DEDICATION

To my parents

ABSTRACT

Reservoir deposition occurs over geologic time and, thus, most reservoirs are heterogeneous in nature. Some common forms of heterogeneity are the presence of layers and the presence of different zones of fluids and/or rocks in the formation. When an enhanced recovery method, such as steam-flooding, is implemented for a heavy-oil reservoir, the reservoir resembles a composite reservoir. Because of the gravity override effect, the fluid front of the swept region not vertical, but tilted or inclined. Sometimes, reservoirs are accompanied by a bottom-water or a gas-cap zone of various sizes. In the presence of a bottom-water or a gas-cap zone, the well is partially-penetrated to avoid or delay the water or gas coning problem.

In this study, a new analytical solution for multi-layer, composite reservoirs with pseudosteady state interlayer crossflow has been developed. Fluid flow in the reservoir has been treated as a generalized eigenvalue problem. The developed analytical solution for an n-layer composite reservoir is applicable for a tilted or irregularly-shaped discontinuity boundary, and for closed, constant-pressure, and infinite outer-boundary conditions. For tilted front cases, a pseudosteady-state (pss) flow period exists in some average sense and pss analysis will result in considerable underestimation of the swept volume for tilted front reservoirs. A correction factor has been developed to correct the estimated swept volume from pss analysis. Well-test analysis under infinite and finite bottom-water conditions has been considered and the effect of aquifer size on well-test analysis has been investigated.

For partially-penetrating wells in multi-layer reservoirs, new analytical expressions for the pseudoskin factor have been developed for both closed top and bottom boundaries, and with bottom-water zones and/or gas caps. Evaluation of the pseudoskin factor using these expressions requires a knowledge of two parameters when the top and the bottom boundaries are closed, and three parameters in the presence of a bottom-water zone or a gas cap, regardless of the number of layers. The estimated pseudoskin factor is very close to the actual pseudoskin obtained from the complete analytical solution.

1.0 INTRODUCTION

Most reservoirs are heterogeneous in nature. The presence of layers and zones of different fluid and/or rocks is a common cause for reservoir heterogeneity. The layers may be communicating or non-communicating. Formation crossflow is present when the layers are communicating. When the layers do not communicate with each other, except through the wellbore, then the reservoir is termed a "commingled reservoir". A layered, composite reservoir situation occurs when all or some of the layers have two or more regions of different rock and/or fluid properties.

Because of thermal recovery processes such as steam-flooding, a layered reservoir may resemble a layered, composite reservoir. As a result of steam-flooding, a swept region is created in the reservoir. Usually, the fluid front in such a reservoir is not vertical, but tilted or inclined, because of the gravity override effect. Tilted fronts can also occur in a thick, homogeneous reservoir owing to gravity override effects. Figure 1.1 schematically shows a steam-flooded reservoir under a bottom-water condition. The inclined line shows the fluid front and θ is the angle of inclination. Vertical arrows show the crossflow between layers and between the reservoir and the aquifer. The size of the aquifer may be finite or infinite. When the aquifer is very large compared to the reservoir, the aquifer is called an infinite aquifer and the boundary between the reservoir and the aquifer is considered as a constant pressure boundary[1].

Under a bottom-water condition, wells are partially perforated to avoid or delay the production of water. Figure 1.1 shows a partially penetrating well. Because of partial penetration, an additional pressure drop occurs near the wellbore which is known as a "pseudoskin factor". Several analytical expressions are available in the literature[2] to estimate the pseudoskin factor due to partial penetration, but are only applicable for closed top and bottom boundaries.

1

Numerous studies have been reported in the literature on layered and composite reservoirs, and Gomes and Ambastha[1] have presented an extensive literature review on these studies. Most of these studies are limited to layered systems without composite zones in the radial direction or to single-layer, composite reservoirs.

A limited number of studies have been conducted on multi-layer, composite reservoirs. Satman[3] presented injectivity and falloff responses for a commingled, multi-layer composite reservoir and introduced the concept of a tilted front. Satman and Oskay[4] considered the discontinuity boundary as a tilted front (inclined front) to account for the gravity override effect and modelled the reservoir as a multi-layer, composite reservoir without formation crossflow.

The objective of this study is to develop an analytical solution for a multi-layer, composite reservoir with pseudosteady-state formation crossflow and conduct transient pressure analysis for thermal recovery processes, such as steam-flooding, in which the gravity override effect is important. Because of layering or the gravity override effects, the fluid boundary is tilted or irregularly-shaped. The objective of this study is to investigate the effect of the tilted or irregularly-shaped front on transient pressure analysis. The objective includes an investigation of the pseudoskin factors for partially-penetrating wells in multi-layer reservoirs with or without a bottom-water condition. The objective also includes a study of the transient pressure behaviour for wells in multi-layer, composite reservoirs under finite or infinite bottom-water conditions.

Chapter 2 presents the development and the verification of the analytical solution for multi-layer composite reservoirs with pseudosteady-state (pps) formation crossflow. Using the eigenvalues and eigenvectors of the system, this method computes transient pressure behaviour more efficiently than the method described by Anbarci et al.[5] The developed model can handle tilted or irregularly-shaped fluid fronts, multiple, composite regions,

2

bottom-water condition, partially-penetrating wells, and all commonly-used outer-boundary conditions. Chapter 3 presents well test analysis for multi-layer composite reservoirs with tilted fronts. The effects of the front angle and layer refinement on transient pressure analysis have been discussed. The applicability of the pseudosteady-state analytical method to estimate the swept volume has been investigated and a correction factor has been developed to correct the swept volume from pss analysis.

Chapter 4 presents new analytical expressions for pseudoskin factors for partially-penetrating wells in multi-layer reservoirs with both closed top and bottom boundaries and with bottom-water zones or gas caps. These new pseudoskin expressions are very easy to use and require a knowledge of two parameters when the top and bottom boundaries are closed, and three parameters in the presence of a bottom-water zone or a gas cap. Chapter 5 presents transient pressure responses of a well in a multi-layer, composite reservoir under bottom-water. Both finite and infinite, bottom-water conditions have been considered and the effect of aquifer size on transient pressure analysis has been investigated.

Chapter 6 presents the algorithm and the computer program of the model. The computer program has been written in FORTRAN 77. Eigenvalues and eigenvectors have been calculated using the IMSL.Math Library. The system of simultaneous equations resulting from the boundary conditions has also been solved using the IMSL.Math Library. Chapter 7 presents a general discussion and the conclusions of the entire study and recommends some studies to extend this work.

Appendices A, B, C, D, and E show the derivations of some expressions in detail. Appendix F shows the computer program for the model developed. Appendices G and H show published or presented papers from this study.

2.0 MODEL DEVELOPMENT

2.1 Introduction

Most reservoirs are heterogeneous in nature. The presence of layers and zones of different fluid and/or rocks is a common cause for reservoir heterogeneity. Figures 2.1a and 2.1b show a layered reservoir and a layered, composite reservoir, respectively. The horizontal lines show the layering and the arrows show the presence of crossflow. The layers may be communicating or non-communicating. Formation crossflow is present when the layers are communicating. When the layers do not communicate with each other, except through the wellbore, then the reservoir is termed a "commingled reservoir". A layered, composite reservoir may result because of artificial processes. Enhanced oil recovery processes, such as steam flooding, CO_2 flooding, and in-situ combustion, tectonic movements, phase changes, acidizing, and temperature differences may cause a reservoir to behave as a composite reservoir. The tilted line in Figure 2.1b shows the discontinuity boundary or the fluid front. A layered, composite reservoir situation occurs when all or some of the layers have two or more regions of different rock and/or fluid properties.

Numerous studies[1-59] have been reported in the literature on layered reservoirs and Table 2.1 lists the relevant papers on layered reservoirs. One aspect in which the studies differ is the way they model crossflow between the layers. Formation crossflow has been modelled mainly by two methods: pseudosteady-state crossflow and transient crossflow. Pseudosteady-state crossflow assumes that the resistance to crossflow is confined to the interlayer boundary and the flow is horizontal within each layer. This assumption reduces a two-dimensional problem to a one-dimensional problem. Transient crossflow utilizes the two-dimensional diffusivity equation for each layer. Table 2.1 also shows that, although numerous studies have appeared on layered reservoirs with formation crossflow, very little work has been reported for layered, composite reservoirs with formation crossflow.

6

Responses of layered reservoirs may be summarized as follows: for commingled reservoirs, the time needed to reach pseudosteady state is an order of magnitude higher than that for homogeneous reservoirs; semi-log analysis can be used to estimate the average permeability-thickness product and the skin effect; initially, a crossflow system and a commingled system have the same responses; then there is a transition period and, finally, the crossflow system behaves like an equivalent homogeneous system.

Satman[21] presented drawdown and buildup responses for a commingled, multi-layered composite reservoir. In his model, he considered different discontinuity boundary radii for different layers. He used the concept of a tilted front for layered composite reservoirs, because the fluid front would propagate at different rates in different layers. For enhanced recovery processes, such as steam flooding, Satman and Oskay[14] considered the discontinuity boundary as a tilted front to account for the gravity-override effects and modelled the reservoir as a multi-layer, composite reservoir without crossflow. They concluded that the tilted front model is a better representation of the actual reservoir than the sharp-front model when the gravity override effect is present. Hatzignatiou et al.[45] presented a solution for interference pressure transient behaviour in a two-layer reservoir having pseudosteady state formation crossflow and described a type-curve matching technique to estimate the reservoir properties. Anbarci et al.[35] presented an analytical solution for a two-layer, composite reservoir. They included wellbore storage and skin, and considered pseudosteady state crossflow between the layers. They conducted a limited sensitivity study and used a type-curve matching technique to locate the front in a particular layer. The preceding discussion shows that a general solution for an n-layer composite reservoir with crossflow is yet to be developed. In this study, an analytical solution and its validation for multi-layered, composite reservoirs with formation crossflow have been presented. The usefulness of this solution for future studies has also been discussed.

7

2.2 Model Development

This study considers an n-layer, radial, composite reservoir as shown in Figure 2.2. A symmetrically located well fully penetrates the reservoir. The well produces at a constant flow rate and pseudosteady-state formation crossflow is present between the layers. The problem is solved by starting with the approach of Anbarci et al.[55]. In Figure 2.2, the discontinuity boundary in each layer is represented by a vertical solid line. These discontinuity boundaries have been vertically extended across all the layers. As a result, depending on the total number of discontinuity boundaries and their locations, an n-layer reservoir may have m number of regions in each layer. Therefore, the reservoir is divided into nXm zones and each zone may be identified by (i,j), in which i and j denote the region and the layer, respectively. Each zone may have different rock and/or fluid properties, and can have variable length in the radial direction depending on the discontinuity boundary locations. In an actual reservoir, we may not need nXm zones of different rock and/or fluid properties. In Figure 2.2, the shaded and non-shaded areas represent two different fluid and/or rock types. Each layer has only two different rock and/or fluid types separated by a discontinuity boundary. In each layer, the discontinuity boundary is placed at a different location to simulate a tilted-front discontinuity boundary for the reservoir and for this particular situation, m=n+1. Layers are assumed to be of constant thicknesses throughout the reservoir.

The crossflow between layers within the reservoir is modelled as in the semi-permeable wall model proposed by Gao[24]. Thus, crossflow resistance is assumed to be confined to the interlayer boundary and flow in each layer is horizontal. It is also assumed that the upper boundary of the top layer and the lower boundary of the bottom layer are closed. Other assumptions for the development of the mathematical model are as follows:

1. Reservoir fluids are slightly compressible and have constant compressibility.

8

2. The effects of gravity and capillary forces are negligible.

3. The flow in the formation is described by Darcy's law.

4. When a fluid crosses the boundary of its zone, it behaves as the fluid on the downstream side.

The flow equation for zone i,j can be written as:

$$\left(\frac{kh}{\mu}\right)_{i,j}\left(\frac{\partial^2 p_{i,j}}{\partial r^2} + \frac{1}{r}\frac{\partial p_{i,j}}{\partial r}\right) = (\phi c_t h)_{i,j}\frac{\partial p_{i,j}}{\partial t} + X_{A,i,j}(p_{i,j} - p_{i,j+1})$$

$$+ X_{B,i,j}(p_{i,j} - p_{i,j-1}) \quad\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots (2.1)$$

where $X_{A,i,j}$ and $X_{B,i,j}$ are defined as follows:

$$X_{A,i,j} = \frac{2}{\left(\frac{h\mu}{k_v}\right)_{i,j} + \left(\frac{h\mu}{k_v}\right)_{i,j+1}} \quad\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots (2.2)$$

$$X_{B,i,j} = \frac{2}{\left(\frac{h\mu}{k_v}\right)_{i,j} + \left(\frac{h\mu}{k_v}\right)_{i,j-1}} \quad\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots (2.3)$$

$$X_{B,i,1} = 0 \quad \text{for } i = 1, \dots m \quad\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots (2.4)$$

$$X_{A,i,n} = 0 \quad \text{for } i = 1, \dots m \quad\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots (2.5)$$

Initial condition: Initially all zones are at initial pressure and thus,

$$p_{i,j}(r,0) = p_{in} \quad \text{for all i and j} \quad\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots (2.6)$$

9

Inner boundary condition:

$$p_{wf} = p_{1,j}(r_w,t) - s_j \left(r \frac{\partial p_{1,j}}{\partial r} \right)_{r=r_w} \quad \text{for } j = 1, \dots n \quad \dots\dots\dots\dots\dots\dots (2.7)$$

$$q = -C \frac{\partial p_{wf}}{\partial t} + 2\pi r_w \sum_{j=1}^{n} \left(\frac{kh}{\mu} \right)_{1,j} \left(\frac{\partial p_{1,j}}{\partial r} \right)_{r=r_w} \quad \text{for } j = 1, \dots n \quad \dots\dots\dots\dots (2.8)$$

Outer boundary conditions:

Infinitely large system:

$$p_{m,j} = p_{in} \quad \text{for } r \to \infty \text{ and } j=1, n \quad \dots\dots\dots\dots\dots\dots\dots (2.9)$$

