Two harzburgites contain metasomatic clinopyroxene, with similar compositions to those found in the dunite xenoliths (Table G.2).

## Garnet dunite

One xenolith contains only olivine and garnet and no visible orthopyroxene or clinopyroxene. Olivine has Mg# = 92.1 (Table G.3 and G.4), however the garnet has a wehrlitic composition (G12) with CaO = 9.02 wt% and Cr<sub>2</sub>O<sub>3</sub> = 2.12 wt% and Mg# = 77.6 (Table G.1).

## 5.6 Victor xenocryst trace element chemistry

### 5.6.1 Garnet

One hundred lherzolic garnets (G9) from Victor were analysed for their trace elements (Table H.1 to H.13) These have sinusoidal or sloped chondrite-normalised (REE<sub>N</sub>) patterns and can be divided into 4 main groups, based on their combined REE<sub>N</sub> and trace element compositions (Figures 5.6 and 5.7):

- 1.) Twenty-nine grains have sinusoidal chondrite-normalised REE patterns.

These have positive slopes in the LREE<sub>N</sub>, with a peak in Sm<sub>N</sub> at  $\sim 7$  x chondrite, followed by negative MREE<sub>N</sub> slopes with a trough in Dy<sub>N</sub> at  $\sim 0.7$  x chondrite. The HREE have a positive slope from Dy<sub>N</sub> to Lu<sub>N</sub> ( $\sim 10$  x chondritic). These garnets have the highest Mg# (82.0 to 84.9) and the lowest Y and Zr concentrations (Zr <18 ppm and Y <8 ppm), with Ti = 18 to 153 ppm.

2.) Eighteen garnets also have sinusoidal chondrite-normalised REE patterns, but with significantly more enrichment in the MREE. They have positive slopes in the LREE<sub>N</sub>, with a peak in Sm<sub>N</sub> at  $\sim 20$  x chondrite. This is followed by a negative slope until a trough in Ho<sub>N</sub> at  $\sim 3$  x chondrite, and a positive slope in the HREE<sub>N</sub> to Lu<sub>N</sub> at about 10-20 x chondrite. These grains have Mg# from 79.8 to 84.3 and the highest Zr content (25 to 73 ppm), with Ti = 22 to 252 ppm and Y = 3 to 10 ppm.

3.) Forty-eight garnets have LREE-depleted patterns, with a positive slope in LREE<sub>N</sub> peaking at Gd (10-20 x chondrite) and slightly fractionated to flat MREE<sub>N</sub> to HREE<sub>N</sub> (average Lu<sub>N</sub>/Gd<sub>N</sub> = 1.66) at approximately 10 x chondrite. These are considered to be 'normal' patterns for lherzolitic garnets. These garnets have Mg# from 79.6 to 84.9 and the highest average Ti content (43 to 368 ppm), with Zr = 3 to 74 ppm and Y = 6 to 23 ppm.

4.) Five garnets with 'sloped' patterns have a positive slope in LREE<sub>N</sub>, with a peak in Tb at  $\sim 30$  x chondrite. Four garnets have broadly flat patterns from Tb<sub>N</sub> / Dy<sub>N</sub> to Lu<sub>N</sub> at  $\sim 30$  x chondrite. One sample has a negative slope from Tb<sub>N</sub> to Lu<sub>N</sub> at about 9 x chondrite. These grains have the lowest average Mg#, ranging from 73.3 to 82.4 and the highest Y concentrations (39 to 47 ppm), with Ti = 38 to 90 ppm and Zr = 11 to 72 ppm.

### 5.6.2 Clinopyroxene

Thirty-three clinopyroxene xenocrysts from Victor were analysed for their trace elements (Table H.14 to H.18). They have enriched LREE<sub>N</sub> compositions with a negative slope from La<sub>N</sub> at  $\sim 10$  x chondrite to Lu<sub>N</sub> at 1-3 times chondritic abundances (Figure 5.8). Eu/Eu\* in clinopyroxene range from 0.71 and 1.27 (with average Eu/Eu\* = 0.97).

## 5.7 Re-Os isotopic compositions and PGE content of peridotitic olivine

Olivine from 12 Delta xenoliths was analysed for its Re and Os isotopic composition and PGE content. Replicate digestions of the GP13 rock standard and replicate analyses of the DrOsS mass spectrometry standard are given in Tables I.1 and I.2. Results for sulphide / alloy inclusions in Delta olivines are given in Table I.3 and I.4. The xenoliths display a range in  $^{187}\text{Os}/^{188}\text{Os}$  ranging from unradiogenic ( $<$  present day  $^{187}\text{Os}/^{188}\text{Os}$  of O-chondrite - 0.1283; Walker et al., 2002) to values more radiogenic than any estimate of the PUM. PGE contents and inter-element fractionation of the olivines are highly variable and can be grouped into several categories based on similar chondrite-normalised PGE patterns ( $\text{PGE}_N$ ). For PGE normalisation, the CI chondrite values of Horan et al. (2003) were used.

1.) This group comprises two samples, with  $^{187}\text{Os}/^{188}\text{Os}$  of  $0.10921 \pm 0.00069$  and  $0.11052 \pm 0.00029$ . The first sample contains lherzolitic garnet and the second sample is a dunite. These have Neoproterozoic  $T_{RD}$  ages of  $2.7 \pm 0.1$  Ga and  $2.47 \pm 0.04$  Ga, respectively (Figure 5.9).

Os content in these olivines are 1.1 and 1.44 ppb. Osmium is slightly fractionated compared to Ir in both samples -  $(\text{Os}/\text{Ir})_N$  is 1.38 in the lherzolitic sample, and 0.73 in the dunitic sample. Both samples are depleted in Pd compared to the I-PGE's (Os, Ir, Ru; Barnes et al., 1985) (Figure 5.10a). The dunitic sample exhibits extreme depletion with a  $(\text{Pd}/\text{Ir})_N$  ratio of 0.01. Olivine from the lherzolitic sample does not show the Pd depletion relative to Ir ( $(\text{Pd}/\text{Ir})_N$  of 1), however it is depleted relative to Ru ( $(\text{Pd}/\text{Ru})_N$  of 0.16).

Both samples show Re enrichment relative to Pd, with  $(\text{Re}/\text{Pd})_N$  of 1.6 and 22.8.  $(\text{Re}/\text{Os})_N$  for the dunitic sample is low (0.31) and slightly enriched for the lherzolitic sample (1.15). Overall, PGE abundances in this group overlap those of whole rock cratonic peridotites (Figure 5.10a) and show similar P-PGE fractionation compared to I-PGE ratios (e.g., Pearson et al., 2004).

2.) Olivines in this group includes two samples with the most unradiogenic  $^{187}\text{Os}/^{188}\text{Os}$  in the suite:  $0.10222 \pm 0.00082$  and  $0.1012 \pm 0.0037$  (garnet dunite

and harzburgite, respectively).

Rhenium depletion ages ( $T_{RD}$ ) are Palaeo-Archaeon -  $3.6 \pm 0.1$  Ga and  $3.7 \pm 0.5$  Ga, respectively. Olivines from these two samples have low Os content - the garnet dunite, 0.14 ppb and the harzburgite, 0.17 ppb. Osmium is depleted relative to Ir in the harzburgite ( $(Os/Ir)_N$  of 0.54), but slightly enriched over Ir in the garnet dunite ( $(Os/Ir)_N$  of 1.75) (Figure 5.10b).

The harzburgite is enriched in Pd ( $(Pd/Ir)_N$  of 24) and depleted in Re ( $(Re/Pd)_N$  of 0.25). The garnet dunite does not show the same levels of Pd enrichment, with  $(Pd/Ir)_N$  of 1.86. Rhenium is slightly enriched with  $(Re/Pd)_N$  of 1.46.  $(Re/Os)_N$  for both samples are high - the harzburgite has the lowest  $^{187}Os/^{188}Os$  and has the highest  $(Re/Os)_N$  in the suite (10.53); and the garnet dunite sample, 1.55. The  $PGE_N$  pattern for olivine from the garnet dunite is approximately flat, with slight enrichment in Os over Ir ( $(Os/Ir)_N$  of 1.75), Pd over Ir ( $(Pd/Ir)_N$  of 1.86) and Re over Pd ( $(Re/Pd)_N$  of 1.46).

3.) Olivine from the pyroxenite sample has  $^{187}Os/^{188}Os$  of  $0.1137 \pm 0.0039$  and a similar  $PGE_N$  pattern to the Palaeoarchaeon harzburgite, discussed above. This pyroxenite has a Proterozoic  $T_{RD}$  age of  $2.0 \pm 0.5$  Ga (Figure 5.9) and the lowest Os content in the suite (0.09 ppb). Osmium is depleted relative to Ir ( $(Os/Ir)_N$  of 0.73) (Figure 5.10b). This sample is enriched in Pd ( $(Pd/Ir)_N$  of 11) and depleted in Re ( $(Re/Pd)_N$  of 0.56).  $(Re/Os)_N$  is high with  $(Re/Os)_N$  of 8.58.

4.) Olivine from two samples have radiogenic  $^{187}Os/^{188}Os$  of  $0.16093 \pm 0.00441$  and  $0.18213 \pm 0.00190$ . One is from a dunite (containing only olivine) and the other is from a peridotite containing harzburgitic garnet. These samples have the highest Os content (2.30 and 3.52 ppb), compared to Os contents of less than 1.50 ppb in the rest of the suite. Os is enriched over Ir and  $(Os/Ir)_N$  values are 87.00 and 12.07, respectively (Figure 5.10c).

Both samples are extremely depleted in Pd and Pt - with  $(Pd/Ir)_N$  of 0.50 and 0.05; and show enrichment of Re over Pd ( $(Re/Pd)_N$  of 14.21 and 18.35). They have the lowest  $(Re/Os)_N$  in the suite (0.11 and 0.06).

5.) Olivines from this group comprise three samples (2 harzburgites and 1 lherzolite) that have Proterozoic  $T_{RD}$  ages ranging from 1.43 to 1.58 Ga; with  $^{187}\text{Os}/^{188}\text{Os}$  of  $0.11700 \pm 0.00030$ ;  $0.11812 \pm 0.00127$  and  $0.11724 \pm 0.00100$  (Figure 5.9). Os contents in these olivines are 0.51, 0.73 and 1.17 ppb. Osmium in the two harzburgitic olivines are fractionated relative to Ir, with  $(\text{Os}/\text{Ir})_N$  of 2.7 and 2.8. The lherzolic sample has  $(\text{Os}/\text{Ir})_N$  of 0.94 (Figure 5.10d).

Two samples are depleted in Pt compared to the I-PGE's (and also Pd with  $(\text{Pd}/\text{Ir})_N$  of 0.26), however, these  $\text{PGE}_N$  patterns do show enrichment in the P-PGE's (Pt, Pd, Re Barnes et al., 1985) with  $(\text{Re}/\text{Pd})_N$  of 8.56 to 14.15. One harzburgite has a different  $\text{PGE}_N$  pattern, with a negative trend in the P-PGE. Pt is enriched to similar levels as the estimate for the primitive upper mantle (PUM; Becker et al., 2006) and Re is depleted relative to Pd ( $(\text{Re}/\text{Pd})_N$  of 0.39).  $(\text{Re}/\text{Os})_N$  for these samples have a wide range. One harzburgite has low  $(\text{Re}/\text{Os})_N$  of 0.36. The other harzburgite has a high  $(\text{Re}/\text{Os})_N$  of 6.61, whereas the lherzolic sample has an intermediate  $(\text{Re}/\text{Os})_N$  of 2.37.

6.) Two olivines have extremely low Os contents and  $^{187}\text{Os}/^{188}\text{Os}$  could not be measured by N-TIMS. This is reflected in their severely depleted Ir compositions. These samples also have negligible Pt content - indicated by the dotted line connecting Ru and Pd in Figure 5.10e. Re is enriched over Pd, with  $(\text{Re}/\text{Pd})_N$  of 18.17 and 35.89.

## 5.8 Geothermobarometry

### 5.8.1 Single clinopyroxene geothermobarometry

#### Compositional suitability

The enstatite-in-clinopyroxene thermometer and Cr-in-clinopyroxene barometer combination of Nimis and Taylor (2000) can be applied to single Cr-diopside grains to obtain pressure and temperature (PT) conditions of last equilibration. Equilibrium with orthopyroxene and garnet is essential and is established through a series of compositional filters. Only Cr-diopside that classified as being derived from garnet lherzolite (compositional constraints after Sobolev et al. (1992), Ramsay and Tompkins (1994) and Ramsay (1995); Figure 5.4a,b,c,d) were selected for geothermobarometry.

Although Al in clinopyroxene is typically considered a good indicator for pressure (with concentrations dropping sharply over the spinel to garnet peridotite transition), clinopyroxenes affected by carbonatite metasomatism have lower Al content (e.g., Rudnick et al., 1994; Nimis, 1998) and therefore grains derived from spinel-bearing lherzolites may erroneously plot in the garnet-bearing field. These low-Al grains may cause pressure overestimates and were excluded by means of the MgO - Al<sub>2</sub>O<sub>3</sub> plot of Nimis (1998) (Figure 5.4e,f). 79% of the clinopyroxenes analysed were eliminated due to their low-Al content. Further compositional filters outlined in the online supplementary data to Grütter (2009) were applied to ensure suitability. After all filters were applied only 31 out of 157 grains remained for geothermobarometry calculations.

### **Xenocryst geotherm**

The enstatite-in-clinopyroxene thermometer (Nimis and Taylor, 2000) can be applied to both xenolith and xenocryst populations, as it accurately ( $\pm 40$  °C ) reproduces experimental temperatures over a wide range of PT conditions. However, the Cr-in-clinopyroxene barometer (Nimis and Taylor, 2000) has been shown by Nimis (2002) and Grütter and Moore (2003) to overestimate pressures at low PT conditions and underestimate pressures at high PT conditions, compared to the modified opx - grt barometer (Nickel and Green, 1985; Taylor, 1998). The single crystal thermobarometer combination of Nimis and Taylor (2000) therefore yields geothermal arrays with significantly more scatter than geotherms created with the combination of the enstatite-in-clinopyroxene thermometer (Nimis and Taylor, 2000) and the modified orthopyroxene - garnet barometer (Nickel and Green, 1985; Taylor, 1998). Grütter (2009) has suggested, however, that these single clinopyroxene geotherms are still useful in "relative" comparative studies between localities, but traditional xenolith-based geotherms may still be preferred for more precise and accurate PT arrays.

Palaeogeotherms were calculated from PT data using the Fitplot program (McKenzie and Bickle, 1988; McKenzie et al., 2005; Mather et al., 2011). This program quantifies the lithosphere thickness, calculated as the intersection of the conductive geotherm (numerically fitted to the PT array) with the adiabatic geotherm of the convecting mantle ('thermal' definition of the base of the

lithosphere after Rudnick et al., 1998; Rudnick and Nyblade, 1999), as well as the "diamond-in" parameter - the point at which the graphite-diamond transition intersects the conductive geotherm.

PT results from single clinopyroxene grains and the resulting Fitplot geotherm is shown in Figure 5.11a. Lithosphere thickness was calculated between 190 and 210 km and diamond stability above 850 °C / 118 km (using graphite-diamond transition of Day, 2012). The resulting diamond window is ~ 85 km thick. These Victor clinopyroxenes are mainly derived from depths between 120 and 180 km, i.e., dominantly in the diamond stability field.