Finite system with a constant pressure equal to the initial pressure at the outer boundary:

$$p_{m,j} = p_{in} \quad \text{for } r=r_{oj} \text{ and } j=1, \dots n \quad \dots\dots\dots\dots\dots\dots (2.10)$$

Finite system with a closed outer boundary:

$$\frac{\partial p_{m,j}}{\partial r} = 0 \quad \text{for } r=r_{oj} \text{ and } j=1, \dots n \quad \dots\dots\dots\dots\dots\dots (2.11)$$

The flow equations for different zones in the same layer are coupled using the following interface conditions defining pressure and flow rate continuity between these zones:

$$p_{i,j} = p_{i+1,j} \quad \text{for } r=R_i \text{ and } i = 1, \dots m-1 \text{ and } j = 1, \dots n \quad \dots\dots\dots\dots (2.12)$$

$$\frac{\partial p_{i,j}}{\partial r} = M_{i,j} \frac{\partial p_{i+1,j}}{\partial r} \quad \text{for } r=R_i \text{ and } i = 1, \dots m-1 \text{ and } j = 1, \dots n \quad \dots\dots\dots (2.13)$$

where,

$$M_{i,j} = \frac{\left(\frac{kh}{\mu} \right)_{i+1,j}}{\left(\frac{kh}{\mu} \right)_{i,j}} \quad \dots\dots\dots\dots\dots\dots\dots\dots\dots\dots (2.14)$$

10

Dimensionless variables are defined as follows:

$$r_D = \frac{r}{r_w} \quad \dotfill \quad (2.15)$$

$$p_{D,j} = \frac{2\pi}{q}\left(\overline{\frac{kh}{\mu}}\right)(p_{in} - p_j) \quad \dotfill \quad (2.16)$$

$$p_{wD} = \frac{2\pi}{q}\left(\overline{\frac{kh}{\mu}}\right)(p_{in} - p_{wf}) \quad \dotfill \quad (2.17)$$

$$t_D = \frac{1}{r_w^2}\frac{\left(\overline{\frac{kh}{\mu}}\right)}{\left(\overline{\phi c_t h}\right)}, \quad \dotfill \quad (2.18)$$

where,

$$\left(\overline{\frac{kh}{\mu}}\right) = \sum_{j=1}^{n}\left(\frac{kh}{\mu}\right)_{i,j}, \quad \dotfill \quad (2.19)$$

$$\left(\overline{\phi c_t h}\right) = \sum_{j=1}^{n}\left(\phi c_t h\right)_{i,j}, \quad \dotfill \quad (2.20)$$

Expressing the flow equation and the boundary conditions in terms of dimensionless variables yields:

$$\kappa_{i,j}\left(\frac{\partial^2 p_{D,j}}{\partial r_D^2} + \frac{1}{r_D}\frac{\partial p_{D,j}}{\partial r_D}\right) = \alpha_{i,j}\frac{\partial p_{D,j}}{\partial t_D} + \lambda_{Ai,j}(p_{D,j} - p_{D,j+1})$$
$$+ \lambda_{Bi,j}(p_{D,j} - p_{D,j-1}), \quad \dotfill \quad (2.21)$$

where,

$$\kappa_{i,j} = \frac{\left(\frac{kh}{\mu}\right)_{i,j}}{\left(\overline{\frac{kh}{\mu}}\right)} \quad \dotfill \quad (2.22)$$

11

$$\omega_{i,j} = \frac{(\phi c_t h)_{i,j}}{(\phi c_t h)} \qquad \text{..} \quad (2.23)$$

$$\lambda_{A i,j} = \frac{r_f^2}{\left(\frac{kh}{\mu}\right)} X_{A i,j} \qquad \text{..} \quad (2.24)$$

$$\lambda_{B i,j} = \frac{r_f^2}{\left(\frac{kh}{\mu}\right)} X_{B i,j} \qquad \text{..} \quad (2.25)$$

Initial condition:

$$p_{D i,j}(r_D,0) = 0, \quad \text{for all i and j} \qquad \text{...} \quad (2.26)$$

Inner boundary condition:

$$p_{wD} = p_{D1,j}(1,t_D) - s_j \left(\frac{\partial p_{D1,j}}{\partial r_D}\right), \quad \text{for } j = 1, ... \, n \qquad \text{..................................} \quad (2.27)$$

$$1 = C_D \frac{\partial p_{wD}}{\partial t_D} - \sum_{j=1}^{n} \kappa_{1,j}\left(\frac{\partial p_{D1,j}}{\partial r_D}\right), \qquad \text{..............................} \quad (2.28)$$

Outer boundary conditions:

Infinitely large system:

$$p_{Dm,j} = 0, \quad \text{for } r_D \to \infty \text{ and } j = 1, ... \, n \qquad \text{.......................................} \quad (2.29)$$

Finite system with a constant pressure at the outer boundary:

$$p_{Dm,j} = 0, \quad \text{for } r_D = r_{eDj} \text{ and } j = 1, ... \, n \qquad \text{.......................................} \quad (2.30)$$

Finite system with a closed outer boundary:

$$\frac{\partial p_{Dm,j}}{\partial r_D} = 0, \quad \text{for } r_D = r_{eDj} \text{ and } j = 1, \dots n \quad \dots\dots\dots\dots\dots\dots\dots \quad (2.31)$$

Interface conditions defining pressure and flow rate continuity between the zones of a layer:

$$p_{Di,j} = p_{Di+1,j} \quad \text{for } r_D = R_{Di} \text{ and } i = 1, \dots m-1 \text{ and } j = 1, \dots n \quad \dots\dots\dots\dots \quad (2.32)$$

$$\frac{\partial p_{Di,j}}{\partial r_D} = M_{i,j} \frac{\partial p_{Di+1,j}}{\partial r_D} \quad \text{for } r_D = R_{Di} \text{ and } i = 1, \dots m-1 \text{ and } j = 1, \dots n \quad \dots\dots\dots \quad (2.33)$$

The Laplace transformation of Equations (2.21), and (2.27) through (2.33), yields:

$$\kappa_{i,j} \left(\frac{d^2 \bar{p}_{Di,j}}{dr_D^2} + \frac{1}{r_D} \frac{d\bar{p}_{Di,j}}{dr_D} \right) = \omega_{i,j} l \bar{p}_{Di,j} + \lambda_{\lambda i,j} (\bar{p}_{Di,j} - \bar{p}_{Di,j+1})$$

$$+ \lambda_{\text{Bi},j} (\bar{p}_{Di,j} - \bar{p}_{Di,j-1}), \quad \dots\dots\dots\dots\dots\dots\dots\dots\dots \quad (2.34)$$

Inner boundary condition:

$$\bar{p}_{wD} = \bar{p}_{D1,j}(1,l) - s_j \left(\frac{d\bar{p}_{D1,j}}{dr_D} \right), \quad \text{for } j = 1, \dots n \quad \dots\dots\dots\dots\dots\dots \quad (2.35)$$

$$\frac{1}{l} = C_D \bar{p}_{wD} l - \sum_{j=1}^{n} \kappa_{1,j} \left(\frac{d\bar{p}_{D1,j}}{dr_D} \right), \quad \dots\dots\dots\dots\dots\dots\dots\dots \quad (2.36)$$

Outer boundary conditions:

Infinitely large system:

$$\bar{p}_{Dm,j} = 0, \quad \text{for } r_D \rightarrow \infty \text{ and } j = 1, \dots n \quad \dots\dots\dots\dots\dots\dots\dots \quad (2.37)$$

Finite system with a constant pressure at the outer boundary:

$$\bar{p}_{Dm,j} = 0, \quad \text{for } r_D = r_{eDj} \text{ and } j = 1, \dots n \quad \dots\dots\dots\dots\dots\dots\dots \quad (2.38)$$

13

Finite system with a closed outer boundary:

$$\frac{d\bar{p}_{Dm,j}}{dr_D} = 0, \quad \text{for } r_D = r_{eDj} \text{ and } j = 1, \dots n \quad \dots\dots\dots\dots\dots\dots (2.39)$$

Interface conditions defining pressure and flow rate continuity between the zones of a layer:

$$\bar{p}_{Di,j} = \bar{p}_{Di+1,j} \quad \text{for } r_D = R_{Di} \text{ and } i = 1, \dots m-1 \text{ and } j = 1, \dots n \quad \dots\dots\dots (2.40)$$

$$\frac{d\bar{p}_{Di,j}}{dr_D} = M_{i,j}\frac{d\bar{p}_{Di+1,j}}{dr_D}, \quad \text{for } r_D = R_{Di} \text{ and } i = 1, \dots m-1 \text{ and } j = 1, \dots n \quad \dots\dots\dots (2.41)$$

Equation (2.34) has the form of a modified Bessel's equation and thus, assume a solution of the following form for Equation (2.34):

$$\bar{p}_{Di,j} = A_{i,j}K_0(\sigma r_D) + B_{i,j}I_0(\sigma r_D), \quad \dots\dots\dots\dots\dots\dots\dots\dots\dots (2.42)$$

Introducing Equation (2.42) into the left-hand side of Equation (2.34), we get:

$$\kappa_{i,j}\left(\frac{d^2\bar{p}_{Di,j}}{dr_D^2} + \frac{1}{r_D}\frac{d\bar{p}_{Di,j}}{dr_D}\right) = \kappa_{i,j}\sigma^2\bar{p}_{Di,j}, \quad \dots\dots\dots\dots\dots\dots (2.43)$$

Substituting Equation (2.43) into Equation (2.34) results in the following general equation:

$$\lambda_{u,j}\bar{p}_{Di,j+1} + \left(\sigma^2\kappa_{i,j} - \omega_{i,j} - \lambda_{Ai,j} - \lambda_{Bi,j}\right)\bar{p}_{Di,j} + \lambda_{Bi,j}\bar{p}_{Di,j-1} = 0 \quad \dots\dots\dots (2.44)$$

Equation (2.44) has the form of a generalized eigenvalue system. As pointed out by Ehlig-Economides and Joseph[43], Equation (2.44) has a non-trivial solution (i.e., $\bar{p}_{Di,j} \neq 0$) if and only if its coefficient matrix is singular. Thus, the determinant of the coefficient matrix has to be zero. The coefficient matrix is an nxm by nxm tridiagonal matrix. The coefficient matrix can be divided into m smaller real-symmetric, positive-definitive tridiagonal matrices, where the σ^2 terms act as the eigenvalues, and these eigenvalues are always positive. The determinant of each of these sub-matrices is an nth order polynomial in σ^2;

14

and, from each determinant, n eigenvalues can be obtained. Now, a general solution for each zone can be written as:

$$P_{Di,j} = \sum_{k=1}^{n} \left[A^k_{i,j} K_0(\sigma^k_i r_D) + B^k_{i,j} I_0(\sigma^k_i r_D) \right], \quad \dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots \quad (2.45)$$

Constants $A^k_{i,j}$ and $B^k_{i,j}$ can be split into two parts as follows:

$$A^k_{i,j} = E^k_{i,j} A^k_i, \quad \dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots \quad (2.46)$$

and

$$B^k_{i,j} = E^k_{i,j} B^k_i, \quad \dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots \quad (2.47)$$

where $E^k_{i,j}$ is the eigenvector for region i, and this eigenvector can be calculated from Equation (2.44). Constants A^k_i and B^k_i are to be determined from the boundary conditions. Now, a general solution for region i and layer j becomes:

$$P_{Di,j} = \sum_{k=1}^{n} \left[A^k_i E^k_{i,j} K_0(\sigma^k_i r_D) + B^k_i E^k_{i,j} I_0(\sigma^k_i r_D) \right], \quad \dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots \quad (2.48)$$

Equation (2.48) contains 2nXm constants to be evaluated from the boundary conditions.

For the inner boundary condition, without considering wellbore storage, we can write:

$$P_{wD} = \sum_{k=1}^{n} \left[\begin{matrix} \left(A^k_1 E^k_{1,j} K_0(\sigma^k_1) + B^k_1 E^k_{1,j} I_0(\sigma^k_1) \right) \\ + s_j \sigma^k_1 \left(A^k_1 E^k_{1,j} K_1(\sigma^k_1) - B^k_1 E^k_{1,j} I_1(\sigma^k_1) \right) \end{matrix} \right] \quad \text{for } j=1, \dots n \quad \dots\dots\dots\dots \quad (2.49)$$

$$\frac{1}{f} = \sum_{j=1}^{n} \kappa_{1,j} \sum_{k=1}^{n} \sigma^k_1 \left[A^k_1 E^k_{1,j} K_1(\sigma^k_1) - B^k_1 E^k_{1,j} I_1(\sigma^k_1) \right] \quad \text{for } j=1, \dots n \quad \dots\dots\dots\dots \quad (2.50)$$

For an infinite outer boundary condition, we can write:

$$\sum_{k=1}^{n} \left[A^k_m E^k_{m,j} K_0(\sigma^k_m r_D) + B^k_m E^k_{m,j} I_0(\sigma^k_m r_D) \right] = 0$$

$$\text{for } r_D \rightarrow \infty \text{ and } j = 1, \dots n \quad \dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots \quad (2.51)$$

15

The condition that the pressure is bounded yields:

$$\sum_{i=1}^{n} B_{m}^{k} = 0 \quad \text{for } j = 1, \dots n \quad \dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots (2.52)$$

A constant-pressure, outer boundary condition yields:

$$\sum_{i=1}^{n} \left[A_{m}^{k} E_{m,j}^{k} K_0\left(\sigma_{m}^{k} r_{eDj}\right) + B_{m}^{k} E_{m,j}^{k} I_0\left(\sigma_{m}^{k} r_{eDj}\right) \right] = 0 \quad \text{for } j = 1, \dots n \quad \dots\dots\dots\dots (2.53)$$

A no-flow, outer boundary condition yields:

$$\sum_{i=1}^{n} \left[A_{m}^{k} E_{m,j}^{k} K_1\left(\sigma_{m}^{k} r_{eDj}\right) + B_{m}^{k} E_{m,j}^{k} I_1\left(\sigma_{m}^{k} r_{eDj}\right) \right] = 0 \quad \text{for } j = 1, \dots n \quad \dots\dots\dots\dots (2.54)$$

The interface conditions defining continuity in pressure and flow rate yield, respectively:

$$\sum_{i=1}^{n} \left[A_{i}^{k} E_{i,j}^{k} K_0\left(\sigma_{i}^{k} R_{Di}\right) + B_{i}^{k} E_{i,j}^{k} I_0\left(\sigma_{i}^{k} R_{Di}\right) \right] =$$

$$\sum_{i=1}^{n} \left[A_{i+1}^{k} E_{i+1,j}^{k} K_0\left(\sigma_{i+1}^{k} R_{Di}\right) + B_{i+1}^{k} E_{i+1,j}^{k} I_0\left(\sigma_{i+1}^{k} R_{Di}\right) \right]$$

$$\text{for } j = 1, \dots n \text{ and } i = 1, \dots m\text{-}1 \quad \dots\dots\dots\dots\dots\dots\dots\dots\dots\dots (2.55)$$

$$\sum_{i=1}^{n} \left[A_{i}^{k} E_{i,j}^{k} K_1\left(\sigma_{i}^{k} R_{Di}\right) - B_{i}^{k} E_{i,j}^{k} I_1\left(\sigma_{i}^{k} R_{Di}\right) \right] =$$

$$\sum_{i=1}^{n} \left[A_{i+1}^{k} E_{i+1,j}^{k} K_1\left(\sigma_{i+1}^{k} R_{Di}\right) - B_{i+1}^{k} E_{i+1,j}^{k} I_1\left(\sigma_{i+1}^{k} R_{Di}\right) \right]$$

$$\text{for } j = 1, \dots n \text{ and } i = 1, \dots m\text{-}1 \quad \dots\dots\dots\dots\dots\dots\dots\dots\dots\dots (2.56)$$

Equations (2.49) through (2.56) give a total of $2n \times m$ simultaneous equations which can be solved to find $2n \times m$ values of the coefficients A_{j}^{k} and B_{j}^{k}.

Thus, the preceding solution models transient fluid flow in an n-layer, composite reservoir with pseudosteady-state crossflow. This new solution uses the eigenvalues and eigenvectors of the system and is computationally more efficient than other methods proposed in the literature. For example, for a 5-layer, composite reservoir (m=6), this new solution requires the solution of only 60 simultaneous equations, whereas the method proposed by Anbarci et al.[55] requires the solution of 300 simultaneous equations to solve the same problem. By assigning a constant-pressure boundary at the top or at the bottom, this new solution can include a gas cap or a bottom-water drive, respectively. This new solution is also capable of treating any irregularly-shaped fluid-front by dividing the reservoir into a number of mathematical layers.

To include bottom-water drive, the lower boundary of the bottom layer is considered as a constant-pressure boundary. Mathematically, the vertical permeability of the bottom-water zone is considered infinite and Equation (2.4) is modified as follows:

$$X_{B_{i,1}} = \frac{2}{\left(\frac{h\mu}{k_v}\right)_{i,1}} \qquad \text{for } i = 1, \dots m \qquad \dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots \quad (2.4a)$$

Also, in the diffusivity equation for layer j=1, $p_{i,j-1}$ is replaced by the initial pressure, p_{in}. Similarly, to include a gas-cap drive, the upper boundary of the top layer is considered as a constant-pressure boundary, and the vertical permeability of the gas-cap zone is considered to be infinite. Therefore, Equation (2.5) is modified as follows:

$$X_{A_{i,n}} = \frac{2}{\left(\frac{h\mu}{k_v}\right)_{i,n}} \qquad \text{for } i = 1, \dots m \qquad \dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots \quad (2.5a)$$

Also, in the diffusivity equation for layer j=n, $p_{i,j+1}$ is replaced by the initial pressure, p_{in}. For a partially-penetrating well, the inner boundary condition needs some modification. Both Equations (2.7) and (2.8) are considered to apply only for layers penetrated by the

17

well. For layers that are not open to flow to the wellbore, the inner boundary condition can be written as:

$$\frac{\partial p_{1,j}}{\partial r} = 0, \quad \text{for } r = r_w \text{ and } j = \text{layers not open to flow to the wellbore} \quad \text{................ (2.8a)}$$

For a partially-penetrating well, Equations (2.7), (2.8) and (2.8a) together describe the inner boundary condition.

2.3 Solution Methodology

The following steps were involved to solve Equation (2.48) at any region i and layer j:

1. From Equation (2.44), eigenvalues and eigenvectors were calculated using an appropriate subroutine from the IMSL Math/Library[40].

2. From the boundary conditions, $2n \times m$ simultaneous equations were set up and then solved using Gauss' elimination routine from the IMSL Math/Library[40] for the constants A_i^k and B_i^k.

3. Dimensionless pressure in Laplace space is calculated using Equation (2.48) and then numerically inverted using the Stehfest algorithm[61].

4. The wellbore storage effect is included using the following well-known relationship:

$$\bar{p}_{wD} = \frac{1}{C_D l^2 + \dfrac{1}{(\bar{p}_{wD})_{C_D = 0}}} \quad \text{... (2.57)}$$

The computation process involves repeated calculation of Bessel's functions. Very small and large arguments of Bessel's functions create an overflow problem during the computational process. This problem is overcome by using a dimensionless radius, r_D,

based on the minimum front radius, R_1, instead of the wellbore radius, and by calculating Bessel's functions in exponentiated form.

2.4 Model Validation

The analytical solution was validated by generating some well-known pressure transient responses for various cases of homogeneous, composite, and layered reservoirs, which are subsets of the general solution developed. Figure 2.3 shows a comparison of results generated by the new analytical solution with an Agarwal et al.[62] type-curve for homogeneous reservoirs. Homogeneous reservoir responses were generated by setting identical reservoir properties for each of the layers of a two-layer reservoir and by setting very high crossflow (of the order of 10^3) parameters. The responses were generated for different wellbore-storage and skin effects. Figure 2.3 shows a successful match between the two solutions. Figure 2.4 shows a comparison of the responses of this study with Tariq and Ramey's solution[18] for a two-layer, commingled reservoir with a closed outer boundary. Commingled layered reservoir responses were generated by setting different layer properties for each layer and by assigning very small (of the order of 10^{-13}) crossflow parameters. Figure 2.4 shows a very good match between the two results for different wellbore-storage effects. Figure 2.5 shows a comparison of responses of this study with the Eggenschwiler et al.[63] solution for a single-layer, two-region composite reservoir. In the model, a single-layer, composite reservoir is obtained by dividing a two-layer reservoir into two regions and setting different properties for them. In each region, the layers are assigned identical fluid and rock properties and a very high crossflow parameter. The responses were generated for different mobility ratios and Figure 2.5 shows a good match between the two solutions. Figure 2.6 shows a comparison of the results of this study with Ambastha and Ramey's[64] pressure derivative solution for a single-layer, two-region, composite reservoir. Again, Figure 2.6 shows a good match between the two solutions. Figure 2.7 shows a comparison of this study with Ambastha

19

and Ramey's solution[65] for a three-region composite reservoir. The three-region composite reservoir response was generated by dividing a 2-layer reservoir into three regions and setting different fluid properties for each region. The layers were assigned identical fluid and rock properties in each region and very high crossflow parameters. Figure 2.7 shows pressure derivative responses for different mobility ratios between zones one and two and the responses show a good match between the two solutions.

Figure 2.8 shows the effect of crossflow on pressure transient responses for a two-layer reservoir. The upper and the lower straight lines represent commingled and homogeneous reservoir responses, respectively. Initially, the reservoir behaves like a commingled reservoir. Then, depending on the crossflow parameter λ, there is a transition period during which the crossflow effect becomes important and the responses change from those for a commingled reservoir to those for a homogeneous reservoir. At late time, the reservoir behaves like an equivalent homogeneous system. The transition from commingled reservoir behaviour to homogeneous reservoir behaviour depends on the crossflow parameter. The higher the crossflow parameter, the earlier the transition occurs. The above observation is consistent with layered reservoir behaviour reported in the literature.

Figure 2.9 shows the pressure drawdown responses of a partially-penetrating well in a two-layer reservoir subject to bottom-water drive. The upper layer is open to flow and the lower layer is closed. For a penetration ratio of 0.5, the two curves show the responses for two different crossflow parameters. Both curves show radial flow characteristics until the effect of the constant-pressure boundary becomes dominant. Similar observations have been made by Streltsova-Adams[66] and Buhidma and Raghavan[67]. For a lower crossflow parameter, it takes a longer time for the constant pressure boundary to have a dominant effect on the pressure drawdown responses.

2.5 Future Possibilities

In this study, a general analytical solution for an n-layer, composite reservoir with pseudosteady state interlayer crossflow has been developed and validated. Formation crossflow has been modelled as pseudosteady state interlayer crossflow. This method is very general and computationally efficient. This method has an advantage over the finite difference method in that this method does not require extensive discretization like the finite difference method.

A reservoir undergoing a thermal recovery process has been idealized as a single-layer, composite reservoir for a long time[63,64,66-71]. This new model can be used to analyze more general scenarios of heterogeneous reservoirs undergoing thermal recovery processes. Effects of gravity override or underride, viscous fingering, and so forth, on a discontinuity boundary can be treated as a tilted or any other irregularly-shaped front and its effects on pressure transient responses can be studied. Pressure transient analysis of both drawdown and buildup tests can be studied with this model.

This new model can also accommodate the situation where each layer has a different outer boundary distance, r_{ej}. This can be done by vertically extending the outer boundary of each layer, the same way as has been done for the discontinuity boundaries. This will create some mathematical zones (which do not exist) which will be taken care of by assigning very small horizontal and vertical permeabilities to them.

Another possibility is to use automated type-curve matching to analyze rate and pressure measurements from different layers of layered, composite reservoirs. The effect of a gas cap or bottom-water can be included by properly specifying pressure and semi-permeabilities at the appropriate boundary to yield a constant-pressure boundary at the top or bottom, respectively. Transient pressure responses of a partially-penetrating well in a

21

layered reservoir subject to the effects of a bottom-water and/or a gas cap can be investigated with this model. The proposed analytical solution may also lead to new and/or improved methods for analyzing well test data from multi-layered, composite reservoirs with formation crossflow. Efforts are underway to develop some simplified type-curves for the system under study.

2.6 Conclusions

1. A general, analytical solution for pressure transient responses for an n-layer, composite reservoir with pseudosteady state interlayer crossflow has been developed and validated.

2. The new, analytical solution developed in this study is a more efficient and versatile solution than presently-available solutions in the literature.

3. The new analytical solution of this study offers new possibilities to analyze more complicated well-testing scenarios than the possibilities offered by presently-available solutions.

3.0 WELL TEST ANALYSIS FOR THERMAL RECOVERY SYSTEMS

3.1 Introduction

Most reservoirs are heterogeneous in nature. The presence of layers and zones of different fluid and/or rocks is a common cause for reservoir heterogeneity. Figures 3.1a and 3.1b show a layered reservoir and a layered composite reservoir, respectively. The horizontal lines show the layering and the arrows show the presence of crossflow. The layers may be communicating or non-communicating. Formation crossflow is present when the layers are communicating. When the layers do not communicate with each other, except through the wellbore, then the reservoir is termed a "commingled reservoir". A layered, composite reservoir situation occurs when all or some of the layers have two or more regions of different rock and/or fluid properties.

Thermal recovery processes, such as steam-flooding, are widely used in heavy-oil reservoirs. As a result of steam-flooding, a swept region is created in the reservoir. A layered reservoir resembles a layered composite reservoir because of steam-flooding. Usually, the fluid front in such a reservoir is not vertical, but tilted or inclined because of the gravity override effect. The tilted line in Figure 3.1b shows the discontinuity boundary or the fluid front and θ is the angle of inclination. A tilted front can also occur in a thick, homogeneous reservoir due to gravity override effects.

Numerous studies have been reported in the literature on layered reservoirs. Among many researchers, Lefkovits et. al.[1], Tariq and Ramey[2] and Bourdet[3] have conducted some significant studies on layered reservoirs. Gomes and Ambastha[4] have done an extensive literature review on layered and composite reservoirs. Responses of layered reservoirs may be summarized as follows: initially, a crossflow system and a commingled system have the same response; then there is a transition period and,

37

finally, the crossflow system behaves like an equivalent homogeneous system. Eggenschwiler et al.[5] have developed an analytical solution for a single-layer, composite reservoir and used the pseudosteady-state analysis method to estimate the swept volume. Ambastha[6] has presented an extensive study on single-layer, composite reservoirs based on pressure derivative responses. The responses of a single-layer, composite reservoir, without wellbore storage and skin effects, consist of the following steps: initially, the responses show a first radial flow period corresponding to the swept region (inner region); then, there is a transition period during which the swept region may show pseudosteady-state flow behaviour if the mobility contrast between the swept and the unswept regions is sufficiently large; and finally, the responses show a second radial (pseudo-radial) flow period corresponding to the unswept (outer) region, if the reservoir is large enough.

A limited number of studies have been conducted on multilayered, composite reservoirs. Satman[7] presented injectivity and falloff responses for a commingled, multilayered composite reservoir. In his model, Satman[7] considered different discontinuity boundary radii for different layers. He introduced the concept of a tilted front for layered, composite reservoirs, because the fluid front would propagate at different rates in different layers. Satman[7] described the methods to estimate the properties of the swept region, distance to the nearest boundary, and the swept volume from transient pressure responses. But he did not consider the effect of the discontinuity boundary shape in his study. For enhanced recovery processes, such as steam flooding, Satman and Oskay[8] considered the discontinuity boundary as a tilted front (inclined front) to account for the gravity override effect and modelled the reservoir as a multi-layer, composite reservoir without formation crossflow. They concluded that the tilted front model is a better representation of the actual reservoir than the sharp-front model when the gravity override effect is present. For an inclined-front

38

reservoir, Satman and Oskay[8] observed that the time to reach pseudosteady-state (pss) can be much longer than that for a sharp-front reservoir, and conventional pss analysis results in considerable underestimation of the swept volume. Hatzignatiou et al.[9] presented a solution for interference pressure transient behaviour in a two-layer, composite reservoir having pseudosteady-state formation crossflow and described a type-curve matching technique to estimate the reservoir parameters from the active and from the observation well data. Anbarci et al.[10] presented an analytical solution for a two-layer, composite reservoir. They included wellbore storage and skin, and considered pseudosteady-state crossflow between the layers. They conducted a limited sensitivity study and used a type-curve matching technique to locate the front in a particular layer.