### 5.8.2 Xenolith geothermobarometry

Pressures and temperatures of last equilibration were calculated iteratively for eight orthopyroxene-bearing xenoliths from Victor, as well as three orthopyroxene-bearing xenoliths and four lherzolite xenoliths from Delta.

Temperatures for Fe-Mg exchange between orthopyroxene and clinopyroxene were calculated using the formulation of Taylor (1998). Al-in-orthopyroxene pressures were calculated after Nickel and Green (1985). Modification of this barometer by Taylor (1998) was recommended for fertile lherzolites and websterites at  $P < 3.5$  GPa, especially those with high Ti contents. However, the Ti content in our samples is much lower than the pyroxenes in the HPY40 experimental dataset of Taylor (1998), which was shown to overlap with fertile lherzolites and websterites.

Equilibrium between the two pyroxenes was assessed by evaluating the temperature differences between the two pyroxene thermometer of Taylor (1998) and the Ca-in-orthopyroxene thermometer of Brey and Köhler (1990) (modified by Nimis and Grütter (2009) for low temperatures). Pyroxene-garnet equilibrium was evaluated through the difference between the two pyroxene thermometer of Taylor (1998) and Fe-Mg orthopyroxene-garnet thermometer of Nimis and Grütter (2009). A summary of the calculated temperatures and the equilibrium evaluations is shown in Table J.1 and J.2. Three pyroxenites from Victor were found to be in disequilibrium and were not used for the geotherm calculations.

One sample from Delta had an assemblage of only garnet, orthopyroxene and olivine but no co-existing clinopyroxene. For this sample, temperatures for Fe-Mg exchange between orthopyroxene and garnet were calculated (Nimis and Grütter, 2009) in combination with Al-in-orthopyroxene pressures (Nickel and Green, 1985).

The Fitplot palaeogeotherm using the combined PT results for lherzolite, pyroxenite and harzburgite xenoliths is given in Figure 5.11b. All samples, except one, plot within the graphite stability field. Lithosphere thickness was calculated to be between 185 and 195 km and diamond stability above 930 °C / 125 km (using graphite-diamond transition of Day, 2012). The resulting diamond window is  $\sim 75$  km thick.

### 5.8.3 Combined xenolith / xenocryst geotherm

All xenolith and xenocryst PT data were combined to produce the Fitplot geotherm in Figure 5.11c. Results compare well to the individual xenolith and xenocryst geotherms, with the calculated lithosphere thickness between 190 and 205 km and diamond stability above 860 °C / 120 km (using graphite-diamond transition of Day, 2012). The resulting diamond window is  $\sim 85$  km thick, compared to the much smaller diamond window of  $\sim 30$  km at Kyle Lake.

The biminerally eclogites and pyroxenites yield temperatures of last equilibration between 770 °C and 980 °C (calculated at 5 GPa; Krogh, 1988). Projecting the temperatures for these biminerally eclogites and pyroxenites onto the combined xenolith/xenocryst palaeogeotherm places them on the boundary between the graphite and diamond stability fields (Figure 5.11c).

## 5.9 Depletion of the SCLM below Attawapiskat

The Kyle Lake kimberlites, about 100 km west of Attawapiskat, are the oldest kimberlites in the western Superior province and the only kimberlites on the Superior craton that sample lithospheric mantle with abundant harzburgitic compositions. The younger kimberlites at Kirkland Lake, Timiskaming

and Attawapiskat, sample predominantly lherzolitic compositions with minor harzburgite (Sage, 2000; Scully, 2000; Armstrong et al., 2004).

The apparent temporal change in SCLM composition, the coincidence in age of Kyle Lake kimberlite eruption to the Midcontinent Rift (1.1 Ga), as well as the elevated geotherm seen in the clinopyroxene xenocrysts at Kyle Lake (Figure 5.11), have led to the suggestion that the lower portions of the SCLM below this region have been refertilised from harzburgite to lherzolite, perhaps by melt infiltration related to the Midcontinent Rift (Sage, 2000; Scully et al., 2004). Alternatively, the lithosphere below Attawapiskat, including Victor and Delta, never experienced high degrees of melting to the point of clinopyroxene exhaustion (leading to depleted harzburgitic or dunitic residues).

Our sample set comprises mainly lherzolitic garnet xenocrysts, consistent with previous studies. However, xenoliths from Delta have a wider range in peridotitic compositions, including lherzolite, harzburgite and dunite. In this section, we investigate evidence for high degrees of partial melting still preserved in the SCLM below Attawapiskat.

### 5.9.1 Residues after high degrees of melting

Approximately half of the Victor olivine xenocrysts have highly depleted compositions with an average Mg# of 92.6 and Mg# up to 93.6 (Table F.7). The mode for Victor olivine overlaps that shown for Slave, Kaapvaal and North Atlantic cratons (compilation of Pearson and Wittig, 2008) (Figure 5.3a).

Mg#'s in olivine of 92.8 - 93.0 can only be produced after extensive melting - after 50 % at 3 GPa or after 37 % melting at 7 GPa (garnet lherzolite melting experiments - Walter, 1998). Natural analogues, such as the Iwaidake peridotite massif (a Phanerozoic ophiolite; Kubo, 2002), show that at Mg#'s of 92.8 the resultant rock type is dunite.

Lower olivine Mg#'s are produced by lower extents of melting and yield harzburgitic residues, i.e., after 20 % melting at 3 GPa (Walter, 1998), corresponding to the point of clinopyroxene exhaustion. At higher pressures, these Mg#'s are produced after 15 % melting and clinopyroxene is only exhausted

after 40 % melting (7 GPa; garnet lherzolite melting experiments of Walter, 1998). Experiments that have more clinopyroxene-rich starting compositions may have clinopyroxene remain in the residue to much higher degrees of melting (e.g., Kinzler and Grove, 1999).

Therefore, depending on depth of melting, Mg#'s between 91 and 92 at Victor may correspond to lherzolitic or harzburgitic residual compositions. The depleted olivine at Victor, with Mg# up to 93.6, requires that the lithospheric mantle underwent high degrees of melting (>37 %) to produce dunitic residual compositions (see also Bernstein et al., 2007; Pearson and Wittig, 2008). High degrees of melting indicated by the olivine compositions, suggests that the other minerals in the Attawapiskat peridotitic lithosphere (i.e., clinopyroxene, garnet, orthopyroxene, less depleted olivine) may have been introduced by secondary enrichment processes in the SCLM, as also suggested for other cratonic roots (e.g., Kelemen et al., 1992; Shimizu et al., 1997; Grégoire et al., 2003; Bell et al., 2005; Rehfeldt et al., 2008; Gibson et al., 2013).

### 5.9.2 Melting in a low-pressure environment

Mg#'s up to 93.6 in Victor olivine require high degrees of partial melting of at least 40%, irrespective of the depth of melting. However, combined evidence from both Cr/Al ratios and HREE content in garnet may provide additional constraints as to the depth of melting - i.e., whether melting occurred in either the garnet or spinel stability fields. The spinel-garnet transition occurs between 1.7 and 2.2 GPa in peridotite with low bulk rock Cr# (where Cr# is the molar proportion of Cr/(Cr+Al)) (Robinson and Wood, 1998). Spinel can however be stable to much higher pressures (7.0 GPa) in peridotites with increased bulk rock Cr#, which results from higher degrees of depletion (e.g., O'Neill, 1981).

1.) *Cr/Al ratios.* Victor lherzolitic garnets with the most depleted compositions (sinusoidal REE<sub>N</sub>; lowest Y and Zr; discussed in Section 5.12.3) have Cr# up to 30. The Cr/Al ratios are the highest in these depleted sinusoidal garnets and the lowest in the garnets with normal and sloped REE<sub>N</sub> patterns (Figure 5.12).

Melt extraction in the garnet stability field is unable to explain high Cr/Al ratios, as shown experimentally by Bulatov et al. (1991), since the partition coefficient of Cr/Al between garnet and ultramafic liquid decreases with pressure and would require numerous melt extraction processes to achieve high Cr contents in garnet (e.g., Trønnes et al., 1992; Canil and Wei, 1992). Residual garnets after experimental melting of garnet lherzolite at 3 - 7 GPa have Cr<sub>2</sub>O<sub>3</sub> content between 1.01 and 1.71 wt% (Walter, 1998), significantly lower than the range of compositions seen in Victor lherzolitic garnets which reach up to 10 wt% Cr<sub>2</sub>O<sub>3</sub> (Figure 5.2). The partition coefficient for Cr/Al between spinel and ultramafic liquid is  $\sim 40$  and therefore high Cr content in garnet can be explained through initial melt extraction at low pressures in the spinel stability field, followed by metamorphic conversion to garnet (Stachel et al., 1998).

2.) *Positive slopes in HREE<sub>N</sub>*. The most depleted Victor lherzolitic garnets have positive slopes in the HREE<sub>N</sub> and display depletion in HREE relative to the primitive mantle, as seen when the REE are normalised to J4, a garnet from a "primitive" lherzolite (Stachel et al., 1998, and references therein) (Figure 5.6a,b) .

Garnets with low HREE content and positive slopes in the HREE<sub>N</sub> have been linked to low pressure melt extraction that starts in the garnet stability field and ends in the spinel stability field (e.g., Kelemen et al., 1998; Stachel et al., 1998). These HREE<sub>N</sub> signatures cannot be explained by melting only in spinel stability field. The partition coefficients of Yb in spinel (and also orthopyroxene and olivine) is low and during partial melting, Yb behaves as an incompatible element and will not be retained in the residue. Therefore, some melting must have occurred in the presence of garnet that would account for the positive slopes observed in the HREE<sub>N</sub> of depleted garnets (Figure 5.6a,b).

To reconcile the Cr# in garnet that indicates melting in the spinel stability field and the positive HREE<sub>N</sub> slopes, indicative of melting in the garnet stability field, fractional polybaric melting starting at high and ending at low pressures is required (e.g., Stachel et al., 1998). The most depleted Victor lherzolitic garnet have slopes in their HREE<sub>N</sub> that correspond to 20% melting in the spinel stability field and 5 to 15% melting in the garnet stability

field (Figure 16 in Simon et al., 2007). Although these melting calculations in Simon et al. (2007) are based on whole rock compositions, the slope in the  $\text{HREE}_N$  (rather than their absolute concentrations) can still be used, as the HREE budget in the whole rock is dominated by the garnet.

### 5.9.3 Comparison to Kyle Lake

Twenty-five olivine xenocrysts from Kyle Lake have a range in Mg# from 90.5 to 93.5, with an average Mg# of 92.2 (Sage, 2000), also indicating that they are residues after high degrees of melting to harzburgitic and dunitic residues (Section 5.9.1; Figure 5.3c). Trace element analyses on a subset of the Kyle Lake garnet samples (Scully et al., 2004) show that harzburgitic and lherzolitic garnet xenocrysts have  $\text{Yb}_N$  between  $\sim 0.8$  and 10, similar in range to those from Victor (distinct  $\text{REE}_N$  patterns for harzburgite vs lherzolite not given).

Whereas Yb concentrations in garnets from Kyle Lake and Victor are similar, harzburgitic garnets from Kyle Lake have significantly higher Cr/Al ratios, with a pronounced mode at  $\text{Cr}\# > 30$  (Figure 5.13; Victor  $\text{Cr}\# < 30$ ). This mainly indicates sampling from deeper lithosphere with elevated Cr/Al at Kyle Lake. The mode for lherzolitic garnets from Kyle Lake ( $\text{Cr}\#$  between 10 and 15) overlaps with the mode for lherzolitic garnets from Victor.

Other explanations for the difference in  $\text{Cr}\#$  between Kyle Lake and Attawapiskat garnets include: 1.) High  $\text{Cr}\#$ 's in garnet may reflect higher extents of melt depletion. This would suggest that the lithosphere sampled at 1.1 Ga at Kyle Lake had not yet undergone refertilisation to the same extent as the lithosphere sampled during the Jurassic at Attawapiskat. Clinopyroxene introduction and conversion to lherzolite may have occurred around 1.1 Ga due to silicate and UML magmatism related to the Midcontinent Rift, or due to kimberlite metasomatism, either at 1.1 Ga or later during the Jurassic (e.g., Foley et al., 2002b, 2006; Simon et al., 2003). Melt infiltration and conversion from harzburgite to lherzolitic, leading to lower  $\text{Cr}\#$  due to influx of Al in the melt, has also been suggested for some Diavik diamondiferous lherzolite xenoliths (Creighton et al., 2008). 2.) The difference in  $\text{Cr}\#$  between Kyle Lake and Attawapiskat could represent sampling of different lithospheres. The

Attawapiskat kimberlites erupted near the boundary of the North Caribou and Northern Superior superterrane, and therefore could conceivably sample lithosphere from either terrane. The Kyle Lake kimberlites erupt further west in the North Caribou superterrane and could be sampling just North Caribou lithosphere (Figure 2.1).

#### 5.9.4 Geodynamic setting for initial melting

Extensive melting in the Attawapiskat lithosphere is indicated by both Mg# in olivine and HREE<sub>N</sub> in garnet, resulting in harzburgitic to dunitic residual compositions. Modelling of garnet HREE<sub>N</sub> (after Simon et al., 2007) indicates at least >25 % total melting at high and low pressures. High Cr# in garnet require that significant melting must have taken place in the spinel stability field.

The geodynamic setting that is most consistent with these compositional characteristics is decompression melting of upwelling mantle, akin to a Mid-Ocean Ridge setting. Melting would start at high pressures in the garnet stability field (3-6 GPa) proceeding to low pressures in the spinel stability field (< 3 GPa) (e.g., Kelemen et al., 1998; Stachel et al., 1998; Bernstein et al., 2007; Herzberg et al., 2010; Herzberg and Rudnick, 2012). During the Archaean (>2.5 Ga), high degrees of melting (30 - 40 %) were possible due to higher mantle potential temperatures, around 1600 °C (Korenaga, 2008).

#### 5.9.5 Palaeoarchaeoan melt depletion

PGE-rich phases encapsulated in depleted olivine from two Delta peridotites record Palaeoarchaeoan T<sub>RD</sub> ages - olivine from a garnet harzburgite has T<sub>RD</sub> = 3.73 ± 0.49 Ga and olivine from a garnet dunite has T<sub>RD</sub> = 3.59 ± 0.11 Ga. The harzburgitic sample does not have a typical depleted PGE<sub>N</sub> pattern, as may be expected for olivine with high Mg# (92.4) and of Palaeoarchaeoan age. Rather, the positive slope in the PGE<sub>N</sub> pattern, along with high (Pd/Ir)<sub>N</sub> and high (Re/Os)<sub>N</sub>, is frequently seen in metasomatic sulphides that result from melt infiltration (Lorand et al., 1993; Luguët et al., 2003, 2004). Since Re>Os, some radiogenic ingrowth is likely and it indicates that the Palaeoarchaeoan T<sub>RD</sub> age in the harzburgite is definitely a *minimum* age and the 'real' age of the trapped sulphide/PGE's is even older.

The garnet dunite has a  $\text{PGE}_N$  pattern that is approximately similar to the estimate for the primitive upper mantle (PUM) (Becker et al., 2006), albeit at lower absolute concentrations (Figure 5.10a,b). This is likely due to these PGE's being diluted by their olivine host, which because of very high sulphide-silicate partition coefficients ( $>10\,000$ ; e.g., Bezmen et al., 1994; Peach et al., 1994; Fleet et al., 1996, 1999; Sattari et al., 2002) is not considered a likely host for PGE's.