The preceding discussion shows that a systematic and in-depth study for the transient pressure behaviour of an inclined-front, multilayered, composite reservoir with crossflow has not been conducted yet. Especially, for steam-flooding, in which the gravity override effect is important, and which can be modelled as a multilayered, composite reservoir with an inclined front, a detailed study has not been carried out. The analytical solution developed by Gomes and Ambastha[4] has been used to conduct a systematic and in-depth study of the transient pressure behaviour of a multilayered, composite reservoir with pseudosteady-state formation crossflow. Although not a limitation of the model, this study assumes that all the layers of the reservoir are of equal thickness. The inclined front has been represented by a minimum front radius and an angle of inclination. The inclined front in each layer has been approximated by an equivalent vertical front (Figure 3.1b). In the absence of actual physical layers, a number of mathematical layers is assumed to be present in the reservoir for the step approximation of the inclined front. In this study, the well is a fully-penetrating well, unless mentioned otherwise. Wellbore storage and skin effects are neglected. All layers

39

in the swept region are assigned a constant value of mobility, and all layers in the unswept region are assigned a different, but constant, value of mobility corresponding to a specified mobility ratio. Assignment of storativities is carried out in exactly the same manner as the mobilities. Appendix A shows the calculation procedure of various front radii using a minimum front radius, layer thicknesses, total reservoir thickness, and the angle of inclination. A representation of an inclined front, as shown in Figure 3.2, has been used in Appendix A. Appendix B describes the derivation of the average front radius for inclined front reservoirs. Appendices A and B follow the approach presented by Kiome[11].

3.2 Effect of Front Angle

When an enhanced recovery process, such as steam-flooding, is applied to a multi-layer reservoir, the discontinuity boundary may be tilted because of the gravity override effect. Satman[7] modelled a tilted front in a two-layer, commingled reservoir by locating the two discontinuity boundaries at two different locations. Later, Satman and Oskay[8] studied the effect of a tilted front in a multi-layer, composite reservoir without formation crossflow. They conducted a limited study by varying the front angle as well as the minimum front radius to investigate the effect on transient pressure responses. For tilted fronts, Satman and Oskay[8] observed that the swept volume is underestimated when calculated from the Cartesian slope after the first radial-flow period. They also observed that it takes a longer time to reach pseudosteady-state for reservoirs with tilted fronts compared to those with sharp fronts. They recommended a type-curve matching technique for locating the pseudosteady-state period.

Figures 3.3 through 3.7 show the effect of front angle on pressure derivative responses. These responses are for a three-layer reservoir with a mobility ratio $M=10$, storativity ratio $F_s=1$, and a fully-penetrating well. Wellbore storage and the skin effect

40

are neglected. The minimum discontinuity boundary distance is the same for all responses and is $R_{Dmin} = 500$. Figures 3.3 through 3.5 show the responses when crossflow is present between the layers, and Figures 3.6 and 3.7 show the responses of a commingled reservoir. These figures show that the transient responses of a layered, composite reservoir with a tilted front consist of the following flow regime sequences: a radial-flow period corresponding to the swept region, a transition period which depends on the front angle, total reservoir thickness, as well as the mobility and the storativity contrast between the swept and the unswept regions, and a second radial-flow period corresponding to the unswept region. After the second radial-flow period, boundary effects will be observed for finite reservoirs. However, this study is limited to infinite reservoirs as well tests for thermal recovery situations are seldom run long enough to observe the effects of outer boundaries. Figures 3.3 and 3.6 show the responses for very thick reservoirs with $h_{tD} = 1000$. For thick reservoirs, the effect of the front angle is more apparent and for smaller front angles, deviation from the first, radial-flow period occurs later than for the sharp-front reservoirs. Figure 3.5 shows that the transient pressure responses of very thin reservoirs do not exhibit much effect due to the front angle and therefore transient pressure analysis of thin reservoirs can be performed with a sharp-front model. This conclusion is consistent with Kiome's[11] observation for thin, commingled, composite reservoirs with a tilted front, where he observed very little effect of the front angle on the transient, wellbore pressure.

A comparison of Figures 3.3 and 3.4 with Figures 3.6 and 3.7, respectively, shows that crossflow does not make a significant difference in these particular situations with $k_v/k = 0.1$ for the crossflow system. When the well is partially penetrated and k_v/k is not very small, crossflow must be taken into consideration to generate proper responses. Figures 3.8 and 3.9 show the effect of crossflow on pressure-derivative responses of a fully- and partially-penetrating well, respectively. In Figure 3.8, the

41

solid line represents a commingled reservoir, and the data points represent various crossflow cases. In Figure 3.8, k_v/k has been varied between 0.01 and 10. Figure 3.8 shows that the crossflow system responses are the same as commingled system responses for fully-penetrating wells. For partially-penetrating wells, Figure 3.9 shows the effect of crossflow on wellbore responses. In Figure 3.9, the penetration ratio is 0.5 and k_v/k has been varied as 0.01, 0.1 and 1. Initially, the crossflow systems and the commingled system have the same response. Then, for crossflow systems, the fluid starts flowing from the closed section to the open section of the reservoir. For the commingled system, there is no fluid flow from the closed section to the open section and the wellbore pressure is not affected by the closed section of the reservoir. At late time, the pressure derivative approaches $M/2$ for crossflow systems. For a commingled system, the late-time pressure derivative approaches $Mh_t/2h_w$, where h_w/h_t represents the penetration ratio. Although not shown, the aforementioned observations regarding Figures 3.8 and 3.9 hold true for different cases of front angle, dimensionless reservoir thickness, mobility ratio, storativity ratio, and dimensionless minimum front radius.

3.3 Layer Refinement Effect

In this study, a composite reservoir with an inclined or tilted front has been approximated by a multi-layer, composite reservoir with a step approximation of the inclined front. The layer refinement effect is studied by varying the number of mathematical layers in a particular reservoir and observing the transient pressure responses. Figures 3.10 and 3.11 show the effect of layer refinement on the pressure derivative responses. These figures show the responses for a multi-layer, composite reservoir with a mobility ratio $M = 10$, a minimum discontinuity distance $R_{Dmin} = 500$, and a dimensionless reservoir thickness $h_{tD} = 500$. The number of layers have been varied as 2, 3, 5 and 10 layers. All the layers in the swept zone have been assigned the same properties with a mobility contrast of $M = 10$ between the swept and the unswept

42

zones. Pseudosteady-state crossflow is present between the layers with $k_v/k = 0.1$. Figures 3.10 and 3.11 show responses for front angles of 30° and 60°, respectively. From these two figures, it is observed that the smaller the front angle is, the more apparent the layer refinement effects are. Layer refinement effects also depend on the reservoir thickness. Very thin reservoirs and reservoirs with sharp fronts do not show any layer refinement effect. This observation is also consistent with Kiome's[11] findings for commingled, composite reservoirs. Layer refinement effects occur because by increasing the number of layers, the definition of the fluid front is improved. Figures 3.10 and 3.11 also show that increasing the number of layers from 5 to 10 makes very little change in the responses. Therefore, for a particular reservoir situation, there is a maximum number of layers beyond which the layer refinement effect would not improve the responses significantly. Larsen[12] has reported a similar layer refinement effect. To minimize the layer refinement effect, a reservoir consisting of five layers is considered for the rest of this study.

3.4 Effect of Mobility and Storativity Ratio

Figures 3.12 through 3.14 show the effect of mobility ratio on semi-log pressure derivative responses. Figures 3.12, 3.13 and 3.14 are for front angles of 30°, 60° and 90°, respectively. For all these figures, the dimensionless minimum front radius (R_{Dmin}) = 500, the dimensionless time is calculated based on the minimum front radius, and the mobility ratio is varied between 1 and 1000. Initially, the reservoir behaves like an infinite-acting radial flow system with a semi-log pressure derivative of 0.5. Then, there is a transition period, the duration of which depends on the mobility ratio. The higher the mobility ratio, the longer the duration of the transition period. At late time, the responses show a second, radial-flow period with a constant semi-log derivative of 0.5M. For all mobility ratios, the time, at which the first radial flow ends, depends on the front angle. This is more evident from Figure 3.15 which shows the effect of front

43

angles for a reservoir with a mobility ratio of 100. Figure 3.15 shows that a reservoir with a sharp front (90°) deviates from the first radial flow period earlier than the tilted front reservoirs and this deviation depends on the front angle. The higher the front angle is, the earlier the response deviates from the first radial flow period. This happens because in a tilted front reservoir, when the pressure response reaches the minimum front, for the rest of the layers, the pressure response still corresponds to the first radial flow period. Since the wellbore response is the combined effect of the responses from all the layers, the wellbore still senses the response as the first radial flow period, although the pressure response has already reached the minimum front radius. In a sharp front reservoir, the pressure response in all the layers reaches the front at the same time and, thus, the wellbore response deviates earlier. For tilted front cases, Table 3.1 shows that the delay in deviation from the first radial flow period and the delay in time to the occurrence of the maximum semi-log slope (for $F_s > 1$) during the transition period are equal to the ratio of the average front radius to the minimum front radius. In Table 3.1, the mobility ratio is varied between 10 and 1000 and the storativity ratio is varied between 1 and 1000. For a fixed minimum front radius, as the front angle becomes smaller, the average radius becomes larger. Therefore, the design equation for the end of the first radial flow period and for the maximum semi-log slope for sharp-front reservoirs should be modified for the tilted front cases. Thus, the design equations derived by Ambastha and Ramey[13] are modified as follows:

$$(t_{DR1})_{end} = 0.18 \frac{R_{Davg}}{R_{Dmin}}$$

(3.1)

$$(t_{DR})_{max} = (1.8 + 0.4 \log F_s) M \frac{R_{Davg}}{R_{Dmin}}$$

(3.2)

where, $(t_{DR1})_{end}$ and $(t_{DR})_{max}$ are the time to the end of the first, radial-flow period and the time of the maximum semi-log pressure derivative during the transition period, respectively.

44

For a sharp-front reservoir, R_{Davg} and R_{Dmin} are identical. Although Table 3.1 shows results for $R_{Dmin} = 500$, Equations (3.1) and (3.2) have been tested for R_{Dmin} values of 300 through 1000 with satisfactory results. Equation (3.1) is important, since it shows that for tilted front reservoirs, the end of the first radial flow period occurs later than it does for sharp-front reservoirs. Thus, the deviation time method can not be used to locate the minimum discontinuity boundary as is currently believed[6]. According to Equation (3.1), the end of the first, radial-flow period occurs at a dimensionless time of 0.18, and this dimensionless time is based on the geometric mean of R_{Dmin} and R_{Davg}, not on R_{Dmin}. A similar modification can be made to the other design equations for the end of the first, radial-flow period developed by Sosa et al.[14] and Tang[15], which are based on pressure data, instead of pressure derivative data.

Figures 3.16 through 3.18 show the effect of the storativity ratio, F_s, on the semi-log pressure derivative responses. Figure 3.16, 3.17 and 3.18 are for front angles of 30°, 60° and 90°, respectively. These figures show that the effect of the storativity ratio is somewhat similar to that of the mobility ratio, but, unlike the mobility ratio, the storativity ratio does not affect the duration significantly of the transition period between the first and the second radial flow periods.

3.5 Pseudosteady-State (pss) Analytical Method

During the pseudosteady-state period, if the mobility contrast is large enough, the swept region of a composite reservoir acts like a closed reservoir for some time and the transient pressure responses are similar to the late-time responses of a closed reservoir.

Ramey and Cobb[16] derived the equation for the variation of the dimensionless pressure with dimensionless time during the pss flow period for a well in a single-layer, homogeneous, closed reservoir as:

$$p_{wD} = 2\pi\, t_{DA} + \frac{1}{2} \ln\left(A/r_w^2\right) + \frac{1}{2} \ln\left(2.2458/C_A\right) \tag{3.3}$$

Here, the dimensionless time, t_{DA}, is based on the swept area. Equation (3.3) shows that during the pss period, pressure is linearly related with time and, thus, the Cartesian slope of pressure versus time will be a constant.

Eggenschwiler et al.[5] developed the solution for the transient-pressure responses of a single-layer, composite reservoir and used the slope of the Cartesian, straight line to estimate the swept volume. From material balance, Eggenschwiler et al.[5] derived the relationship between the swept volume and the Cartesian slope as:

$$V_s = \frac{qB}{m'_i c_t} \tag{3.4}$$

Eggenschwiler et al.[5] also pointed out that estimation of the swept volume from Equation (3.4) is independent of the geometry of the swept volume. Thus, the pss analytical method might be applicable for multilayered, composite reservoirs with inclined fronts and with any other irregularly-shaped fronts.

3.6 Pseudosteady-state Analysis

Figures 3.19 through 3.21 show the Cartesian pressure derivative responses for a five-layered, tilted-front composite reservoir. The Cartesian derivatives have been calculated with respect to t_{DRavg}, which is defined as $t_{DRavg} = t_D/R_{Davg}^2$. Here R_{Davg} is the dimensionless average front radius of the swept region and is defined in Appendix B. All these figures are for a mobility ratio $M = 1000$ and a storativity ratio $F_s = 1$. Figure 3.19 is graphed for a dimensionless reservoir thickness $h_D = 400$ and front angles of $30°$, $45°$, $60°$, and $90°$. When the front is at $90°$, the discontinuity boundary moves as a piston and the front is called a sharp front. In the case of a sharp front, the average radius of the swept region is equal to the minimum front radius, R_{Dmin}. During the

46

pseudosteady-state period, the Cartesian slope is constant and if the dimensionless time is based on the swept area, the Cartesian slope should be 2π for vertical or sharp-front swept boundaries. When dimensionless time is based on the average front radius, the Cartesian slope should be 2 for sharp-front cases. In Figure 3.19, at early times the Cartesian derivatives form a single straight line with a slope of -1 for all front angles, and this corresponds to the first infinite-acting radial flow period. Then the Cartesian slopes tend to become constant, which represents the pseudosteady-state period. At late times all the responses form another straight line of slope -1, which represents the second radial flow period. Figure 3.19 shows that, during the pseudosteady-state flow period, the Cartesian slopes for different front angles are approximately constant, but depend on the front angle. This can be explained with reference to Figure 3.1b. When the well starts producing, the pressure transient starts to move away from the well. Assuming that the layer diffusivities do not vary much from layer to layer, the pressure transient will reach the closest front (i.e., the bottom layer front) first, while in most of the layers, the pressure transient will still be propagating through the swept region. Similarly, by the time the pressure transient reaches the front in the top layer (i.e., the farthest layer), the pressure transient in the bottom layer (the layer with the closest front) has already travelled into the unswept region. This phenomenon becomes more significant for more acute front angles. Thus, in the true sense, pseudosteady-state flow never happens for an inclined front. For an inclined front case, pseudosteady-state flow occurs only in some average sense and, thus, it is not possible to get a constant Cartesian slope from pss analysis which is independent of the front angle. For a sharp-front reservoir (90°), the value of the Cartesian slope is 2.0 during the pseudosteady-state period when dimensionless time is based on the average front radius. For tilted-front reservoirs, the slopes are higher than the slope for the sharp-front reservoir. The smaller the front angle, the higher the value of the Cartesian slope. This means that, for tilted front reservoirs, if the swept volume is estimated from the Cartesian slope of

47

the pseudosteady-state period, the calculated swept volume will be considerably underestimated. One way to solve this problem is to develop a correction factor which, when multiplied with the underestimated swept volume, will result in the correct swept volume. Table 3.2 shows the equivalence between the ratios of R_{Davg}/R_{Dmin} and m_t/m_{sf}, where m_{sf} is the Cartesian slope for a sharp-front reservoir. In Table 3.2, h_D has been varied between 100 and 400 and R_{Dmin} has been varied between 300 and 1000. For tilted-front reservoirs, $R_{Davg}/R_{Dmin} = m_t/m_{sf} = m_t/2$, since $m_{sf} = 2$. This means that for tilted-front reservoirs, the Cartesian slope of the pss flow period increases by a factor of R_{Davg}/R_{Dmin} more than that for the sharp-front reservoirs. Thus, the underestimated swept volume can be corrected by multiplying it by a correction factor, $f_c = R_{Davg}/R_{Dmin}$. Figures 3.20 and 3.21 also show that the Cartesian slope during the pseudosteady-state flow period is affected by reservoir thickness as well. Figures 3.20 and 3.21 show the responses for a dimensionless reservoir thickness of 300 and 100, respectively. As the reservoir thickness decreases, the effect of front angles on the Cartesian slope also decreases. Table 3.2 shows the relationship between R_{Davg}/R_{Dmin} and m_t/m_{sf}, for different average radii and reservoir thicknesses. For the same front angle, the ratio R_{Davg}/R_{Dmin} will depend on the reservoir thickness. The definition of the average swept radius, R_{Davg}, takes into account both the front angle and the reservoir thickness. To use the correction factor, f_c, knowledge of the reservoir thickness, the front angle, and the minimum and average front radii are required a priori. The reservoir thickness can be estimated from drilling and log data, and from geological information. An approximate value of the angle can be assumed from the available geological data, and from the reservoir and injected fluid properties. The minimum and average front radii can be obtained using a trial-and-error method. A minimum front radius is first assumed, and using the reservoir thickness and front angle, the average front radius is calculated following the method described in Appendix B. The geometric mean of R_{Dmin} and R_{Davg} is calculated and is compared with that obtained from the

48

deviation time method based on Equation (3.1). If the two geometric means do not agree, the assumed value of R_{Dmin} is adjusted and the above procedure is repeated until agreement between the two geometric means is achieved.

Figures 3.22 through 3.24 show the effect of reservoir thickness on pseudosteady-state analysis. These figures show responses for a five-layered reservoir and for different front angles. For the same front angle, as the reservoir thickness decreases, the ratio of R_{Davg}/R_{Dmin} also decreases. Since it has been shown before that R_{Davg}/R_{Dmin} = m_s/m_{sf}, as the reservoir thickness decreases, the responses come closer to the sharp-front response. For the conditions specified in Figures 3.22 through 3.24, the responses for h_{tD} = 100 are very close to the sharp-front reservoir and, thus, a reservoir with h_{tD} = 100 or less can be considered as a thin reservoir for pseudosteady-state analysis. Therefore, for all front angles, a thin reservoir can be analyzed as a sharp-front reservoir. But for thick reservoirs, the assumption of a sharp front will cause significant error in pseudosteady-state analysis. Figures 3.22 through 3.24 also show that as the front angle increases, the effect of the reservoir thickness decreases, since for a particular reservoir thickness, as the front angle increases, the ratio R_{Davg}/R_{Dmin} decreases and the responses become closer to the sharp-front response.

Figures 3.25 and 3.26 show the effect of front angle on Cartesian derivative responses for R_{Dmin} of 300 and 1000, respectively. For the same front angle and reservoir thickness, as R_{Dmin} becomes smaller, the ratio R_{Davg}/R_{Dmin} becomes larger and thus deviation from the sharp-front response is also larger. Although Figure 3.26 shows results for h_{tD} = 400 (h_{tD} = 300 in Figure 3.25), the ratios R_{Davg}/R_{Dmin} for various front angles are smaller for the responses shown on Figure 3.26 as compared to Figure 3.25, since R_{Dmin} = 1000 in Figure 3.26.

Figures 3.27 and 3.28 show the effect of mobility ratio on the Cartesian pressure derivatives. Figures 3.27 and 3.28 describe responses for front angles of 45° and 60°, respectively. Both of these figures are for a storativity ratio, $F_s = 1$. Figures 3.27 and 3.28 show that the mobility ratio does not change the Cartesian slope. An increase in the mobility ratio increases the length of the pseudosteady-state period and delays the beginning of the second radial flow period. For a pss analysis to be possible, the mobility ratio, M, should be significantly greater than 10 for $F_s=1$. A comparison between Figures 3.27 and 3.28 shows that as the front angle moves closer to 90°, the Cartesian slope moves closer to 2.

Figures 3.29 and 3.30 show the effect of the storativity ratio, F_s, on the Cartesian derivatives. Figures 3.29 and 3.30 are for front angles of 45° and 60°, respectively. Like the mobility ratios, the higher storativity ratios increase the length of the pseudosteady-state flow period and the storativity ratios do not change the Cartesian slope of the pseudosteady-state period. Thus, Figures 3.27 through 3.30 suggest that the correction factor developed in Table 3.2 applies for most-commonly encountered mobility and storativity ratios for thermal recovery processes.

3.7 Conclusions

For multi-layer, composite reservoirs with tilted fronts, the following conclusions have been drawn from this study:

1. Design equations for the end of the first, radial-flow period for sharp front reservoirs are inadequate for tilted-front reservoirs. Modified design equations have been developed for the end of the first, radial-flow period and for the time to the maximum derivative for tilted-front reservoirs.

50

2. The deviation time method yields an estimate of the geometric mean of the minimum front radius and the average front radius of the swept region.

3. For inclined fronts, traditional pseudosteady-state analysis does not produce a constant Cartesian slope which is independent of the front angle and the reservoir thickness. For an inclined-front reservoir, pseudosteady-state flow exists in some average sense.

4. A correction factor has been developed to estimate the correct swept volume from the pseudosteady-state analysis for situations where a tilted front is suspected to occur. This correction factor should apply for most-commonly encountered thermal recovery situations.

5. For the cases studied in this paper, thermal well test responses obtained from a crossflow system can be analyzed using a commingled system solution for a fully-penetrating well. However, crossflow must be taken into account for proper analysis of thermal well test responses for partially-penetrating wells.

4.0 PSEUDOSKIN UNDER VARIOUS RESERVOIR CONDITIONS

4.1 Introduction

Reservoir deposition occurs over a geologic period of time and, because of this, many reservoirs are layered instead of being homogeneous. Oil reservoirs are often accompanied by a bottom-water zone and/or a gas cap. In such situations, wells are completed over a fraction of the productive zone to delay water and/or gas coning. These wells are known as partially-penetrating wells. Because of partial penetration, pressure transient responses show an additional pressure drop in comparison to the pressure drop for a fully-penetrating well. This additional pressure drop is referred to as pseudoskin. Partially-penetrating wells have their own characteristic responses which, if not properly evaluated, may lead to errors in the interpretation of well-test data. The purpose of this paper is to study the pressure transient responses and the pseudoskin factor in a partially-penetrated, multi-layer reservoir with or without a bottom-water zone or a gas cap.

Muskat[1] studied partially-penetrating wells in single-layer reservoirs under steady-state conditions using the method of images and estimated the productivity loss because of partial penetration. Nisle[2] presented buildup pressure transient responses for a partially-penetrating well in a single-layer homogeneous reservoir. He considered a partially-penetrating well in an infinite slab and used the method of images to solve the problem. He observed two different straight lines for early and late time pressure buildup responses and used the ratio of the slopes of these two straight lines to estimate the penetration ratio. Brons and Marting[3] observed three sequences in pressure transient responses of a partially-penetrating well in a single-layer isotropic reservoir: a radial flow period with a slope corresponding to the open interval thickness, a transition period, and a pseudoradial flow period with a slope corresponding to the total formation thickness. They presented an empirical expression for the pseudoskin factor, s_p. But they did not consider the variation

in the horizontal and the vertical permeabilities when defining dimensionless wellbore thickness and their pseudoskin factor had to be numerically evaluated.

Bilhartz and Ramey[4] used a two-dimensional, finite-difference model to study wellbore storage and skin effects in a single-layer, partially-penetrated reservoir. They concluded that the radial flow period and the transition to pseudoradial flow period may be masked in the presence of significant wellbore storage. They extended the Brons and Marting[3] pseudoskin expression to anisotropic reservoirs and discussed methods to estimate horizontal and vertical permeabilities.

Streltsova-Adams[5] used Laplace and Hankel transformations to solve the partial-penetration problem in a single-layer reservoir and derived an expression for the pseudoskin factor in terms of infinite sine and cosine series. She considered the presence of a gas cap as a constant-pressure boundary in her solution. She investigated the effect of open interval (penetrated portion) location on the pseudoskin factor and concluded that the pseudoskin factor is minimum for centrally-located open intervals, other parameters remaining unchanged. She also observed that for a reservoir with a gas cap, the pseudoskin factor is lower than that for a reservoir with no gas cap, when the open interval is adjacent to the constant-pressure boundary. Saidikowski[6] investigated the combined effect of wellbore damage and partial penetration on transient pressure analysis and presented a relationship for the total skin obtained from transient pressure analysis with wellbore skin and pseudoskin. Buhidma and Raghavan[7] studied drawdown and buildup behaviour of a partially-penetrating well in a square reservoir subject to bottom-water drive. Using Green's function to obtain the solution, they concluded that, under bottom-water drive, pseudoradial flow does not exist and the pseudoskin factor can not be calculated by the methods presented by Brons and Marting[3] and other researchers. Although a pseudoradial flow period does not exist under bottom-water or gas-cap drive, the expression for pseudoskin developed in this study can be used to estimate the pseudoskin factor under

these reservoir conditions.

Using a two-dimensional finite-difference simulator, Reynolds et al.[8] graphically presented the pressure transient responses of a partially-penetrated, two-layer reservoir. Analyzing the steady-state analytical solution, they identified the correlating parameters and then obtained a correlation for the pseudoskin factor by regressional analysis. They also concluded that by using different layers for different fluid regions, a multi-phase flow system can be approximated by a layered, single-phase flow system.

Papatzacos[9] used the method of images to solve the partial-penetration problem for a single-layer, homogeneous reservoir and derived an expression for the pseudoskin factor in terms of the dimensionless open interval, its location and the dimensionless wellbore radius.

Olarewaju and Lee[10] studied the buildup pressure behaviour of a partially-penetrating well in a two-layer reservoir with closed top and bottom boundaries. Of the two layers they considered, one layer is open to flow and the other layer is closed. In the closed layer, they considered flow only in the vertical direction, neglecting the radial component of the flow, which may limit the applicability of their model. Olarewaju and Lee[10] considered crossflow as a time-dependent source term for the open layer based on the vertical flow component for the closed layer. By regressional analysis, they developed a series of expressions correlating the pseudoskin factor with the penetration ratio for various k_1/k_2 values.

Using a numerical simulator, Yeh and Reynolds[11] presented some type-curves for partially-penetrated, multi-layer reservoirs with transient crossflow. Using the same numerical model, Yeh and Reynolds[12] graphically presented pseudoskin factors for a partially-penetrated, multi-layer reservoir. Using regressional analysis, they obtained an expression for the pseudoskin factor.

Vrbik[13] derived a simplified approximate expression for a single-layer, homogeneous

reservoir in terms of three correlating parameters which are related to the dimensionless open interval length, its location and the dimensionless wellbore radius. Ding and Reynolds[14] extended Papatzacos[9] expression for the pseudoskin for a single-layer reservoir to that for a multi-layer reservoir and reported a good match with simulated results.

Shah and Thambynayagam[15] presented an analytical solution for a two-layer, partially-penetrated reservoir by successive application of Laplace and Hankel transformations. They considered transient crossflow between the two layers and the presence of a gas-cap drive. They presented some pressure transient responses for fully- and partially-penetrating wells and they did not study the pseudoskin factor because of the partial penetration.

Table 4.1 summarizes most of the studies[1-20] conducted on partially-penetrated reservoirs and on the pseudoskin factor. Table 4.1 shows that most of the studies considered single-layer reservoirs and only a limited number of studies have focussed on partially-penetrated, multi-layer reservoirs. The partially-penetrated, multi-layer reservoir problem has been studied either by using a numerical simulator with graphical presentation of pressure transient responses and pseudoskin values (Yeh and Reynolds[11,12]), or by extending the single-layer expression of pseudoskin to the multi-layer case by redefining some of the parameters (Ding and Reynolds[14]). Table 4.1 also shows that very few studies have been conducted for a partially-penetrated reservoir subject to a bottom-water or a gas-cap drive.