These old depletion ages in *metasomatic* sulphides/PGE's require the existence of a depleted mantle reservoir beneath Attawapiskat since at least the Palaeoarchaeon. There are no crustal ages in the North Caribou superterrane older than 3.0 Ga, however these Palaeoarchaeon depletion ages correspond with gneisses in the Pikwitonei domain of the Northern Superior superterrane that were dated to about 3.6 Ga (Böhm et al., 2000; Skulski et al., 2000).

Other evidence for a Palaeoarchaeon depleted mantle reservoir below the Superior craton is mainly from the southern Superior: 1.) Archaean zircons from the Winnipeg River and Quetico Terranes in the south-western Superior province have  $\epsilon_{Hf}$  compositions that require extraction from the convecting mantle in the Palaeoarchaeon (3.8 - 3.2 Ga) (Davis et al., 2005). 2.) The oldest detrital zircons in Quetico metasediments are 3.45 Ga (Fralick and Davis, 1999). 3.) Zircon cores in lower crustal xenoliths of the Minnesota River Valley Terrane have 3.5 Ga ages (Zartman et al., 2013).

## 5.10 Mantle processes associated with $\sim 2.7$ Ga subduction

### 5.10.1 Depleted residual patterns with Nearchaeon $T_{RD}$ ages

Two samples record Nearchaeon  $T_{RD}$  ages (including errors these range between 2.8 and 2.4 Ga) and have  $\text{PGE}_N$  patterns that are typical for depleted cratonic residues (Figure 5.10a). These residual  $\text{PGE}_N$  patterns are complimentary to that of basaltic melt (e.g., Bockrath et al., 2004), due to the different partitioning behaviour of the I-PGE's and P-PGE's during man-

tle melting. P-PGE's have lower partition coefficients between monosulphide solid solution (mss) and sulphide melt and therefore behave incompatibly; whereas the I-PGE's, due to their higher partition coefficients, remain in the mss residue (Fleet et al., 1993; Li et al., 1996; Sinyakova et al., 2001; Ballhaus et al., 2001; Brenan, 2002; Mungall et al., 2005; Barnes et al., 2006).

The  $\text{PGE}_N$  patterns for these two Delta samples are similar to those of Lesotho depleted peridotites, that were P-PGE depleted during partial melting (with  $(\text{Pd}/\text{Ir})_N = 0.01$  in one sample), followed by Re enrichment during later melt/kimberlite infiltration (Pearson et al., 2004) (Figure 5.10a). Apart from their Re enrichment, these Pd-depleted patterns, are also comparable to the residues calculated for komatiite melts in the Abitibi greenstone belt (Superior craton) (Puchtel et al., 2004).

Their  $T_{RD}$  ages correlate with the timing of subduction-accretion of the Northern Superior and North Caribou superterrane at  $\sim 2.7$  Ga and associated continental arc magmatism (see Section 2.1), and suggests that melting took place in the mantle wedge during this time. These ages also overlap with a 2.6 Ga whole-rock  $T_{RD}$  age for a peridotite xenolith from Kirkland Lake in the Wawa-Abitibi Terrane (Pearson et al., 1997) (Figure 5.9).

The majority of Kaapvaal peridotite xenoliths have Re-Os  $T_{RD}$  ages between 2.9 and 2.7 Ga (Pearson et al., 1995; Carlson et al., 1999; Menzies et al., 1999; Irvine et al., 2001; Carlson and Moore, 2004; Simon et al., 2007), which overlap with the 2.9 Ga collision of the Witwatersrand and Kimberley blocks of the Kaapvaal (Schmitz et al., 2004), suggesting that mantle melting in an arc environment during collisional tectonics took place, similar to that proposed for the Attawapiskat peridotites analysed here.

### 5.10.2 I-PGE alloy formation in a supra-subduction zone

Olivine from two samples have radiogenic  $^{187}\text{Os}/^{188}\text{Os}$  (0.16093 to 0.18213) and high Os content (2.3 to 3.5 ppb). Due to their extremely low Re/Os (0.06 to 0.11) (Figure 5.10c), these isotopic compositions must be an inherent attribute of the phase/s hosting Os in these olivines (i.e., the radiogenic  $^{187}\text{Os}/^{188}\text{Os}$  did not develop as a result of radiogenic ingrowth from high

Re/Os).

The Os-rich nature of these olivines could be indicative of I-PGE-alloy or sulphide inclusions. These are highly refractive grains which remain after extensive melting has depleted the protolith of its sulphide budget ( $\sim 25\%$  melting; Barnes et al., 1985) and should normally preserve depleted  $^{187}\text{Os}/^{188}\text{Os}$  indicative of the time of melting. However, the radiogenic  $^{187}\text{Os}/^{188}\text{Os}$  of the Os-rich PGE grains suggest the possibility of another influence.

I-PGE-rich alloys can form in conjunction with chromite from hydrous melts (Matveev and Ballhaus, 2002). During exsolution of fluid from the melt, chromite and I-PGE's are strongly partitioned into the hydrous fluid. A likely setting for generation of radiogenic  $^{187}\text{Os}/^{188}\text{Os}$  would be during dehydration and melting of a subducting slab, with hydrous melts percolating through the overlying mantle wedge where PGE alloys are formed (e.g., Brenker et al., 2003; Pearson et al., 2007). The very high  $(\text{Os}/\text{Ir})_N$  of these olivines from the Delta peridotites, and their high Ru, indicate the inclusion of Os-Ru alloys in these alloys. The relative enrichment in Re may derive from the olivine itself.

### 5.10.3 Pyroxenite formation

Similarity of the  $\text{PGE}_N$  pattern in a harzburgite sample to that in a pyroxenitic sample with significantly younger  $T_{RD}$  age of  $2.0 \pm 0.5$  Ga, is consistent with the petrogenetic model for Victor pyroxenites, whereby melts generated from the melting of low-Mg eclogites infiltrate and react with surrounding depleted peridotites to form pyroxenites (Chapter 3). A melt generated from a low-Mg eclogite (recycled oceanic crust) is expected to have high Re/Os due to long-term isolation from the convecting mantle, and is observed in the high  $(\text{Re}/\text{Os})_N$  seen in this harzburgite and pyroxenite (10.53 and 8.58, respectively), the highest observed in this suite (Figure 5.10).

The process of P-PGE enrichment in wallrock peridotite is analogous to melt infiltration from pyroxenite layers to surrounding peridotites, documented in ultramafic massifs (e.g., van Acken et al., 2008, 2010). If the percolating silicate melt is close to S saturation (e.g., with progressive fractional crystallisation; Li and Ripley, 2005, and references therein), it may not be saturated in

clinopyroxene. Therefore HSE enrichment could occur in a depleted harzburgite without the simultaneous addition of Al and Ca, as shown for harzburgites from the Samail ophiolite, Oman (Lorand et al., 2009).

### 5.11 PGE<sub>N</sub> patterns resulting from the Midcontinent Rift

Three samples have Meso-proterozoic  $T_{RD}$  ages between 1.6 and  $1.4 \pm 0.2$  Ga and correlate with 1.5 and 1.1 Ga whole-rock  $T_{RD}$  age for two peridotite xenoliths from Kirkland Lake in the Wawa-Abitibi Terrane (Pearson et al., 1997) (Figure 5.9).

A major tectonothermal event that affected the Superior during the Proterozoic is basaltic and alkaline magmatism related to the Midcontinent Rift ( $\sim 1.1$  Ga; Paces and Miller, 1993; Heaman and Machado, 1992; Heaman et al., 2007). Ultramafic lamprophyre (UML) magmatism occurred prior to the main phase of rift volcanism from 1172 to 1141 Ma (Queen et al., 1996; Heaman et al., 2004).

These Proterozoic  $T_{RD}$  ages could reflect mixing of older, unradiogenic Os ( $\gg 1.6$  Ga) from depleted peridotite with that of younger, more radiogenic  $^{187}\text{Os}/^{188}\text{Os}$  from Midcontinent Rift basalts ( $\gamma_{\text{Os}} = 5.7$  at 1.13 Ga; Shirey, 1997). There are no published PGE data for the Midcontinent Rift basalts, however, the enrichment in P-PGE's and Re seen in olivine from these three Delta samples (Figure 5.10d) is similar to that of other basalts, including mid-ocean ridge basalts (MORB), and both tholeiitic and alkali ocean island basalts (OIB) (Figure 5.10f).

The strong Mesoproterozoic imprint of Midcontinent Rift melt infiltration on the deep mantle lithosphere beneath the Attawapiskat region is consistent with that seen in the southern Superior lower crust. Granulites from Minnesota River Valley Terrane in Michigan, shown to be the metamorphic equivalent of Midcontinent Rift basalts, contain  $1104 \pm 42$  Ma zircons and also have a  $1046 \pm 100$  Ma Sm-Nd whole-rock errorchron (Zartman et al., 2013). Rift basalts also led to the formation of magmatic sulphide deposits in the southern Superior (1107 Ma; U-Pb baddeleyite; Ding et al., 2010, 2012).

## 5.12 Other enrichment processes in the SCLM below Attawapiskat

Metasomatism is common in the continental lithosphere and even ancient harzburgitic garnets that have sinusoidal chondrite-normalised REE patterns, are affected by early fluid metasomatism (e.g., Richardson et al., 1984; Stachel et al., 1998). The best example of highly depleted cratonic lithosphere, without significant enrichment processes, is the North Atlantic / West Greenland peridotites (e.g., Bernstein et al., 1998, 2006; Wittig et al., 2008). The effect of silica addition (orthopyroxene) and incompatible element enrichment is widely seen in Kaapvaal peridotites (Boyd et al., 1999; Simon et al., 2003), where enrichment may be due to fluids/melts from the subducting slabs infiltrating the overlying mantle wedge (Kelemen et al., 1998; Yaxley and Green, 1998; Simon et al., 2007). In this section we discuss evidence for enrichment processes that impacted the Superior lithosphere at Attawapiskat.

### 5.12.1 Modal metasomatism in Delta peridotite xenoliths

There are abundant secondary (or non-texturally equilibrated) mica, amphibole and clinopyroxene in the xenoliths from Delta. Modal metasomatic phases present in each xenolith is summarised in Table E.1 and could derive from enrichment that began during formation of the Midcontinent Rift, or could have formed a few million years prior to Jurassic kimberlites, similar to Kaapvaal craton metasomites (Hamilton et al., 1998; Konzett et al., 2000).

### 5.12.2 "Less depleted" olivine compositions

Approximately half of the Victor olivine xenocrysts analysed have "less depleted" compositions, which are not seen at Kyle Lake (Sage, 2000) (Figure 5.3a,c). The average Mg# for these olivines (90.3) is lower than the 'less depleted' (i.e., lherzolite) mode in Slave craton olivine (Figure 5.3 and olivine from worldwide lherzolite xenoliths, that have  $\text{Mg\#} = 91.8 \pm 0.9$  ( $2\sigma$ ) (database of Stachel and Harris, 2008).

Even though these olivines have Mg# that overlap with kimberlitic olivine, they are probably not kimberlitic as they have higher average Ni contents (Ni

from 0.30 to 0.40 wt%) than a compilation of kimberlitic olivines (average Ni between 0.25 and 0.30 wt%) (Kaminsky et al., 2002; Armstrong et al., 2004; Birkett et al., 2004; Kamenetsky et al., 2008; Matveev and Stachel, 2009; Patterson et al., 2009; de Hoog et al., 2010).

Cratonic olivine with lower forsterite contents than typical SCLM (Section 5.9.1), is associated with melt metasomatism (e.g., Green and Ringwood, 1967; Quick and Gregory, 1995). For example, Fe-rich lherzolites from Siberia with Mg# from 84 to 89 formed due to percolation of melts into depleted peridotites (Ionov et al., 2005). In the Trinity peridotite in California, infiltrating melts reacted with clinopyroxene to form orthopyroxene and olivine with Mg# from 89 to 91 (Quick, 1981; Kelemen et al., 1992).

For the North China craton, Liu et al. (2011) showed that "less depleted" olivine compositions (Mg# 87.4 - 92.2) in the Northern region are associated with Proterozoic  $T_{RD}$  ages, whereas more refractory compositions in the Southern Region have older 2.5 - 2.1 Ga depletion ages. For the Delta xenoliths however, there is no correlation between "less depleted" Mg# and younger  $T_{RD}$  ages for olivine. Olivine from the two samples with the oldest  $T_{RD}$  ages of 3.7 - 3.6 Ga have Mg# 92.1 and 92.4. However, olivine with the youngest  $T_{RD}$  age of 1.4 Ga also has Mg# of 92.1 (Tables I.3 and I.4).

The presence of economic diamond grades at Victor, indicates that melt infiltration resulting in these "less depleted" olivine compositions is not necessarily detrimental to diamond formation or preservation in the SCLM. Although rare, a number of worldwide localities have olivine diamond inclusions with these compositions. For example, olivine diamond inclusions with Mg# of 88 have been documented at both Premier and Ellendale (Gurney et al., 1985; Jaques et al., 1989); and olivine inclusions with Mg# of 86 were reported in diamonds from Yubileynaya and Internacionalnaya (Sobolev et al., 2008).

### 5.12.3 Metasomatism in lherzolitic garnet (G9) and clinopyroxene xenocrysts

In this section the metasomatic characteristics of the Victor garnet and clinopyroxene xenocrysts are discussed, and hypothetical liquids in equilibrium

with these minerals calculated. Liquids were calculated using partition coefficients for minerals in equilibrium with both basaltic and carbonatite melts (Green et al., 2000; Dasgupta et al., 2009; Girmis et al., 2013) and their correlation with compositions of natural basaltic and carbonatite melts evaluated. Also, melts in equilibrium with Si-rich tonalitic melts (partition coefficients of Barth et al., 2002c) were calculated to evaluate whether the peridotitic lithosphere was metasomatised by melts of low-Mg eclogites subducted into the SCLM, as proposed for the origin of high-Mg eclogites and pyroxenites at Victor (Chapter 3).

### Fluid and melt metasomatism in lherzolitic garnet

All lherzolitic garnet xenocrysts from Victor, even those that retain depleted signatures in the HREE<sub>N</sub> (discussed in Section 5.9.2), show some form of enrichment in their REE<sub>N</sub> and other trace elements.

1. *Fluid-dominated metasomatism in sinusoidal garnets.* Garnets that have sinusoidal chondrite-normalised REE patterns (Section 5.6 and Figure 5.6a) fall into both the depleted and low temperature metasomatism fields, defined by Y-Zr systematics (Figure 5.7; Griffin and Ryan, 1995). Sinusoidal garnets in the depleted field have low Y and Zr contents (< 5 ppm and 25 ppm, respectively) and low Ti contents, which indicates that they were only affected by mild, fluid-dominated metasomatism.

With these REE characteristics and the modest levels of Y-Zr re-enrichment, these "depleted" lherzolitic garnets from Victor resemble garnets from diamondiferous lherzolite xenoliths from the Diavik Mine (Creighton et al., 2008). They are also similar to harzburgitic and lherzolitic garnets from Kyle Lake (Scully et al., 2004). Only a small subset of lherzolitic garnets from AT56 (also at Attawapiskat; see Figure 2.1) have sinusoidal REE<sub>N</sub> patterns (Armstrong et al., 2004). Calculated equilibrium basaltic and carbonatitic melts for these sinusoidal garnets (figure not shown) have extremely fractionated REE<sub>N</sub> patterns where LREE  $\gg$  HREE, and are not a match for any natural mantle melts, further suggesting these garnets were metasomatised by fluids (CH<sub>4</sub> / CO<sub>2</sub>?) or extremely low-degree  $\ll$ 1% melts.

2. *Melt-dominated metasomatism.* Garnets that have 'normal' REE<sub>N</sub> compo-

sitions, with relatively flat  $MREE_N$  to  $HREE_N$  (Section 5.6 and Figure 5.6c) show an enrichment in Y, Ti and Zr content, compared to the most depleted compositions (Figure 5.7). These compositions are consistent with silicate melt-dominated metasomatism and overlap with those seen in harzburgitic and lherzolithic garnets at AT56, however Ti content in AT56 garnets also extend to much higher concentrations up to 2485 ppm (Armstrong et al., 2004).

Garnets with 'sloped'  $REE_N$  compositions (Section 5.6 and Figure 5.6d) display enrichment in Y but not in Zr or Ti (Figure 5.7). Calculated equilibrium liquids for these 'sloped' garnets are not a match for silicate melts - calculated basaltic melts are too LREE-enriched to match Midcontinent Rift basalts (Shirey, 1997) (Figure 5.14a) and calculated tonalitic melts have positive Eu anomalies not seen in natural tonalites (Rogers, 2002) (figure not shown). They do, however, have similar compositions to carbonatites and kimberlites. In particular, carbonated silicate melts calculated using the Girnir et al. (2013) partition coefficients are strongly depleted in Zr and Hf and have LREE and Nb concentrations similar to natural carbonatites (Bizimis et al., 2003; Tappe et al., 2006) (Figure 5.14b).

During percolation through the garnet peridotite lithosphere, this melt may become progressively depleted in HREE and Y and will evolve to more LREE and volatile-rich compositions (e.g., Navon and Stolper, 1987; Bedini et al., 1997). Therefore both the melt-dominated and fluid-dominated metasomatic signatures in Victor garnets can potentially be explained by the percolation of a single metasomatic agent, represented here by the melt in equilibrium with the 'sloped' garnet (Figure 5.14), as also suggested for Renard peridotites (Superior craton) by Hunt et al. (2012a) and for Slave peridotites (Aulbach et al., 2013).

### **Metasomatism of clinopyroxene xenocrysts**

Victor clinopyroxene xenocrysts are strongly LREE-enriched (Figure 5.8), unlike depleted peridotites, which are residual after melt extraction and typically have LREE-depleted compositions (e.g., residual abyssal peridotites; Johnson and Dick, 1992; Warren and Shimizu, 2010). This suggests either their secondary metasomatic origin or cryptic metasomatism of primary clinopyroxene by percolating low-degree melts.

However, major element compositions for these clinopyroxene xenocrysts are distinct to metasomatic clinopyroxene in dunite and harzburgite xenoliths that is not texturally equilibrated and have high Na and Cr compositions. They have similar major element compositions to texturally equilibrated clinopyroxene in Delta lherzolithic xenoliths (Section 5.5.3 and Table G.2), which suggests their LREE-enriched compositions are the result of cryptic metasomatism.

Calculated silicate liquids (basaltic and tonalitic) in equilibrium with clinopyroxene do not resemble either basalts from the Midcontinent Rift (Shirey, 1997) or natural tonalites (Rogers, 2002). A better compositional match is found between calculated carbonated silicate melts (Girnis et al., 2013) and kimberlite-carbonatite. These calculated melts have compositions intermediate between kimberlite and carbonatite - they have LREE content and Nb, Ta contents higher than those present in kimberlite and Zr, Hf anomalies similar to carbonatite melts. However, these calculated melts are not a perfect match to carbonatite melts as they do have corresponding Nb and Ta anomalies. A clear distinction between kimberlite and carbonatite melt metasomatism could therefore, not be made. Crystallisation from kimberlite-like melts just prior to eruption would, however, explain the apparent trace element disequilibrium between garnet and clinopyroxene (i.e., clinopyroxene melt compositions are a match to none of the garnet melt compositions).

### 5.13 Diamond stable portions of the lithosphere

Victor is a productive diamond mine, yet the typical depleted harzburgite signature that is normally expected at almost all kimberlite-hosted diamond deposits (e.g., Sobolev, 1977; Gurney, 1984a), is missing. The xenocryst population is predominantly lherzolithic and eclogitic / pyroxenitic; even though more depleted compositions, including dunite and harzburgite, are sampled in the xenoliths. In the following section, we discuss the likely diamond stable portions of the Victor lithosphere and their possible relation to the Victor diamond production.

### 5.13.1 Diamond stable lherzolite

Several compositional characteristics suggest that a thick cool diamond stable lherzolitic SCLM persisted below Attawapiskat after the Midcontinent Rift and into the Jurassic. The strongest evidence is from high shear wave velocities below Attawapiskat (Darbyshire et al., 2007, 2013; Faure et al., 2011; Schaeffer and Lebedev, 2013) that indicates the present-day lithosphere is about 220 km thick. During the Jurassic, the geotherm calculated from both xenolith and xenocryst data, indicates that the lithosphere was  $\sim 200$  km thick with a relatively broad "diamond window" of  $\sim 70$  km thickness. This geotherm is constrained by a very high proportion of diamond stable Cr-diopside xenocrysts (Figure 5.11a,c). After all the compositional filters of Nimis (1998, 2002) and Grütter (2009) (see Section 5.8.1) were applied, 74% (23 of the remaining 31) Cr-diopside grains originate inside the diamond stability field.

The mantle geotherm at Attawapiskat corresponds to between 35 and 40 mW/m<sup>2</sup> surface heat flow (Hasterok and Chapman, 2011) (Figure 5.11c). This is slightly "cooler" than the geotherm at Kyle Lake, which corresponds to 40 mW/m<sup>2</sup> (and slightly higher) surface heat flow resulting in a smaller "diamond window" of  $< 30$  km. Indicated depths for Victor lherzolitic garnets are predominantly in the graphite stability field  $< 4$  GPa (Cr-in-grt barometry; Grütter et al., 2006) (Figure 5.2a). However, their Cr-in-garnet pressures are *minimum* pressures, as bulk peridotite at Attawapiskat has not been shown to be Cr-saturated (i.e., precipitate chromite).

Similarly, MnO contents in only  $\sim 5\%$  of lherzolitic garnets are  $< 0.36$  wt% (Figure 5.17a), an approximate cutoff for diamond stable conditions by Grütter et al. (2004), based on Mn-in-garnet thermometry (Grütter et al., 1999). The thermometric expression of Grütter et al. (1999) does, however, ignore crystal chemical effects and, as a consequence, a number of lherzolitic garnet inclusions in diamond with elevated grossular content and relatively low Mg-number fall above the 0.36 wt% MnO cut-off. Therefore, the 5% diamond stable lherzolitic garnets indicated by MnO contents is considered a minimum value.

Ni-in-garnet temperatures for lherzolitic garnets range between 690 °C and 1036 °C (using the formulation of Canil, 1999). 87% of these lherzolitic garnets have temperatures above 860 °C, the minimum temperature for diamond sta-

bility on the combined xenolith and xenocryst geotherm (Figure 5.11c). Nearly half of Victor lherzolitic garnets analysed in this study have depleted compositions and display sinusoidal  $REE_N$  patterns (Figure 5.6), which are considered typical for peridotitic garnet inclusions in diamonds worldwide (e.g., Stachel et al., 2004). These combined results indicate that a high proportion of Victor lherzolitic garnets are diamond-stable and are consistent with the results reported in Januszczyk et al. (2013).

### 5.13.2 Diamond stable eclogites and pyroxenites

The majority of eclogite and pyroxenite xenoliths have Fe-Mg exchange temperatures  $< 980$  °C (Section 5.8.3) which according to the established geotherm for Attawapiskat, places them near the boundary between the graphite and diamond stability field (Figure 5.11). Additionally,  $Na_2O$  in garnet and  $K_2O$  in clinopyroxene in the majority of eclogite and pyroxenite xenoliths are low ( $< 0.09$  wt% and  $< 0.08$  wt%, respectively) (Figure 5.17b), which is usually taken as an indication that they are not derived from high pressures in the diamond stability field (McCandless and Gurney, 1989). Only one of the 17 eclogite xenoliths has garnet with elevated Na contents ( $Na_2O = 0.1$  wt%). However, garnet from five of the 19 pyroxenite xenoliths and 26% of the high Ca-eclogitic (G3) and low Ca-eclogitic/pyroxenitic (G4) garnets picked from mineral concentrate have  $Na_2O > 0.09$  wt% (Figure 5.17b).

As bulk rock chemistry exerts a major control on  $Na_2O$  in garnet, many high Mg# garnets originating in the diamond stability field may have low  $Na_2O$  (Grütter and Quadling, 1999). For example, garnet from diamondiferous high-Mg eclogites at Jericho do not classify as diamond stable on the basis of their low  $Na_2O$  (0.04 to 0.06%), even though garnet diamond inclusions at Jericho do have high  $Na_2O$  (Smart et al., 2009). Therefore, it is possible that more pyroxenite and eclogite xenoliths at Victor are derived from the diamond stability field, even if it is not indicated in their  $Na_2O$  content. High Na content in several high Mg pyroxenitic garnet xenocrysts can be taken as strong indication of their derivation from diamond-stable portions of the lithosphere.

## 5.14 Summary

### *Initial Melting in the Palaeoarchaeon*

Initial melting to form the proto-craton occurred at low pressures, likely in a mid-ocean ridge setting. This led to highly depleted harzburgitic and dunitic residues, with Mg#’s in olivine up to 93.6 (average Mg# 92.6). This depletion event likely occurred during the Palaeoarchaeon, with preservation of >3.2 Ga depletion ages in two xenoliths. There are no Palaeoarchaeon ages in the North Caribou superterrane, however these old ages do correlate with old crustal ages (3.8 - 3.5 Ga) at Assean Lake in Manitoba and the Inukjuak domain in Quebec (Böhm et al., 2000; Skulski et al., 2000; David et al., 2002, 2009). This supports the assertion that Attawapiskat is underlain by the Northern Superior superterrane, i.e., that the Winisk River Fault is the boundary between the North Caribou and Northern Superior superterranes (Sage, 2000).

### *Subduction at 2.7 Ga*

Further mantle melting, likely in an arc environment during subduction - accretion, occurred at 2.7 Ga with PGE<sub>N</sub> residual patterns preserved in two xenoliths. Hydrous melts infiltrating the overlying mantle wedge led to I-PGE alloy formation with radiogenic <sup>187</sup>Os/<sup>188</sup>Os (e.g., Matveev and Ballhaus, 2002; Brenker et al., 2003).

### *Midcontinent Rift at 1.1 Ga*

Midcontinent Rift basalts interacted with variably depleted peridotite. This led to P-PGE-enrichment and T<sub>RD</sub> ages ranging between 1.6 and 1.4 ± 0.2 Ga. Basaltic melts did not overprint the lithosphere and older, depleted domains are preserved (e.g., depleted sinusoidal garnets). Calculated basaltic equilibrium melts from neither garnet or clinopyroxene xenocrysts is similar to that of Midcontinent Rift basalts. The thermal impact of the rift is seen in the elevated geotherm at the 1.1 Ga Kyle Lake kimberlite, which due to extreme narrowing of the diamond window (Figure 4.8), must have led to some diamond destruction.

### *Diamond stable portions of the lithosphere*

Diamond-stable conditions were prevalent in the lithosphere after the thermal impact of the rift subsided and was present during the Jurassic when the At-

tawapiskat kimberlites erupted. This is indicated in the thick lithosphere of about 200 km, with a large diamond window compared to the PT conditions prevalent in the Proterozoic at nearby Kyle Lake.

Lherzolithic garnets have favourable compositions for diamond, in both their MnO content and Ni-in-garnet temperatures. Their sinusoidal REE<sub>N</sub> patterns are typical for harzburgitic and lherzolithic garnet inclusions in diamonds worldwide (e.g., Stachel et al., 2004). High Na content in high Mg eclogite and pyroxenite indicate that these lithologies also have the potential to be an important mantle source of diamonds in this region, as previously suggested for the AT56 kimberlite at Attawapiskat (Armstrong et al., 2004).

Figure 5.1: Thin sections of selected Delta xenoliths in plane-polarised light. Due to the small size of most the samples, they were not classified on modal abundance but rather on garnet chemistry.

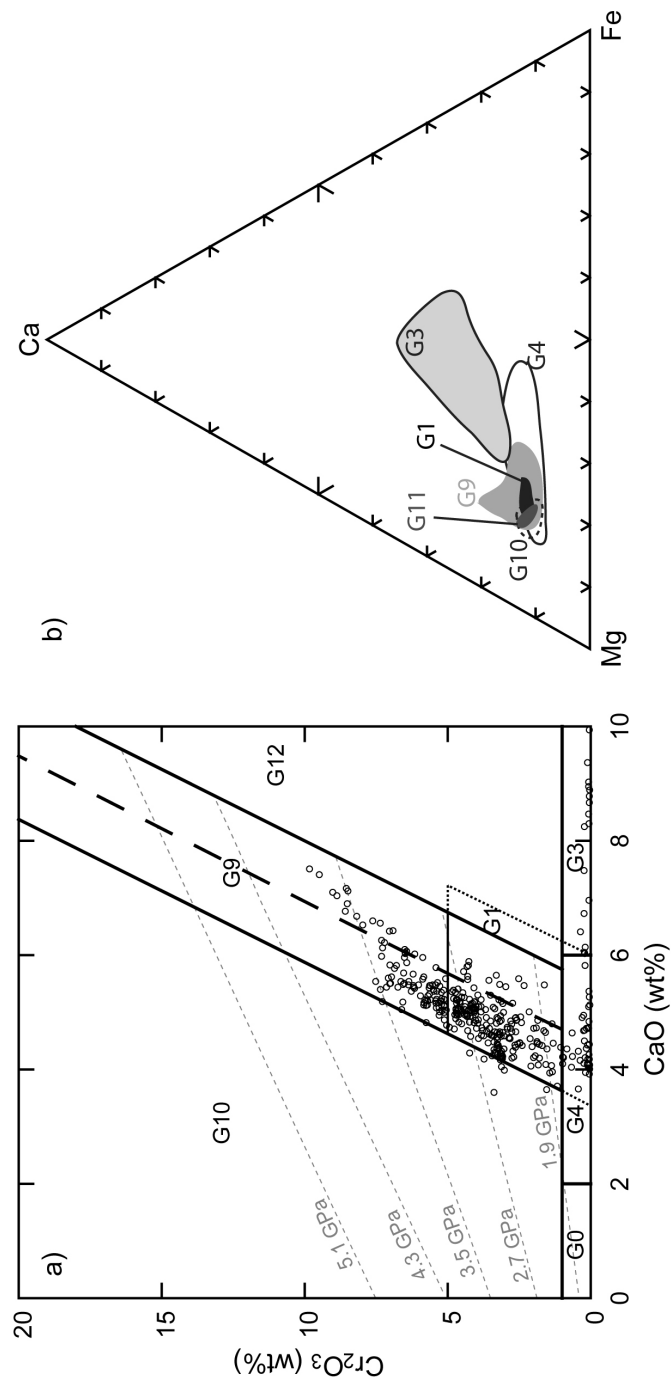

Figure 5.2: a) Victor garnet xenocryst compositions in Ca-Cr space with classification from Grütter et al. (2004) and Cr-saturation arrays (grey dashed lines) that indicate minimum pressure where peridotite does not contain chromite (Grütter et al., 2006). b) Garnet xenocryst Mg-Ca-Fe compositions.