This study attempts to give some new insights into understanding partially-penetrated, multi-layer reservoirs and covers both pressure transient responses and pseudoskin factors in situations where the top and bottom boundaries are closed and where one of the boundaries is at a constant pressure because of a bottom-water or a gas-cap drive.

4.2 Pseudoskin Factor Expression for Closed Top and Bottom Boundaries

Figure 4.1 schematically shows a two-layer, partially-penetrated reservoir . In this study, the layers are numbered from the bottom to the top. Thus, layer 1 is always the bottom-most layer. In Figure 4.1, Layer 1 is penetrated and Layer 2 is closed at the wellbore. The upper boundary of Layer 2 and the lower boundary of Layer 1 are considered as closed boundaries. Pseudosteady-state crossflow is considered between the two layers. Appendix C shows a detailed derivation of the pressure transient solution and the late-time limiting solution for this case. From the late-time limiting solution, we obtain the expression for pseudoskin as:

$$s_b = \frac{(1-\kappa)}{\kappa} \frac{K_0\left(\sqrt{\frac{\lambda_A}{\kappa(1-\kappa)}}\right)}{\sqrt{\frac{\lambda_A}{\kappa(1-\kappa)}} \, K_1\left(\sqrt{\frac{\lambda_A}{\kappa(1-\kappa)}}\right)} \tag{4.1}$$

where s_b denotes the pseudoskin, and λ_A and κ denote the dimensionless crossflow parameter and the mobility-thickness ratio of the open interval, respectively. Equation (4.1) can be extended for a multi-layer reservoir by appropriately defining λ_A and κ as:

$$s_b = \frac{(1-\bar{\kappa})}{\bar{\kappa}} \frac{K_0\left(\sqrt{\frac{\bar{\lambda}_A}{\bar{\kappa}(1-\bar{\kappa})}}\right)}{\sqrt{\frac{\bar{\lambda}_A}{\bar{\kappa}(1-\bar{\kappa})}} \, K_1\left(\sqrt{\frac{\bar{\lambda}_A}{\bar{\kappa}(1-\bar{\kappa})}}\right)} \tag{4.2}$$

where, $\bar{\kappa}$ = total mobility-thickness ratio of the open interval

$\bar{\lambda}_A$ = average crossflow parameter

Equation (4.2) is applicable for a multi-layer reservoir having any arbitrary number of layers making up the open interval and any arbitrary location of the open interval. In Equation (4.2), $\bar{\kappa}$ and $\bar{\lambda}_A$ are calculated by adding the individual layer mobility-thickness ratio of the open interval, and by adding the bottom and the top boundary crossflow parameters of the open interval, respectively. For multi-layer reservoirs, instead of

76

considering the crossflow parameters of each and every layer, only the top and bottom boundary crossflow parameters of the open interval are considered in defining the average crossflow parameter. This was done because Equation (4.2) gives better results with an average crossflow parameter defined in this manner, rather than with an average crossflow parameter which considers the crossflow parameters of each and every layer. A similar observation is made by Ding and Reynolds[14] in defining the average vertical permeability. Irrespective of the number of layers in the reservoir, only two parameters (that is, $\bar{\kappa}$ and $\bar{\lambda}_A$) are required to estimate the pseudoskin using Equation (4.2).

For a single-layer, anisotropic reservoir, the mobility-thickness ratio, κ, and the crossflow parameter, λ_A, reduce to the penetration ratio (b) and $2b^2/h_D^2$, respectively. With these simplifications, Equation (4.1) reduces to:

$$ s_b = \frac{h_D}{\sqrt{2}} \left(\frac{1-b}{b} \right)^2 \frac{K_0\left(\sqrt{\frac{2b}{h_D^2(1-b)}} \right)}{K_1\left(\sqrt{\frac{2b}{h_D^2(1-b)}} \right)} \tag{4.3} $$

$$ \text{where,} \quad h_D = \frac{h_w}{r_w} \sqrt{\frac{k}{k_v}} \tag{4.4} $$

Equation (4.3) estimates the pseudoskin factor for a single-layer, anisotropic reservoir with closed top and bottom boundaries. Equation (4.3) is also applicable for homogeneous reservoirs with an appropriate change (that is, $k = k_v$) in the definition of h_D.

4.3 Pseudoskin Factor Expression for a Gas-Cap or a Bottom-Water Drive

Figure 4.2 schematically shows a two-layer, partially-penetrated reservoir subject to a gas cap drive. The gas cap is considered to be very large compared to the size of the reservoir and the boundary between the reservoir and the gas cap is considered as a constant pressure boundary. An infinitely-large bottom-water zone can be treated in a similar fashion. A finite gas-cap or bottom-water zone can be modelled as a layer of finite thickness with

77

appropriate properties, and a partially penetrating well in such a reservoir can be treated in the same way as in the previous section. Layer 1 is penetrated and Layer 2 is closed at the wellbore. The upper boundary of Layer 2 is considered as a constant-pressure boundary because of the gas cap, whereas the lower boundary of Layer 1 is considered as a closed boundary. Pseudosteady-state crossflow is considered between the two layers. Appendix D shows a detailed derivation of the pressure transient solution and late-time limiting solution. From the late-time limiting solution, the pseudoskin expression can be obtained as:

$$ s_b = \frac{a_{2L}K_0(\sigma_{2L})}{(a_{2L}-a_{1L})\kappa\sigma_{2L}K_1(\sigma_{2L})} - \frac{a_{1L}K_0(\sigma_{1L})}{(a_{2L}-a_{1L})\kappa\sigma_{1L}K_1(\sigma_{1L})} - \frac{(a_{2L}-a_{1L})K_0(\sigma_{1L})K_0(\sigma_{2L})}{b_L} \quad (4.5) $$

where s_b denotes the pseudoskin factor, and σ_{1L}, σ_{2L}, a_{1L}, a_{2L}, and b_L are late-time limiting values defined by Equations (D.22) through (D.26) and (D.30) in Appendix D. The variable, λ_C, in Equations (D.22) through (D.26), is the crossflow parameter between the reservoir and the gas cap and this parameter is required to calculate the late-time limiting values in Equation (4.5). Equation (4.5) estimates the pseudoskin in a two-layer, partially-penetrated reservoir subject to a gas-cap or a bottom-water drive. Equation (4.5) is also applicable for a multi-layer reservoir having any arbitrary number of layers representing the open interval and any arbitrary location of the open interval, provided κ and λ_A are calculated by adding the individual layer mobility-thickness ratio of the open interval, and by adding the top and bottom boundary crossflow parameters of the open interval, respectively. Irrespective of the number of layers in the reservoir, only three parameters (that is, $\overline{\kappa}$, $\overline{\lambda_A}$ and λ_C) are required to estimate the pseudoskin. An effort was made to simplify Equation (4.5) for a single-layer reservoir without much success.

4.4 Accuracy of Pseudoskin Factor Expressions

For multilayered reservoirs, Table 4.2 compares the estimated pseudoskins using the simplified expressions of Equations (4.2) and (4.5) with those calculated using the actual

78

analytical solutions. Layered reservoi- ·_   :av·· are considered. Various cases
of reservoir configuration in Table ·   ··   cd ·· Table 4.3. In Table 4.2, for a
particular reservoir, s_{hc} denotes th· ··..   ·rrcc·' pseudoskin from the analytical
solution of Gomes and Ambasth·   ·hich ·· ·h· late-time dimensionless pressure
difference between the response ·· ·h· p·rt··!·· penetrating well and that of the fully-
penetrating well at a particular ti··· ··h··r··· ··,· denotes the estimated pseudoskin using
the simplified expressions of Eq····· · ?) and (4.5). For different values of open
interval mobility-thickness ratio $(\bar{\kappa})$ and crossflow pararneter $(\bar{\lambda}_A)$ and for different open
interval locations, pseudoskin factors are estimated for layered reservoirs having a different
number of layers. For both the closed top and bottom boundaries and the bottom-water
zone, Table 4.2 shows an excellent match between the estimated and the actual pseudoskins
for all the different cases considered.

4.5 Comparison with Reference 3

Figure 4.3 compares the pseudoskin factors estimated using Equation (4.3) of this study
with those from Figure 2 of the Brons and Marting[3] study for a single-layer, homogeneous
reservoir. Figure 4.3 shows that, except for small penetration ratios (b < 0.3), the
pseudoskin factors estimated using Equation (4.3) are very close to those estimated in the
Brons and Marting[3] study. The difference between the two pseudoskin values increases
with a decrease in penetration ratios. Also, pseudoskin factors calculated from Equation
(4.3) are consistently higher than those from the Brons and Marting[3] study. The reason for
the differences in pseudoskin values may be the difference in crossflow modelling in the
two studies. For the pseudoskin factor comparison shown in Figure 4.3, Figure 4.4 shows
the ratio of the pseudoskin factor obtained from the Brons and Marting[3] study to that
obtained from this study. When the penetration ratio is not very small (b > 0.2), the
pseudoskin ratio for a particular h/r_w is approximately constant. Thus, the pseudoskin
factor obtained from this study can be corrected to the Brons and Marting[3] pseudoskin

value by multiplying by the pseudoskin ratio.

4.6 Comparison with References 12 and 14

Table 4.4 compares the pseudoskin factors estimated from this study with those estimated from the Yeh and Reynolds[12] and Ding and Reynolds[14] studies. Various cases in Table 4.4 refer to different data sets. The cases in Table 4.4 are not related to the cases in Table 4.3. Table 4.4 shows data for a three-layer reservoir with closed top and bottom boundaries and with layer 3 open to flow. These data are taken from the Ding and Reynolds[14] study. In Table 4.4, s_{pYR} and s_{pDR} denote the pseudoskin obtained from the Yeh and Reynolds[12] study and the Ding and Reynolds[14] study, respectively. Table 4.4 shows that the pseudoskins obtained in this study are very close to those of the Ding and Reynolds[14] study, and of the Yeh and Reynolds[12] study. Ding and Reynolds[14] reported a good match between their pseudoskin and that obtained from the numerical simulator. In most cases, pseudoskin factors obtained from the analytical solution as well as from the the simplified expression developed in this study are observed to be greater than those obtained from the Ding and Reynolds[14] study, and from the Yeh and Reynolds[12] study. This is probably because of the pseudosteady state crossflow assumption in the development of the analytical model of this study. The significance of this assumption is that the resistance to vertical flow is assumed to be limited in the interlayer area instead of uniformly dispersed in the vertical direction. This pseudosteady state crossflow assumption is more applicable when shale streaks are present in the interlayer areas.

4.7 Development of New Time Criteria and Comparison with Reference 4

Figure 4.5 shows the effect of the crossflow parameter, λA, on the pressure derivative responses of a two-layer reservoir with different open interval mobility-thickness ratios, κ. The crossflow parameter (λ_A) has been varied between 0.5×10^{-5} and 0.5×10^{-7}, and the mobility-thickness ratio (κ) has been varied between 0.25 and 0.75. For all values of the

crossflow parameter and mobility-thickness ratio, the early time responses show radial flow behaviour with a constant semi-log slope of $0.5/\kappa$. At very early times, the semi-log slopes are slightly lower than their constant value because of the numerical errors introduced in solving the system of equations. After some time, the responses show a transition from radial flow behaviour, and the time at which the transition occurs is a strong function of the crossflow parameter and the mobility-thickness ratio. At late times, all responses show pseudoradial flow behaviour with a semi-log slope of 0.5. Again, the time to the beginning of the pseudoradial flow is a function of the crossflow parameter and the mobility-thickness ratio. The higher the crossflow parameters are, the sooner the radial flow period ends and the sooner the pseudoradial flow period begins. The lower the mobility-thickness ratio is, the earlier the radial flow period ends and the later the pseudoradial flow period begins. Analysis of the pressure derivative responses shown in Figure 4.5 results in the following criteria for the end of the radial flow period and the beginning of the pseudoradial (second radial) flow-period:

$$t_{D1} = 0.0196 \, \kappa^2/\lambda_A \tag{4.6}$$

and

$$t_{D2} = 0.658 / \left(\lambda_A \sqrt{\kappa} \right) \tag{4.7}$$

Equations (4.6) and (4.7) describe the times at which the semi-log pressure derivatives are within 5% of the correct slope values. Equations (4.6) and (4.7) have been extended for reservoirs having more than two layers by replacing λ_A and κ by $\overline{\lambda}_A$ and $\overline{\kappa}$, respectively, and have been shown to be applicable for three-layer and five-layer reservoirs. Table 4.5 shows the data used to obtain Equations (4.6) and (4.7). Figures 4.6 and 4.7 show the verification of the accuracy of Equations (4.6) and (4.7), respectively.

Bilhartz and Ramey[4] used a two-dimensional, finite-difference model to study the pressure

81

transient responses of a partially-penetrating well with wellbore storage and skin effects. Based on an analysis of the pressure responses, they developed the time criteria for the end of radial flow and the beginning of the pseudoradial flow periods as follow:

$$t_{D1} = 0.02 \, h_D^2 \tag{4.8}$$

and

$$t_{D2} = h_D^2 \left(\frac{h}{h_w \pi}\right)^2 \left[\ln\left\{\frac{2}{\pi}\sin\left(\frac{\pi h_w}{h}\right)\cos\left(\frac{\pi h_w}{2h}\right)\cos\left(\frac{3\pi h_w}{4h}\right)\right\} - \ln(0.02)\right] \tag{4.9}$$

where, h_D is defined by Equation (4.4).

For a single-layer reservoir, Equations (4.6) and (4.7) degenerate to the following forms:

$$t_{D1} = 0.0098 \, h_D^2 \tag{4.10}$$

and

$$t_{D2} = 0.329 \frac{h_D^2}{b^{5/2}} \tag{4.11}$$

The time for the end of the first radial flow period given by Equation (4.10) is about half of that given by Equation (4.8). Thus, the first radial flow period ends earlier as predicted by Equation (4.10) than by Equation (4.8). For a single-layer reservoir, Equation (4.11) estimates the time for the beginning of the second radial flow period, $t_{D2} = 837,500$ with a crossflow parameter $\lambda_A = 1.11 \times 10^{-6}$ and a penetration ratio of 0.5. For the same data, Equation (4.9) estimates $t_{D2} = 196,500$. Analysis with some other values of the crossflow parameter and penetration ratio showed that the time for the beginning of the second radial flow period estimated from Equation (4.11) is approximately 2 to 4 times greater than that estimated from Equation (4.9).Thus, according to the time criteria obtained in this study, the first radial flow period ends earlier and the second radial flow period begins later than

82

the times predicted by Bilhartz and Ramey's[4] correlations. Some of the differences in these time criteria may be attributed to different ways of modelling the crossflow in these two studies. However, a smaller t_{D1} and a larger t_{D2} based on pressure derivative responses (Equations (4.10) and (4.11)) than those based on pressure responses (Equations (4.8) and (4.9)) are consistent with the general observations regarding time criteria based on pressure and pressure derivative responses presented by Ambastha[22].