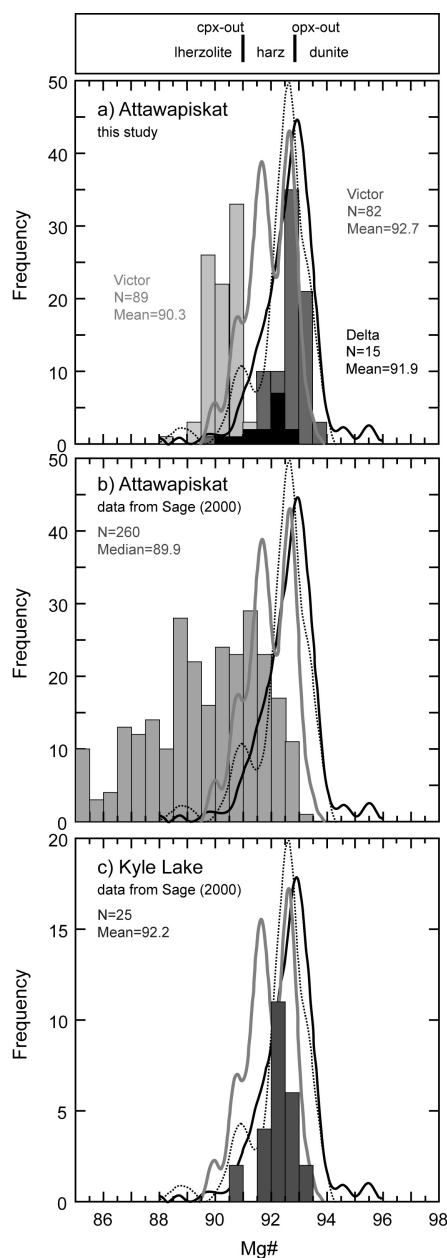

Figure 5.3: Histogram of olivine Mg# from this study compared to those of Kyle Lake and Attawapiskat reported in Sage (2000). a) Two populations of Victor olivine xenocrysts and olivine from Delta peridotite xenoliths; b) Compilation of olivine xenocrysts from several Attawapiskat kimberlites (Sage, 2000) and c) Kyle Lake olivine xenocrysts (Sage, 2000). Relative probability curves for olivine from the Slave (grey), Kaapvaal (black) and North Atlantic (dashed) cratons are shown for reference (compilation of Pearson and Wittig, 2008).

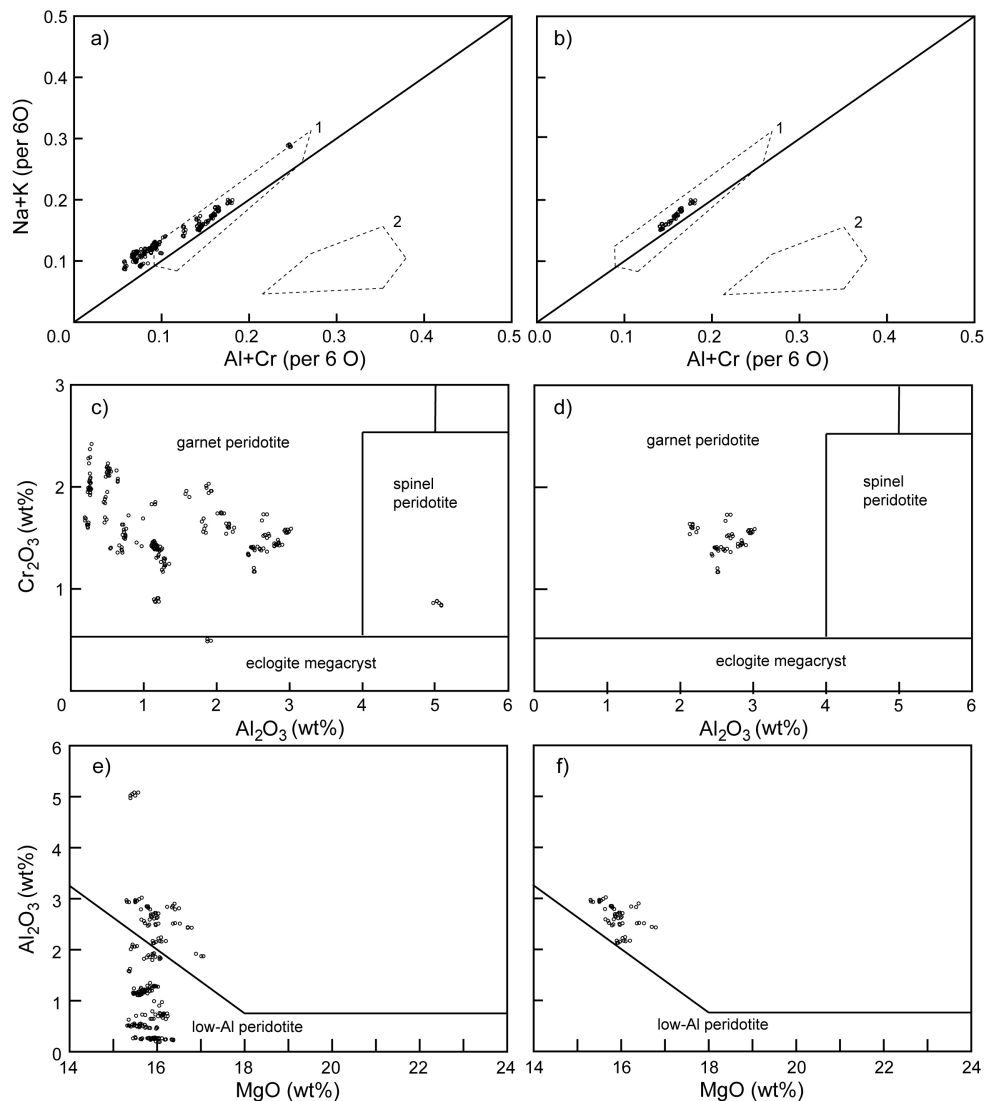

Figure 5.4: Compositional filters applied to clinopyroxene grains prior to geothermobarometry calculations. a) and b) Filter to distinguish between jadeite (field 1 for garnet stability field) and Tschermak (field 2 for spinel stability field) components (Sobolev et al., 1992). c) and d) Cr<sub>2</sub>O<sub>3</sub> and Al<sub>2</sub>O<sub>3</sub> compositions, used to distinguish different mantle lithologies after Ramsay and Tompkins (1994) and Ramsay (1995). e) and f) Low-Al and low-Mg grains were removed as they may be due to carbonatite metasomatism (Nimis, 1998).

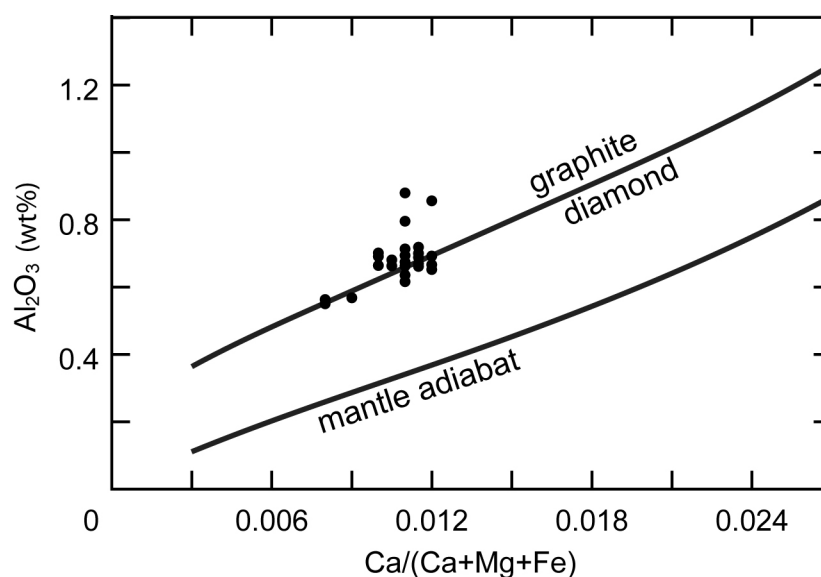

Figure 5.5: Al<sub>2</sub>O<sub>3</sub> vs Ca/(Ca+Mg+Fe) for Victor orthopyroxene xenocrysts. Grütter (2009) has shown that a coexisting equilibrium assemblage of cpx and opx in garnet lherzolite may record mutually consistent compositional arrays and therefore, that the graphite-diamond transition (Kennedy and Kennedy, 1976) and the mantle adiabat ( $T = 1300\text{ }^{\circ}\text{C}$ ) can be interpolated into orthopyroxene compositional space. These orthopyroxenes are lherzolitic and straddle the graphite-diamond transition.

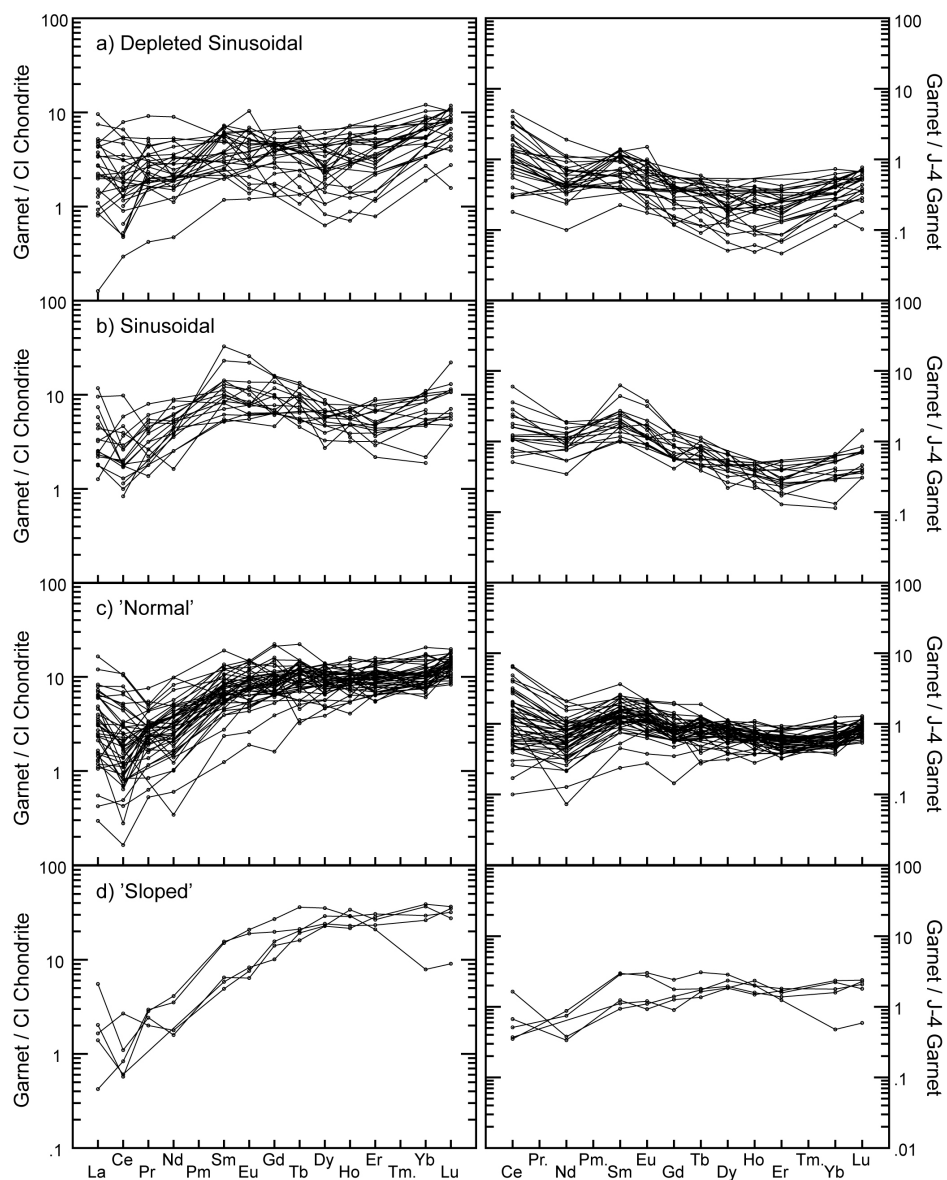

Figure 5.6: REE compositions for garnet xenocrysts normalised to chondrite Sun and McDonough (1989) and J4 (a Jagersfontein garnet with a primitive mantle composition (Stachel et al., 1998, and references therein). a) Sinusoidal garnets with the most depleted Y and Zr concentrations. These concentrations overlap with those of harzburgitic and lherzolithic garnets from Kyle Lake (Scully et al., 2004). b) Sinusoidal garnets with more Zr enrichment indicative of mild fluid-metasomatism. These garnets still show good overlap with those from Kyle Lake (Scully et al., 2004) c) "Normal" garnet with approximately flat chondrite normalised MREE to HREE. The J4 normalised plot show that these are at primitive mantle concentrations. d) Melt metasomatised garnet with enriched MREE to HREE relative to both chondrite and J4.

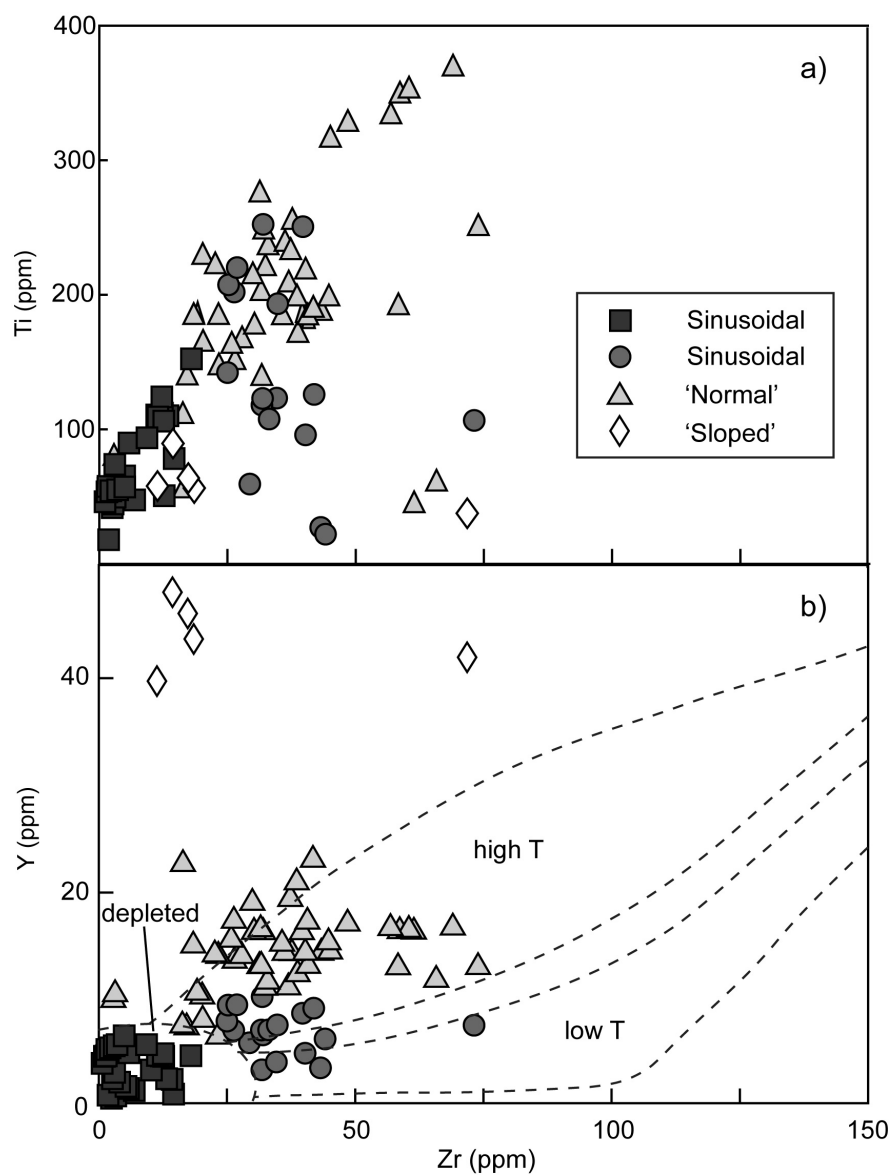

Figure 5.7: Garnet Ti-Y-Zr compositions for the four main groups of lherzolitic garnets, with divisions based on their combined  $REE_N$  and trace element compositions. Fields for depleted and low temperature (fluid) and high temperature (melt) metasomatism from Griffin and Ryan (1995).

Figure 5.8: REE compositions for clinopyroxene xenocrysts. All data normalised to Sun and McDonough (1989).

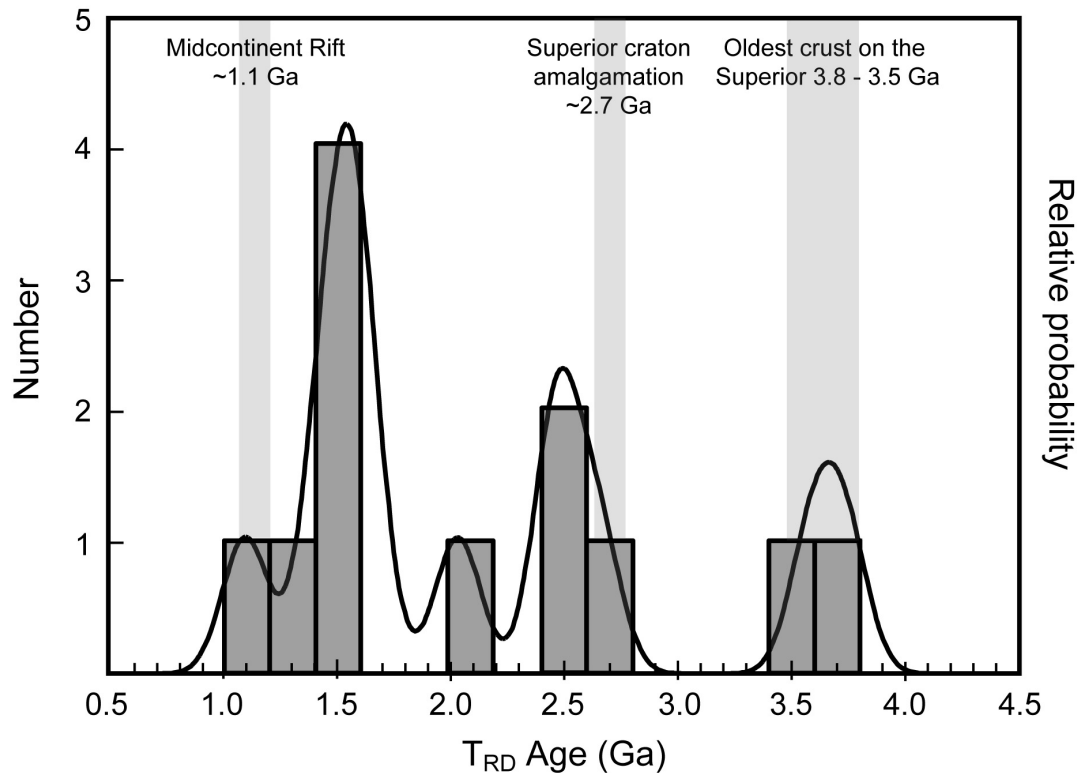

Figure 5.9: Relative probability plot for the  $T_{RD}$  ages for olivine from Delta xenoliths with unradiogenic  $^{187}\text{Os}/^{188}\text{Os}$ , calculated using equations given in Shirey and Walker (1995) and the O-chondrite reservoir ( $^{187}\text{Os}/^{188}\text{Os} = 0.1283$ ; Walker et al., 2002). Also included are a whole-rock  $T_{RD}$  age for a pyroxenite from Victor (Chapter 3) and three peridotite whole rocks from Kirkland Lake (Pearson et al., 1997). A uniform error on all  $T_{RD}$  ages was used, to avoid any over-emphasis on samples with higher analytical precision.

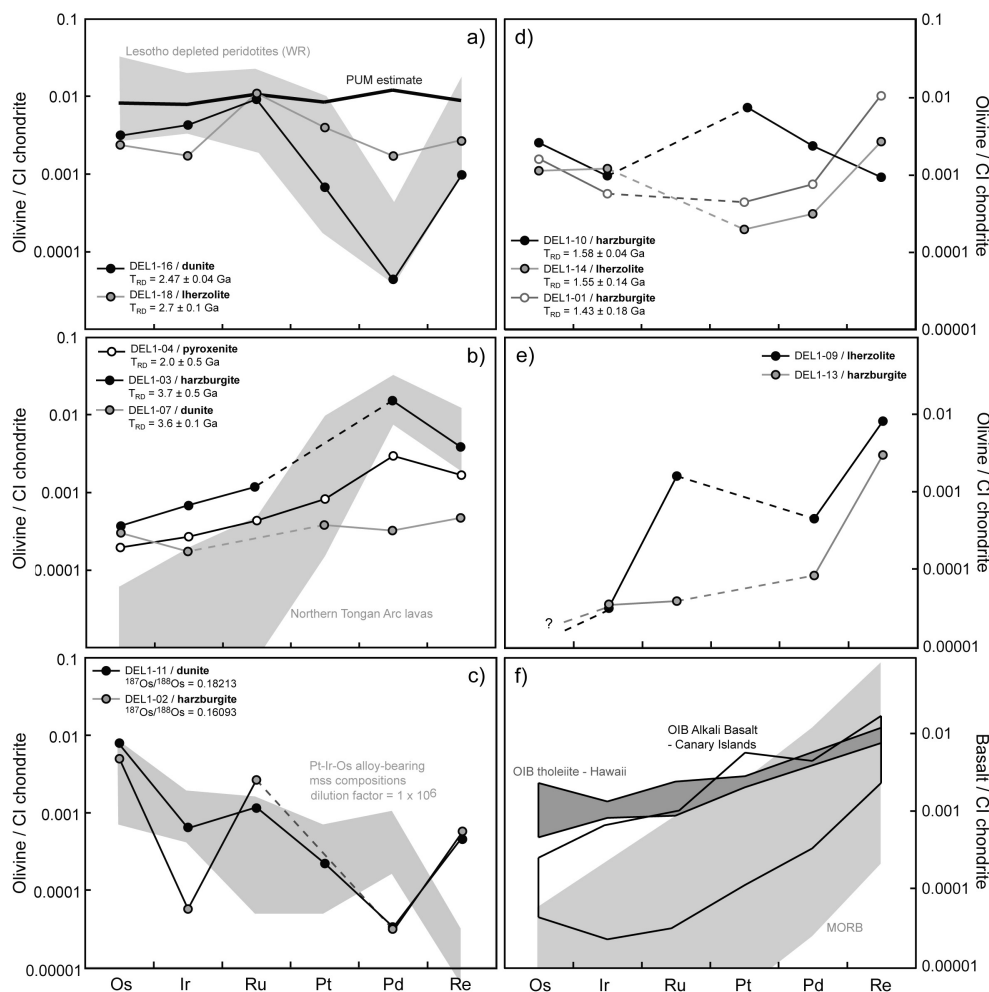

Figure 5.10: PGE compositions for samples grouped according to their  $^{187}\text{Os}/^{188}\text{Os}$  and calculated  $T_{RD}$  ages. a.) Samples with 2.7 to 2.5 Ga  $T_{RD}$  ages. Compositions for Lesotho depleted peridotites (WR) from Pearson et al. (2004) and the PUM estimate from Becker et al. (2006). b.) Samples with Palaeoarchaean  $T_{RD}$  ages, and pyroxenite with a Proterozoic  $T_{RD}$  age. Composition for Northern Tongan Arc lavas from Dale et al. (2012). c.) Os-rich samples with radiogenic  $^{187}\text{Os}/^{188}\text{Os}$ . Composition for Pt-Ir-Os alloy-bearing monosulphide solid solution (mss) from Griffin et al. (2002), which had to be diluted by a factor of  $1 \times 10^6$  to be comparable to inclusions in olivine. d.) Samples with 1.6 to 1.4 Ga  $T_{RD}$  ages, with P-PGE and Re enrichment similar to the basalts in e. e.) Two samples with extremely low Os content, for which no  $^{187}\text{Os}/^{188}\text{Os}$  and  $T_{RD}$  determinations could be made. f.) Basalt  $\text{PGE}_N$  compositions compiled from the literature. Range for tholeiitic ocean island basalts (OIB) from Ireland et al. (2009) and alkali OIB from Day et al. (2010). Day (2013) reports the average and standard deviations for both these localities. Mid-ocean ridge basalts (MORB) from Rehkämper et al. (1999), Bezos et al. (2005), Gannoun et al. (2007) and Dale et al. (2008). All compositions normalised to CI Chondrite of Horan et al. (2003).

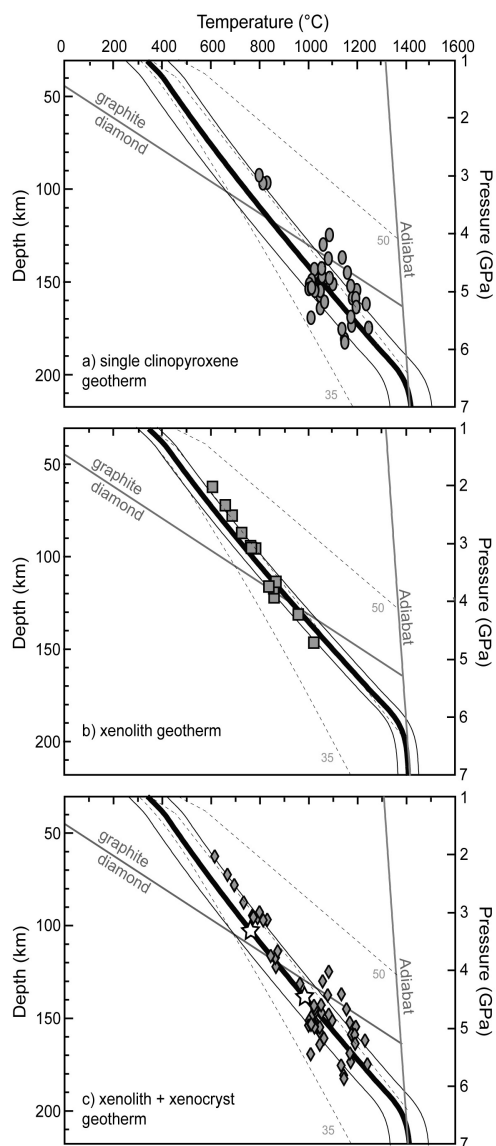

Figure 5.11: Fitplot geotherms calculated using both xenoliths and xenocrysts from Attawapiskat. Grey dashed lines are geotherms that correspond to 35, 40 and 50  $\text{mW/m}^2$  surface heat flow (Hasterok and Chapman, 2011). Graphite-diamond transition from Day (2012). Pressure (GPa) was converted to depth (km) using a constant density conversion of 0.0324. a) Geotherm for single clinopyroxenes from Victor b) Harzburgite, lherzolite and pyroxenite xenolith geotherm from Delta and Victor. c) Combined xenolith and xenocryst geotherm, which corresponds to between 35 and 40  $\text{mW/m}^2$  surface heat flow. Bimineralic eclogites and pyroxenites have temperatures between 770 and 980  $^{\circ}\text{C}$  (range indicated by stars); which places them around the transition between the graphite and diamond stability fields when plotted on this combined xenocryst/xenolith geotherm.

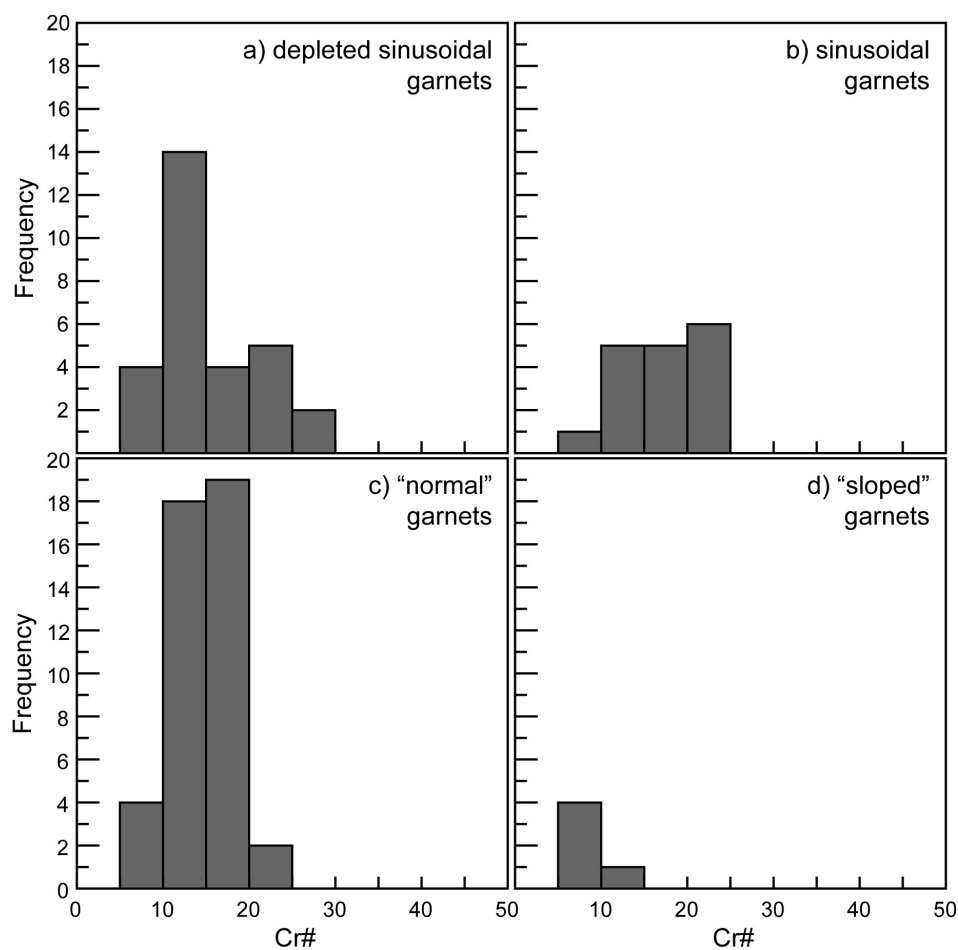

Figure 5.12: Cr#, given as  $\text{Cr}/(\text{Cr}+\text{Al}) \times 100$ , for different groupings of lherzolitic garnet xenocrysts from Victor. Garnets with the most depleted compositions that were only affected by mild fluid-metasomatism (Section 5.12.3) have the highest Cr# up to to 30. "Sloped" garnets, that were affected by melt metasomatism have the lowest average Cr#.