Figure 4.8 compares the correlations for the time to the beginning of the second radial flow period from this study (Equation 4.11) and that from the Bilhartz and Ramey[4] study (Equation 4.9) for a single-layer reservoir. Equation (4.9) is not applicable for all penetration ratios. Equation (4.9) becomes meaningless for $b \geq 2/3$ because $\cos(3\pi h_w/4h)$ becomes zero or negative. However computationally, Equation (4.9) is applicable for $b <$ 0.64, because beyond this penetration ratio, t_{D2} becomes negative. To the best of my knowledge, this limitation of Equation (4.9) has not been pointed out in the literature. But Equation (4.11) has been derived for $0.1 \leq b \leq 0.8$ and for h_D between 100 and 10,000. Although there is no mathematical or computational limitation to Equation (4.11), t_{D2} value calculated at $b = 1$ becomes physically meaningless, since there is no pseudoradial flow in this case.

Figure 4.9 compares the pressure transient responses from this study with those from Figure 3 of Bilhartz and Ramey's[4] study. Figure 4.9 graphs dimensionless wellbore pressure against dimensionless time for penetration ratios of 0.25 and 0.5. Initially, the responses show a straight line corresponding to the first radial flow period with a semi-log slope of 0.5/b. After the first radial flow period, there is a transition period after which, the responses again show straight lines corresponding to the second radial (pseudoradial) flow period with a slope of 0.5. Since pseudoskin factors obtained from this study are slightly higher than those obtained from Bilhartz and Ramey's[4] study, pressure responses for the second radial flow period are slightly higher than those of Bilhartz and Ramey[4]. For

83

penetration ratios of 0.25 and 0.5, pseudoskin factors obtained from this study are 19.6 and 5.98, respectively, whereas those obtained from Bilhartz and Ramey's[4] study are 17.83 and 5.47, respectively. Thus, the pseudoskin factors obtained from the two studies are very close.

4.8 Effects of Gas-Cap (or Bottom-Water) Drive on Pseudoskin and Comparison with Reference 5

Table 4.6 shows the effects of a gas cap on the pseudoskin factor for a three-layer reservoir with $k_1 = k_2 = k_3 = 4.9346 \times 10^{-14}$ m^2 and with h = 200 m. The various cases of reservoir configuration in Table 4.6 are explained in Table 4.3. Cases 1 and 2 show pseudoskins when there is no gas cap and Cases 3 and 4 show pseudoskins when the reservoir is subject to a gas-cap drive. In the absence of the gas cap, the pseudoskin is lower when the open interval is away from the top or the bottom boundary than when the open interval is located adjacent to the top or the bottom boundary. This happens because the crossflow parameter, $\overline{\lambda}_A$, is higher when the open interval is away from the top or bottom boundary. But Case 3 shows that when the gas cap is present, the pseudoskin is smaller when the open interval is adjacent to the constant-pressure boundary than when the open interval is away from the constant-pressure boundary. This happens because, when the open interval is adjacent to the constant-pressure boundary, the wellbore pressure stabilizes faster than when the open interval is away from the constant-pressure boundary. Similar observations were also made by Streltsova-Adams[5]. The above observations are also valid for the corresponding cases when the reservoir is accompanied by a bottom-water zone.

Figure 4.10 compares the pseudoskin factors from this study with those from the Streltsova-Adams[5] study for a partially-penetrating well in a reservoir subject to a gas-cap drive. The gas-oil contact has been modelled as a constant pressure boundary in both studies. Figure 4.10 compares pseudoskin factors with those from Figure 9 of the

84

Streltsova-Adams[5] study. The solid lines in Figure 4.10 show the pseudoskin factors estimated from Equation (4.5) of this study for various penetration ratios and under a gas-cap condition. Streltsova-Adams[5] estimated the pseudoskin by taking the difference between the late-time pressure responses of a partially-penetrating well and a fully-penetrating well in a particular reservoir. Figure 4.10 shows that the pseudoskin factors estimated in this study differ only slightly from those obtained in the Streltsova-Adams[5] study, exept for small penetration ratios (b < 0.3). Pseudoskin factors estimated in this study are slightly higher than those obtained in the Streltsova-Adams[5] study. This is likely due to the different ways of modelling the crossflow in the two studies. For the pseudoskin factor comparison shown in Figure 4.10, Figure 4.11 shows the ratio of the pseudoskin factor obtained in the Strelsova-Adams[5] study to that obtained in this study. Although the pseudoskin factors obtained from the two studies are very close, the pseudoskin factor obtained from this study can be corrected to that of Streltsova-Adams[5] pseudoskin value by multiplying by the pseudoskin ratio.

4.9 Comparison with Reference 10

Figure 4.12 shows a comparison of the pseudoskin factors obtained from Equation (4.1) of this study with those obtained from Figure 8 of Olarewaju and Lee's[10] study. Figure 4.12 graphs the pseudoskin factors against various penetration ratios for a two-layer reservoir with layer two open to flow and layer one closed. Note that because of the reverse order of the numbering of the layers, k_2/k_1 of this study is equal to k_1/k_2 in Olarewaju and Lee's[10] study. Figure 4.12 shows that the pseudoskin factors obtained from this study are significantly higher (more than double when $k_2/k_1 = 1$) than those obtained from Olarewaju and Lee's[10] study. The reason for this may be the assumption that Olarewaju and Lee[10] made in developing their model. They assumed that there is no radial flow component in the closed layer (that is, layer one). Because of this restriction, fluid particles travel shorter distances and only vertically to move from the closed layer to the open layer (layer two). If

there were a radial flow component in the closed layer, fluid particles would have travelled longer distances to move from the closed layer to the open layer and this would have caused higher pressure drops; that is, higher pseudoskin factors. Thus, neglecting the radial flow component in the closed layer may not be a satisfactory assumption while studying pressure-transient responses for partially-penetrating wells.

4.10 Effect of Layer Refinement on Pseudoskin Factor

Table 4.7 shows the effects of layer refinement on the pseudoskin factor. For a particular reservoir thickness and open interval, the reservoir is divided into a number of mathematical layers to study the effect of layer refinement on the pseudoskin factor. In Table 4.7, Cases 1 through 3 represent a reservoir height of 30 m with an open interval thickness of 10 m, and Cases 4 through 6 represent a reservoir thickness of 100 m with an open interval thickness of 20 m, respectively. For both reservoir thicknesses of 30 m and 100 m, the open interval is considered as a single layer, and the closed interval of the reservoir is divided into 1, 2 and 4 layers. The results in Table 4.7 show a small decrease in the pseudoskin factor as the number of mathematical layers increases and this decrease in pseudoskin factor is greater when the reservoir thickness is larger. But the value of the pseudoskin factor stabilizes as the number of mathematical layers is further increased. This layer refinement effect occurs because of the pseudosteady-state crossflow assumption. The layer refinement effect has also been observed by Larsen[23].

4.11 Conclusions

1. Pressure transient responses and pseudoskin factors for a partially-penetrated, multi-layer reservoir can be studied analytically by a pseudosteady-state crossflow model.

2. Simplified expressions for the pseudoskin factor have been derived for a partially-penetrated, multi-layer reservoir with or without a bottom-water or a gas-cap drive and

the pseudoskin factors can be estimated from these expressions with reasonable accuracy.

3. Times for the end of the radial flow period and the beginning of the pseudoradial flow period depend on the crossflow parameter and the mobility-thickness ratio of the open interval. Simplified expressions have been derived for these time criteria.

4. Pseudoskin factors obtained from this study have been compared with those obtained from other studies in the literature and these comparisons have shown good matches with all but one of the studies.

5.0 THERMAL WELL TEST ANALYSIS UNDER BOTTOM-WATER CONDITIONS

5.1 Introduction

The steam injection process is widely used in heavy oil recovery operations. As a result of steam injection, at least two regions of different fluid properties are created and the reservoir resembles a composite reservoir. Because of the gravity override effect, an inclined fluid front is created between the hot and the cold zones. In many cases, heavy oil reservoirs are accompanied by a bottom-water zone. The purpose of this study is to investigate the transient pressure behaviour of a steam-stimulated heavy oil reservoir under bottom-water conditions.

A reservoir undergoing a thermal recovery process has been idealized as a composite reservoir for a long time[1-6]. But most of the studies consider piston-like movement of the fluid front, neglecting the gravity-override effect. Satman[7] used the concept of a tilted (inclined) front in the pressure transient analysis of a two-layer composite reservoir. He suggested that the fluid front would propagate at different rates in different layers. For steam flooding, Satman and Oskay[8] considered the discontinuity boundary as a tilted front to account for the gravity override effect and modelled the reservoir as a multi-layer composite reservoir without crossflow. They concluded that the tilted-front model is a better representation of the actual reservoir.

According to published reports on steam-drive projects[9,10], the gravity override effect is a common phenomenon which results in a tilted front between the swept and the unswept zones. If the gravity override effect is not taken into consideration, the predicted performance of the steam flooding project may be quite different than the actual one. Singhal[11] conducted some scaled physical model studies of a steam-flood in a reservoir

101

containing heavy oil. He presented some temperature profiles obtained from his model which showed a very strong gravity override effect. Blevins et al.[9] discussed the application of steam-flooding for light oil reservoirs. They mentioned that the gravity override effect also exists for light oil reservoirs, although it is less prominent than that for heavy oil reservoirs.

Recently, Nasr and Pierce[12] studied steamflooding in a scaled, oil-sand reservoir through a bottom-water zone. They presented some temperature profiles with time and observed steam underruning in the bottom-water zone and the gravity override effect in the oil-sand zone.

Many times, heavy oil reservoirs are accompanied by a bottom-water zone. In such a situation, both the stimulation well (with good injectivity) and the producing well are partially perforated to avoid injecting the steam into the bottom-water region and to avoid a water-coning problem, respectively. For a partially-penetrating well, transient pressure responses show additional pressure drop around the wellbore because of flow convergence. This additional pressure drop is referred to as a "pseudoskin" in the literature. Streltsova-Adams[13] investigated the pseudoskin under bottom-water or gas cap conditions, in which she graphically presented the pseudoskin factor. Gomes and Ambastha[14] presented simplified expressions for pseudoskin factors both for closed top and bottom boundaries and for a bottom-water condition. They also presented an extensive literature review on partially penetrating wells.

The objective of this study is to investigate the transient pressure responses for a heavy oil reservoir undergoing steam flooding under bottom-water conditions. Both finite and infinite bottom-water zones have been considered. A new analytical solution developed by Gomes and Ambastha[15] for multi-layer composite reservoirs has been used to generate the responses.

5.2 Modelling of Infinite and Finite Bottom-Water Zones

Figures 5.1 and 5.2 show two different bottom-water situations, where a heavy-oil reservoir has undergone a steam-flooding process. Though there is no limitation to the number of layers that can be used in the analytical model, this study uses two layers to represent the reservoir and one layer to represent the finite bottom-water zone (for the finite bottom-water case) unless mentioned otherwise. Wellbore storage and skin are neglected in this study. In Figure 5.1, the bottom-water zone is very large compared to the size of the reservoir. Thus, the boundary between the the bottom-water zone and the reservoir has been approximated as a constant-pressure boundary. Because of the bottom-water zone, the well has been partially penetrated to avoid or delay the water coning problem. In Figure 5.1, Zones 1 and 3 represent the swept zone, and Zones 2 and 4 represent the unswept zone. Because of the gravity override effect, Zone 3 extends a longer distance than does Zone 1. Thus, the swept front has propagated further in Zone 3 than in Zone 1. Although Zone 1 is considered as a part of the swept zone, it may have different fluid properties than Zone 3. In Figure 5.1, a discontinuity boundary between Zones 1 and 2 is denoted as R_1. The discontinuity boundary between Zones 3 and 4 is denoted as R_2. In dimensionless form, R_1 and R_2, have been represented by R_{D1} and R_{D2}, respectively. In reality, a bottom-water zone may not be very large for all reservoirs. Figure 5.2 shows a heavy-oil reservoir with a finite bottom-water zone. As in Figure 5.1, Zones 1 and 3 represent the swept zone and Zones 2 and 4 represent the unswept zone. Because of the gravity override effect, the swept fronts have been located at different positions in Zones 1 and 2. In Figure 5.2, R_{D1} and R_{D2} represent the dimensionless discontinuity boundary radii between Zones 1 and 2 and between Zones 3 and 4, respectively.

103

5.3 Infinitely Large Bottom-Water Zone and No Bottom-Water Zone Cases

The reservoir configuration considered in this section is shown schematically in Figure 5.1. Since the aquifer is very large, the water-oil contact has been represented as a constant-pressure boundary. R_{D1} and R_{D2} are the dimensionless discontinuity boundary radii between Zones 1 and 2, and between Zones 3 and 4, respectively. For an infinite bottom-water condition, λ_A represents the crossflow parameter between layers 1 and 2 and λ_C represents the crossflow between Layer 1 and the bottom-water layer. Figure 5.3 shows the effect of mobility-thickness ratio on wellbore pressure. The mobility-thickness ratio has been defined as:

$$\kappa = \frac{\left(\frac{kh}{\mu}\right)_{penetrated}}{\left(\frac{kh}{\mu}\right)_{total}} \qquad (5.1)$$

In defining the mobility-thickness ratio, reservoir and fluid properties of the swept zone (Zones 1 and 3) have been used. For example, for the case depicted by Figure 5.1, $(kh/\mu)_{penetrated} = (kh/\mu)_{Zone3}$ and $(kh/\mu)_{total} = (kh/\mu)_{Zone1} + (kh/\mu)_{Zone3}$. In a limiting case, where the penetrated and the non-penetrated sections in the swept zone have the same reservoir and fluid properties, the mobility-thickness ratio becomes the penetration ratio. The mobility-thickness ratio has been varied by changing the thickness of Layer 1 for a fixed thickness of Layer 2. Changing the mobility-thickness ratio in this way also changes the crossflow parameter because the thickness of Layer 1 appears in the definitions of both λ_A and λ_C. Figure 5.3 shows that, initially, the responses show the radial flow period corresponding to the swept zone mobility of the penetrated interval of the reservoir. After some time, the well feels the presence of the bottom-water zone and the wellbore responses show constant pressure values. The smaller the mobility-thickness ratio is, the longer it takes for the wellbore pressure to attain the constant value. This late-time constant p_{wD}

104

value includes the additional pressure drop that occurs at the wellbore because of the partial penetration. This additional pressure drop is known as the "pseudoskin factor". The pseudoskin factor depends on the mobility-thickness ratio. A mathematical expression for this "pseudoskin" has been presented in Reference 14.