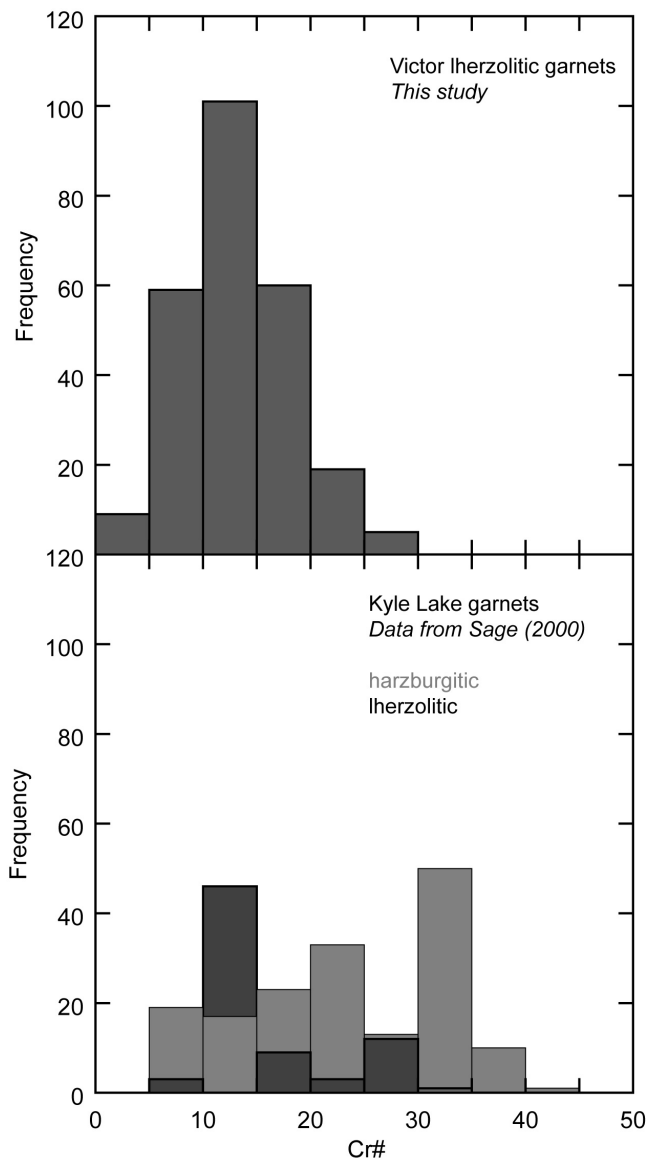

Figure 5.13: Cr#, given as  $\text{Cr}/(\text{Cr}+\text{Al}) \times 100$ , for lherzolitic garnets from Victor compared to harzburgitic and lherzolitic garnets from Kyle Lake (Sage, 2000). Cr# in the Kyle Lake harzburgites have a higher mode than Victor, whereas the mode for Cr# in Kyle Lake lherzolites is similar to lherzolites at Victor.

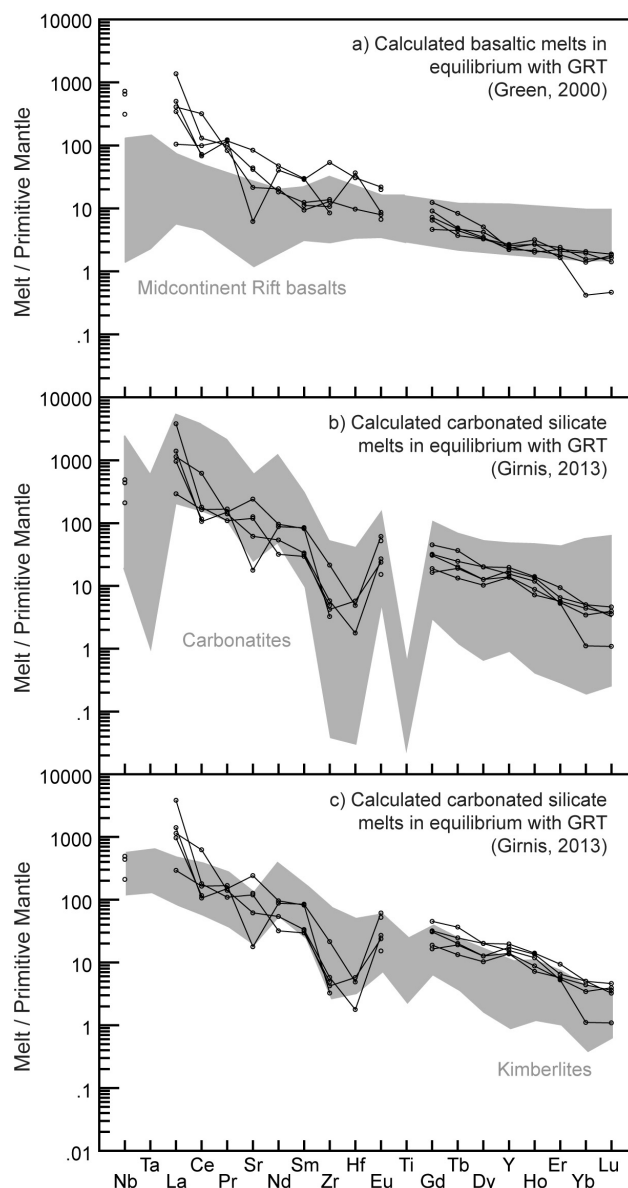

Figure 5.14: Calculated liquids in equilibrium with the 'sloped' lherzolitic garnet xenocrysts, normalised to the primitive mantle composition of (Sun and McDonough, 1989). a) Basaltic melts using partition coefficients for garnet and basaltic melt (Green et al., 2000). These are not a good compositional match for Midcontinent Rift basalts (Shirey, 1997). b and c) Carbonatitic / kimberlitic melts calculated using partition coefficients for garnet and carbonated silicate melt (Girnis et al., 2013). These calculated melts have a closer compositional match to natural carbonatites (Bizimis et al., 2003; Tappe et al., 2006) than to kimberlites (Kaminsky et al., 2002; le Roex et al., 2003; Birkett et al., 2004; Nielsen et al., 2009; Patterson et al., 2009).

Figure 5.15: Calculated melts in equilibrium with clinopyroxene xenocrysts, normalised to the primitive mantle composition of (Sun and McDonough, 1989). a) Basaltic melts using partition coefficients for clinopyroxene and basaltic melt (Green et al., 2000). These are not a good compositional match for Midcontinent Rift basalts (Shirey, 1997). b and c) Carbonatitic / kimberlitic melts calculated using partition coefficients for clinopyroxene and carbonated silicate melt (Girnis et al., 2013). These calculated melts have an intermediate composition between kimberlite (Kaminsky et al., 2002; le Roex et al., 2003; Birkett et al., 2004; Nielsen et al., 2009; Patterson et al., 2009) and carbonatite (Bizimis et al., 2003; Tappe et al., 2006).

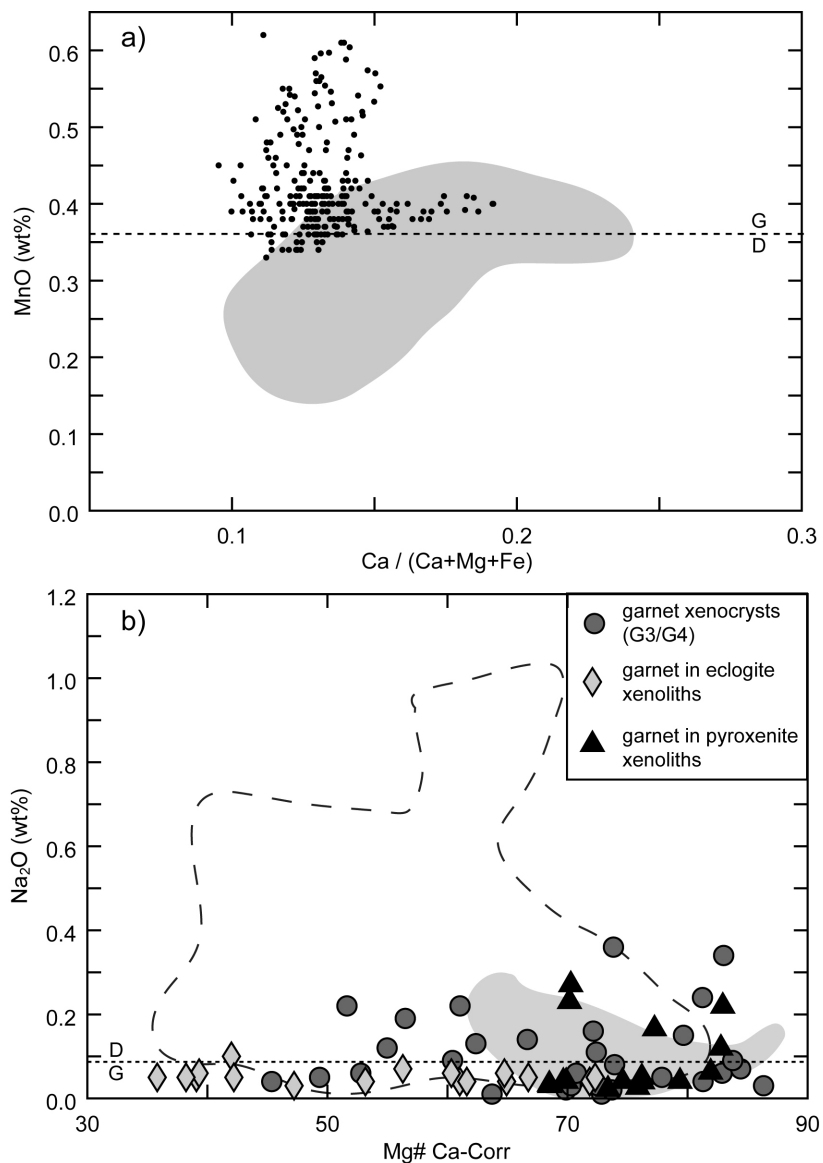

Figure 5.16: a) MnO vs Ca/(Ca+Mg+Fe) in lherzolitic garnet xenocrysts. Dashed line is the traditional cut-off for diamond-stable lherzolitic garnets (MnO < 0.36 wt%; Grütter et al., 2004). Shaded field for garnet diamond inclusions (database of Stachel and Harris, 2008). b) Na content vs Ca-corrected Mg# in xenocryst garnets and garnets from eclogite and pyroxenite xenoliths. The dashed line is the cut-off for diamond stable eclogitic garnets (Na<sub>2</sub>O > 0.09 wt%; McCandless and Gurney, 1989). The shaded field is for pyroxenitic garnet diamond inclusions and the dashed field for eclogitic diamond inclusions (database of Stachel and Harris, 2008). 'D' is for diamond stability field and 'G' is for graphite stability field.

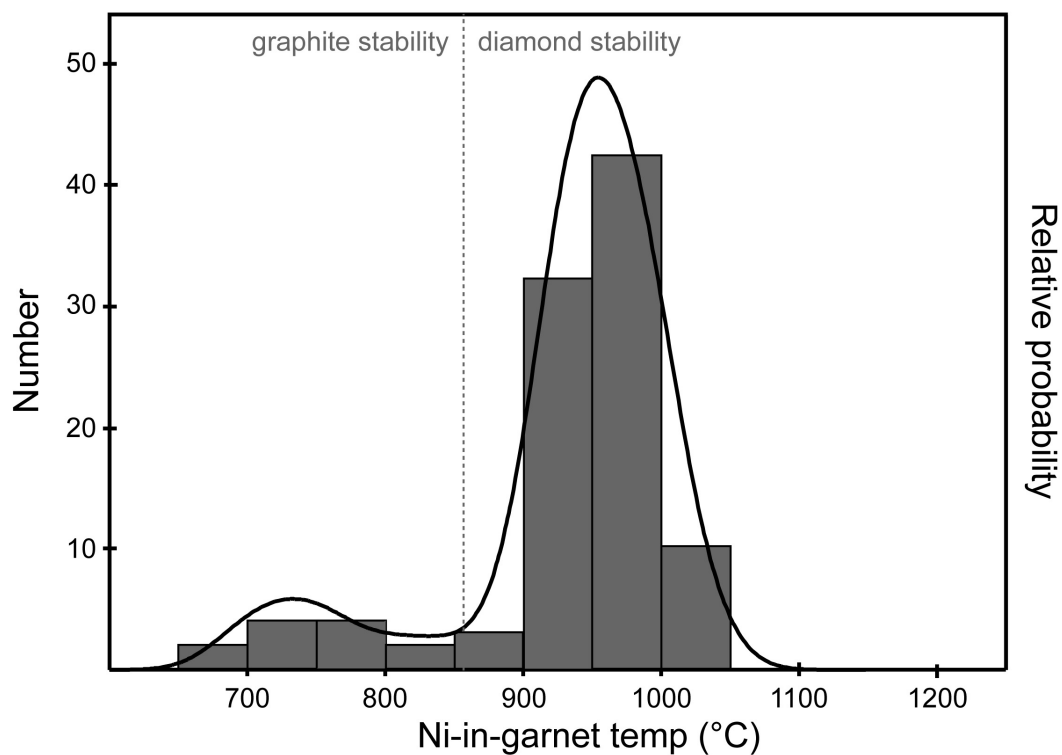

Figure 5.17: Ni-in-garnet thermometry for lherzolitic garnet xenocrysts, using the formulation of Canil (1999). 87% of these lherzolitic garnet xenocrysts have temperatures above 860 °C, the minimum for diamond stability as indicated by the combined xenolith and xenocryst geotherm in Figure 5.11c. Bin sizes for the histogram are 50 °C, equivalent to the average error on mantle geothermometers. The probability distribution was plotted in Isoplot (Ludwig, 1991).

## Chapter 6

### Conclusions

#### 6.1 Composition of the SCLM below the Attawapiskat area

Similar to the results in Sage (2000) and Scully (2000), Victor xenocrysts analysed during this study are predominantly lherzolitic (G9 garnets, clinopyroxene and orthopyroxene), however, more depleted compositions are also present. One population of Victor olivine xenocrysts has high Mg# from 92.0 up to 93.6, indicating their origin from highly depleted harzburgite to dunite, comparable to many xenoliths from Delta, as well as the nearby Kyle Lake kimberlites (Sage, 2000). A second population of Victor olivine xenocrysts with lower Mg# around 89-90, likely represent melt infiltration into the SCLM. Attawapiskat has a higher proportion of eclogite and pyroxenite, in both the xenocrysts and xenoliths, than the lithosphere sampled by the Kyle Lake kimberlites (Sage, 2000).

#### 6.2 Formation of the western Superior SCLM

##### *Shallow versus deep melting*

High Cr# in garnet and positive slopes in depleted garnet HREE<sub>N</sub> indicate that initial melting to form the proto-cratonic root must have occurred in both the garnet and spinel stability fields, similar to fractional polybaric melting occurring at modern mid-ocean ridges (e.g., Kelemen et al., 1998; Stachel et al., 1998). This rules out plume subcretion processes (e.g., Boyd, 1989; Arndt et al., 1998; Aulbach, 2012) as a viable mechanism for Superior lithosphere formation. High degrees of partial melting (~40%) are indicated by olivines with high Mg# up to 93.6, resulting in harzburgitic to dunitic residues (e.g.,

Kubo, 2002; Bernstein et al., 2007).

#### *Age of the lithosphere*

$T_{RD}$  ages of  $3.7 \pm 0.5$  Ga and  $3.6 \pm 0.1$  Ga in sulphides or PGE inclusions in olivine, require the existence of a depleted mantle reservoir beneath the Attawapiskat area since at least the Palaeoarchaeon. These ages do not correspond to crustal ages in the North Caribou superterrane, which are  $<3.0$  Ga (e.g., Thurston et al., 1991; Stevenson, 1995); however they correspond with gneisses in the Pikwitonei domain of the Northern Superior superterrane that were dated to about 3.6 Ga (Böhm et al., 2000; Skulski et al., 2000). Since the Attawapiskat kimberlites erupt near the boundary of the North Caribou and Northern Superterrane (Figure 2.1), these Palaeoarchaeon ages in Attawapiskat peridotites support the notion that these kimberlites mainly sampled lithospheric mantle from the Northern Superior superterrane.

#### *Role of eclogites in SCLM formation*

The low-Mg eclogites have a shallow origin as plagioclase-bearing protoliths likely in former oceanic crust. This is supported by their generally flat MREE to HREE compositions, the presence of kyanite and a positive Eu anomaly in the high-Ca sample, and  $\delta^{18}\text{O}$  values in three low-Mg eclogites that are higher than the pristine mantle value. The origin of these eclogites as oceanic crust requires that they were emplaced into the SCLM by subduction, in general agreement with seismic studies in the western Superior (White et al., 2003; Musacchio et al., 2004) that image dipping subducting slabs into the lower crust and upper mantle. Moreover, there is abundant evidence from crustal geology that suggests subduction - accretion processes and associated arc magmatism contributed to the amalgamation of the western Superior craton (see references in Chapter 2), similar to mechanisms for craton formation and stabilisation advocated by Helmstaedt and Schulze (1989) and Pearson and Wittig (2008).

The radiogenic  $^{187}\text{Os}/^{188}\text{Os}$  of the majority of eclogites - similar to Archaean komatiites and basalts - requires long term isolation of a high Re/Os component from the convecting mantle after melt extraction. A Neoarchaeon age for the formation of these eclogites is therefore likely, consistent with the timing of  $\sim 2.7$  Ga subduction and amalgamation of the Superior craton (e.g., Langford

and Morin, 1976) and  $\sim 2.8$ - $2.6$  Ga U-Pb crystallisation ages for lower crustal granulite xenoliths from Attawapiskat (Moser et al., 1997), which may be the lower grade metamorphic equivalent to the low-Mg eclogites (e.g., Green and Ringwood, 1972; Toft et al., 1989).

#### *Impact of subduction on the SCLM*

Partial melting of the low-Mg eclogites and interaction of these melts with overlying peridotite in the mantle wedge resulted in the formation of the high-Mg eclogites and pyroxenites. Their bulk compositions, LREE<sub>N</sub>-enriched trace element patterns and in particular, occurrence of unradiogenic  $^{187}\text{Os}/^{188}\text{Os}$  (less than the  $^{187}\text{Os}/^{188}\text{Os}$  of O-chondrites = 0.1283; Walker et al., 2002), are consistent with formation by reaction of broadly siliceous melts (generated from the melting of low-Mg eclogites) with depleted peridotite.

$T_{RD}$  ages of  $\sim 2.7$  Ga are preserved in two samples that have residual PGE<sub>N</sub> patterns, which indicates that additional melting occurred at this time, likely corresponding to subduction events, similar to that inferred for samples from the Kaapvaal craton (see references in Section 5.10). Hydrous melts infiltrating the overlying mantle also, in some cases, introduced radiogenic Os. While these results indicate that some melt / fluid percolation into the overlying mantle took place as a result of subduction, this was not sufficient to lead to craton destruction, as suggested for the North China craton (e.g., Peng et al., 1986; Ling et al., 2013).

### **6.3 Impact of the Midcontinent Rift**

In the Attawapiskat area, the thermal impact of the Midcontinent Rift is seen in the elevated palaeogeotherm derived for the 1.1 Ga Kyle Lake kimberlite (Figure 4.8). Some diamond destruction must have occurred in response to thermal impact of the rift and is indicated by extreme narrowing of the diamond window at 1.1 Ga and high mantle residence temperatures recorded in T1 diamonds. These diamonds also preserve evidence for platelet degradation, which typically occurs due to thermal pulses and / or deformation events in the SCLM (Woods, 1986), and may relate to the Midcontinent Rift, which affected the Superior craton around the time of kimberlite eruption.

In the Delta peridotite xenoliths, there is evidence that magmas related to the Midcontinent Rift interacted with variably depleted peridotite. This led to P-PGE-enrichment and  $T_{RD}$  ages ranging between 1.6 and  $1.4 \pm 0.2$  Ga. These melts did not overprint the lithosphere though, and older depleted domains are preserved (e.g., depleted sinusoidal garnets). In particular, it is significant that the trace element compositions of calculated equilibrium melts from neither garnet or clinopyroxene (Victor xenocrysts) are similar to that of Midcontinent Rift basalts.

## 6.4 Diamonds in the Attawapiskat lithosphere

Diamond-stable conditions were prevalent in the lithospheric mantle after the thermal impact of the rift subsided, i.e., during the Jurassic when the Attawapiskat kimberlites erupted. This is indicated in the thick lithosphere of about 200 km, with a large diamond window of 80 km, compared to the PT conditions prevalent in the Mesoproterozoic at the nearby Kyle Lake kimberlites.

The  $^{13}\text{C}$ -depleted composition for one diamond from U2 indicates an eclogitic or pyroxenitic paragenesis. The strong mode around  $-5.7$  ‰ for the main population at U2, however, may represent both peridotitic and eclogitic parageneses, as also suggested by the compositions of Victor garnet xenocrysts. Lherzolitic garnets have diamond-favourable compositions, in both their MnO contents and their sinusoidal  $\text{REE}_N$  patterns, which are typical for harzburgitic and lherzolitic garnet inclusions in diamonds worldwide (e.g., Stachel et al., 2004). These results are consistent with the high proportion of Victor diamond-stable peridotitic garnets reported in Januszczyk et al. (2013). Additionally, high Na content in several high Mg pyroxenitic garnet xenocrysts from Victor can be taken as strong indication of their derivation from diamond-stable portions of the lithosphere.

These results are contrary to the prevalent mindset in diamond exploration that depleted harzburgitic compositions need to be present in order for a diamondiferous kimberlite to be productive (e.g., Sobolev, 1977; Gurney, 1984a). However, this study clearly shows that diamondiferous kimberlites sampling lherzolitic compositions should not be overlooked.

Diamonds sampled at Attawapiskat likely formed after the Midcontinent Rift, as indicated by their low degrees of nitrogen aggregation compared to diamonds from the Mesoproterozoic T1 kimberlite. The overall  $\delta^{13}\text{C}$  distribution for U2 diamonds is distinct to T1 diamonds (and other Superior diamond sources), further suggesting that U2 diamonds are not related to the older pre-rift diamonds.

Diamond growth after a major tectonothermal event is not unique to the Superior. Examples from other cratons are Premier and Venetia on the Kaapvaal craton, where lherzolitic diamond formation (1.93 Ga and 2.0 Ga, respectively; Richardson et al., 1993, 2009) post-date magmatism of the Bushveld Igneous Complex at  $\sim 2.05$  Ga. At Artemisia in the northern Slave craton, diamonds were sampled at  $\sim 616$  Ma (U-Pb perovskite; Armstrong et al., 2012), after the plume impact associated with the MacKenzie large igneous province ( $\sim 1.27$  Ga; LeCheminant and Heaman, 1989). The lherzolitic diamond population at Ellendale on the Kimberley craton has an age of  $\sim 1.4$  Ga, younger and unrelated to Archaean craton formation (Graham et al., 1999; Luguét et al., 2009; Smit et al., 2010) and likely associated with later reworking events in the lithospheric mantle.

## Appendix A

### Major element data for Victor eclogite and pyroxenite xenoliths

All major element data in weight %. "-" indicates not measured or below detection.

$2\sigma$  for the major element data is the standard deviation of the mean of 'n' analytical spots per xenolith.

FeO tot as ferrous iron.

## Appendix B

### Trace element data for Victor eclogite and pyroxenite xenoliths

Data are averages for "n" analyses per xenolith, given in ppm. "-" indicates below detection.  $2\sigma$  errors given as the average of the in-run precision for "n" analyses.

Table B.1: Garnet trace element compositions of Victor high-Ca and low-Mg eclogites

MC-ICP-MS  $^{87}\text{Sr}/^{86}\text{Sr}$  are reported as the weighted average of  $n^*$  number of line scans. 2 standard errors (SE) report the in-run precision. Calculated  $^{87}\text{Sr}/^{86}\text{Sr}$  are for the time of kimberlite eruption ( $\sim 180$  Ma; Janaszczak et al., 2013). " $n^*$ " indicates not measured or below detection.

Table C.2: Garnet oxygen isotopic compositions of Victor eclogites and pyroxenites

Sample		n	$\delta^{18}\text{O}$	$2\sigma$

VIC8401	opx-bearing pyroxenite	3	5.64	0.38

Oxygen isotope data is given in per mill (‰) and as the average of "n" analytical spots. The total uncertainty on each analytical spot is the combination of uncertainty on the mean UAG value for the session, the standard deviation of UAG, and uncertainty in the matrix correction. Analyses for each sample were averaged, with the uncertainty for each sample given as the largest error of the single spot analyses.

These data relate to CCIM Project 1110.

Table C.3: Whole Rock Re-Os isotopic compositions of Victor eclogites and pyroxenites

Sample	Re (ppb)	Os (ppb)	Common Os (ppb)	$^{187}\text{Re}/^{188}\text{Os}$	2SE	$^{187}\text{Os}/^{188}\text{Os}$	2SE	$T_{RD}$ (Ga)	$T_{MA}$ (Ga)	$\gamma_{\text{Os}}$ present day	$\gamma_{\text{Os}}$ initial

Common Os is given as the Os concentration after in-grown  $^{187}\text{Os}$  is subtracted. Initial  $\gamma_{\text{Os}}$  calculated at the time of kimberlite eruption ( $\sim 180$  Ma; Januszczak et al., 2013). 2 standard errors include the in-run precision, the uncertainty in the concentration and isotopic composition of the blank, and the uncertainty in the spike calibration.

$2\sigma$  uncertainties for  $\delta^{13}\text{C}$  include in-run precision (internal error), between spot error and uncertainty related to instrumental mass fractionation and reference material composition (external error). All results are reported relative to the international Vienna Pee-Dee Belemnite standard (V-PDB).

$2\sigma$  uncertainties for nitrogen concentration include within-spot counting statistics and the error in the nitrogen abundance calibration. An additional error of  $\sim 10\%$  ( $2\sigma$ ) is associated with uncertainty in the FTIR-determined nitrogen abundance, and should be used when comparing data with FTIR-determined concentrations. '-' indicates not measured.

These data relate to CCIM Project 1202.

$2\sigma$  uncertainties for  $\delta^{13}\text{C}$  include in-run precision (internal error), between spot error and uncertainty related to instrumental mass fractionation and reference material composition (external error). All results are reported relative to the international Vienna Pee-Dee Belemnite standard (V-PDB).

$2\sigma$  uncertainties for nitrogen concentration include within-spot counting statistics and the error in the nitrogen abundance calibration. An additional error of  $\sim 10\%$  ( $2\sigma$ ) is associated with uncertainty in the FTIR-determined nitrogen abundance, and should be used when comparing data with FTIR-determined concentrations. '-' indicates not measured.

These data relate to CCIM Project 1202.

## Appendix E

### Mineralogy and calculated temperatures for the Delta and Victor xenoliths

## Appendix F

### Major element data for Victor xenocrysts

All major element data in weight %. "-" indicates not measured or below detection.

FeO tot as ferrous iron.

Table F.1: Major element compositions of Victor G9 xenocrysts

Sample	SiO <sub>2</sub>	TiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	Cr <sub>2</sub> O <sub>3</sub>	V <sub>2</sub> O <sub>3</sub>	FeO tot	MnO	MgO	CaO	Na <sub>2</sub> O	K <sub>2</sub> O	P <sub>2</sub> O <sub>5</sub>	NiO	Total

## Appendix G

### Major element data for Delta xenoliths

All major element data in weight %. "-" indicates not measured or below detection.

$2\sigma$  is the standard deviation of the mean of 'n' analytical spots per xenolith.

FeO tot as ferrous iron.

Table G.1: Garnet major element compositions of Delta xenoliths

## Appendix H

### Trace element data for Victor xenocrysts

Data are given in ppm. "-" indicates below detection.

$1\sigma$  errors given as the average of the in-run precision for "n" analyses.

Table H.1: Trace element compositions of Victor G9 xenocrysts - 1

"bd" and "-" refers to analyses below detection or not applicable.

2SE uncertainties for  $^{187}\text{Os}/^{188}\text{Os}$  include the in-run precision, the uncertainty in the concentration and isotopic composition of the blank and the uncertainty in the spike calibration.

Os concentrations determined by NTIMS. Errors include the in-run precision, uncertainty in the blank concentration and error magnification due to overspiking.

2SE uncertainties for  $^{187}\text{Re}/^{188}\text{Os}$  include in in-run precision, the uncertainty in the concentration and isotopic compositions of the blanks.

PGE and Re concentrations determined by ICP-MS. Errors include the in-run precision and the uncertainty in the blank concentration.

$T_{RD}$ ,  $T_{MA}$  and  $\gamma_{\text{Os}}$  calculations relative to the O-chondrite reservoir ( $^{187}\text{Os}/^{188}\text{Os} = 0.1283$ ;  $^{187}\text{Re}/^{188}\text{Os} = 0.422$ ; Walker et al., 2002).

$^{187}\text{Os}/^{188}\text{Os}_{(i)}$  is the initial isotopic composition calculated at the time of kimberlite eruption ( $\sim 180$  Ma; Januszczak et al., 2013).

## Appendix J

### Disequilibrium evaluation in Delta and Victor xenoliths

Table J.1: Tests for disequilibrium between two pyroxenes after Grütter (2009)

Sample	Temperature (°C ) Ca-in-Opx Brey and Kohler (1990) modified by Nimis and Grütter (2009) if under 900 °C using Nickel and Green (1985) pressure	Difference in Temperature Taylor (1998) - Ca-in-Opx	Disequilibrium between Pyroxenes? for samples with diff more than 90 °C