Figures 5.4 through 5.6 show the effect of mobility-thickness ratio on the semi-log pressure derivative responses. Figures 5.4, 5.5 and 5.6 show responses for mobility ratios of 10, 100, and 1000, respectively. For all these figures, the properties of Zones 1 and 3 are assumed to be the same, and R_{D1} and R_{D2} are assumed to be 500 and 600, respectively. Initially, semi-log pressure derivatives are constant, which corresponds to the first radial-flow period. The relationship between the dimensionless semi-log slope for the first radial flow period (m) and the mobility-thickness ratio (κ) is :

$$m = \frac{0.5}{\kappa}$$

(5.2)

In Equation 5.2, the constant 0.5 is the dimensionless semi-log slope for a fully-penetrating well. For a homogeneous reservoir, the mobility-thickness ratio becomes the penetration ratio. In Figures 5.4 through 5.6, the initial constant values of the semi-log slopes decrease because of the influence of the bottom-water zone. When the transient effects reach the front boundary, the semi-log slopes increase because of the mobility difference between the swept and the unswept regions. The effect of the discontinuity boundary and, therefore, mobility ratio is more pronounced when the mobility-thickness ratio is less than 0.5. However, the effects of the constant-pressure bottom boundary ultimately cause the semi-log pressure derivative to sharply decline toward zero, which is equivalent to attainment of a constant p_{wD} value at late time.

To understand how the responses for an infinite bottom-water zone differ from those for a no bottom-water zone situation, Figure 5.7 shows the effect of the mobility-thickness ratio on semi-log pressure derivative responses when there is no bottom-water zone. In this

case, both the bottom and the top boundaries are closed and the responses graphed are for $M = 10$. Initially, the responses show the first radial flow period with a semi-log slope = $0.5/\kappa$. Then there is a transition flow period. During the transition period, the effect of the bottom-water zone would have been felt, if a bottom-water zone had been present. Then all the responses show the second radial-flow (pseudoradial-flow) period corresponding to the unswept region with a dimensionless semi-log slope $m = 0.5M$. A comparison of Figure 5.7 with Figures 5.4 through 5.6 shows that the transition flow period does not develop completely in the presence of the bottom-water zone. This is especially true for higher mobility-thickness ratio cases ($\kappa > 0.5$). For a mobility-thickness ratio of 0.5 or smaller, the transition flow period develops to a certain extent and, thus, pseudosteady-state analysis may be possible. As expected, the second radial flow period does not occur in the presence of a bottom-water zone.

Figures 5.8 through 5.10 show the effect of mobility-thickness ratio on Cartesian pressure derivatives. Figures 5.8, 5.9, and 5.10 are for mobility ratios of 10, 100, and 1000, respectively. For these figures, dimensionless time is based on the discontinuity boundary distance between Zones 3 and 4 (R_{DO}). In Figure 5.8 ($M=10$), the transition flow period is of very short duration and, thus, a pseudosteady-state flow period with a constant Cartesian derivative value has not developed at all. Theoretically, the dimensionless slope of the Cartesian graph, m_c, should be equal to $2/\kappa$, where 2 is the dimensionless Cartesian slope for a fully-penetrating well with a sharp front. The preceding statement is true when the swept front is vertical (sharp), and when the top and the bottom boundaries of the reservoir are closed. But in Figures 5.8 through 5.10, both Zones 1 and 3 represent the swept zone, and the front is a tilted front (see Figure 5.1) and the reservoir is under an infinitely-large bottom-water condition. An in-depth investigation of pseudosteady-state behaviour for a tilted front has been presented in Reference 16. In Figures 5.9 and 5.10, Cartesian slopes for the pseudosteady-state flow period tend to flatten at a value smaller

106

than the value of $2/\kappa$ discussed before, because of the effects of the bottom-water zone and the tilted-front.

To understand the differences between the Cartesian derivative responses for an infinite bottom-water zone and no bottom-water zone, Figure 5.11 shows the effect of the mobility-thickness ratio on the Cartesian pressure derivative for a reservoir with no bottom-water zone. Here, after the first radial flow period (initial -1 slope line), the transition flow period is more developed in comparison to the responses shown on Figure 5.8, and after the transition flow period, all responses merge to another -1 slope line corresponding to the second radial (pseudoradial) flow period.

In the preceding discussion, the mobility-thickness ratio has been varied by changing the thickness of Layer 1 for a fixed thickness of Layer 2. Changing the mobility-thickness ratio in this way also changes the crossflow parameters since the thickness of Layer 1 appears in the definitions of the crossflow parameters. By changing the horizontal permeability of the penetrated layer (that is, Layer 2 in Figure 5.1), the mobility-thickness ratio of the penetrated interval can be varied without changing the crossflow parameters. However, the vertical permeability of the penetrated layer has not been changed while changing the horizontal permeability, since it will affect the crossflow parameter. Figure 5.12 shows the effect of the mobility-thickness ratio on semi-log pressure derivative responses, when the mobility-thickness ratio has been varied by changing the horizontal permeability of the penetrated layer (Layer 2). Thus, in Figure 5.12, the mobility-thickness ratio has been varied independently, without varying the crossflow parameters. A comparison of Figure 5.12 with Figure 5.5 shows that the pressure derivative responses are different when the mobility-thickness ratio is varied independently without affecting the crossflow parameters. For small mobility-thickness ratios ($\kappa < 0.6$), Figure 5.12 shows that the wellbore responses are dominated by the bottom-water zone before the front boundary is felt. This happens because small mobility-thickness ratios in Figure 5.12 have been obtained by

assigning a small horizontal permeability to Layer 2. Thus, the pressure transient can move more easily (because of less resistance) in the vertical direction than in the horizontal direction for small mobility-thickness ratios. However, when a small mobility-thickness ratio is obtained because of a small penetrated thickness (as in the case of Figures 5.5 and 5.6), the responses reach the front boundary before the wellbore responses are dominated by the bottom-water zone.

Figure 5.13 shows the effect of storativity ratio on the semi-log pressure derivative responses. Figure 5.13 is for a mobility ratio M = 100, and a mobility-thickness ratio κ = .5. The storativity ratio influences the responses during the intermediate time period after the end of the first radial flow period. But for the reservoir parameters utilized in Figure 5.13, increasing the storativity ratio above 10 does not affect the wellbore responses due to the presence of a bottom-water zone .

Figure 5.14 shows the effect of the dimensionless discontinuity radius in Layer 1 (R_{D1}) on the semi-log pressure derivative responses. Responses in Figure 5.14 have been generated for M = 100, F_s = 100, and κ = 0.5. The discontinuity radius, R_{D1}, has been varied as 300, 500 and 1000. When R_{D1} = 300, the responses reach the fluid front before the bottom-water zone dominates the wellbore pressure. But when R_{D1} = 1000, the wellbore responses do not feel the fluid front, because the wellbore response is dominated by the bottom-water zone after the end of the first radial flow period.

Figures 5.15 and 5.16 show the effect of the crossflow parameters on the semi-log pressure derivative responses. As mentioned before, the variables λ_A and λ_C denote the crossflow parameter between the penetrated and the non-penetrated section of the reservoir, and the crossflow parameter between the reservoir and the aquifer, respectively. Crossflow parameters have been varied by changing the vertical permeability of Zone 1 of Figure 5.1. Everywhere else in the reservoir, k_v = 0.1k. The crossflow parameter ranges shown on

108

Figures 5.15 and 5.16 correspond to vertical permeabilities of 2.4×10^{-15} m^2 (2.4 mD) to 9.5×10^{-18} m^2 (0.001 mD). Figures 5.15 and 5.16 are for mobility ratios of 100 and 1000, respectively, and for $\kappa = 0.5$. Figures 5.15 and 5.16 show that, as the crossflow parameters decrease, the transition flow period after the first radial flow period becomes longer, and it takes a longer time for the pressure transient to reach the bottom-water zone. Figures 5.17 and 5.18 show the corresponding Cartesian derivative graphs. In Figures 5.17 and 5.18, dimensionless time has been computed based on R_{D2}. For small crossflow parameters, the responses in Figures 5.17 and 5.18 show some flattening of the Cartesian derivative and thus, some modification of traditional pseudosteady-state analysis may be possible. In Figures 5.17 and 5.18, a horizontal line corresponding to a Cartesian derivative of 4 (that is, $2/\kappa$) has been shown for comparison purposes. A Cartesian derivative of 4 is expected when $\kappa = 0.5$ and for a sharp-front reservoir with no bottom-water zone. When the front is tilted, the Cartesian slope is higher (for small crossflow parameters) than that for a sharp-front reservoir and the swept volume obtained from pseudosteady-state analysis is underestimated. This has been explained in more detail in Chapter 3.

5.4 Finite Aquifers

In reality, most of the aquifers accompanying the reservoirs are finite in size. Figure 5.2 schematically shows a finite bottom-water zone accompanying a reservoir. Figures 5.19 and 5.20 show the effect of aquifer mobility-thickness ratio on the semi-log pressure derivative responses. Aquifer mobility-thickness ratio has been defined as:

$$\kappa_a = \frac{\left(\frac{kh}{\mu}\right)_{aquifer}}{\left(\frac{kh}{\mu}\right)_{reservoir}} \tag{5.3}$$

109

Figures 5.19 and 5.20 are for mobility ratios of 100 and 1000, respectively. For both the reservoir and the aquifer, $k_v = 0.1k$. Figures 5.19 and 5.20 show that after the first radial flow period, wellbore responses are affected by the non-penetrated section of the reservoir and the aquifer. At late time, the responses show a second radial flow period corresponding to the total mobility-thickness ratio of the reservoir and the aquifer. As the aquifer size becomes larger (that is, κ_a becomes larger), the response for a reservoir with a finite bottom-water zone approaches that for a reservoir with an infinite bottom-water zone. In Figures 5.19 and 5.20, after the transition flow period, semi-log slopes become constant at late times. For higher values of κ_a ($\kappa_a > 0.1$), the value of this constant semi-log slope is $0.5/\kappa_a$. This happens because, at late times, the pressure transient response is dominated by the bottom-water zone because of the much higher mobility in the bottom-water zone compared to the mobility in the reservoir. However, when κ_a becomes smaller ($\kappa_a < 0.1$), the pressure transient response is also affected by the unswept region of the reservoir and, thus, the semi-log derivative is affected by the mobility contrast between the swept and the unswept zones of the reservoir. To quantify the relative effects of κ_a and M on the late-time semi-log slope requires more sensitivity studies.

In Figures 5.19 and 5.20, the responses have been presented when Layer 2 is penetrated and Layer 1 is closed (see Figure 5.2). However, when the reservoir does not possess sufficient injectivity, the well is penetrated closer to the bottom-water zone to take advantage of the higher injectivity of the bottom-water zone. Figure 5.21 shows the semi-log pressure derivative responses when Layer 1 is penetrated instead of Layer 2, and Layer 2 is closed. A comparison of Figures 5.21 and 5.19 shows the effect of the bottom-water zone is felt earlier in Figure 5.21 as compared to that in Figure 5.19. This is expected because, in Figure 5.21, Layer 1 is penetrated which is closer to the bottom-water zone than Layer 2. However, late-time responses in Figure 5.21 are the same as those of Figure

110

5.19, because, at late-time, responses are dominated by the bottom-water zone for the both cases.

In the preceding discussion of a finite aquifer, the bottom-water zone has been represented by a single layer as shown in Figure 5.2. This may not be adequate for large bottom-water zones. Figure 5.22 shows the effect of layering in the bottom-water zone on the semi-log pressure derivative responses. Figure 5.22 shows responses for an aquifer mobility-thickness ratio (κ_a) of 50. A very large κ_a value has been chosen to enforce the layering effect. In Figure 5.22, the solid line represents responses when the bottom-water zone consists of a single layer. The solid circles and triangles represent the responses when the bottom-water zone consists of two layers and three layers, respectively. Figure 5.22 shows that the responses for a two-layer and a three-layer bottom-water zone are almost identical with that for a single-layer bottom-water zone. Thus, for the analysis done in this study, the bottom-water zone can be adequately represented by a single layer without causing significant error.

Figures 5.23 and 5.24 show the effect of a closed outer boundary on wellbore responses for a reservoir with a finite bottom-water zone. In Figures 5.23 and 5.24, the well is partially-penetrating with $\kappa = 0.5$ and $\kappa_a = 1$. Figure 5.23 shows the effect of the outer boundary on the wellbore pressure. The dimensionless outer boundary radius, r_{eD}, has been varied as 10000, 20000 and 50000. The outer boundaries of the reservoir and the aquifer are assumed to be at the same distance. Initially, the responses show the first radial flow period corresponding to the penetrated section of the reservoir. Though not obvious on Figure 5.23, after the end of the first radial flow period, the wellbore pressure is affected sequentially by the pressure transient in the non-penetrated section of the reservoir, by the fluid front between the swept and the unswept zones of the reservoir, and by the pressure transient in the aquifer before the effect of the outer boundary is felt. This is more clearly shown in Figure 5.24, which shows the corresponding semi-log pressure derivative

responses. Initially, the responses show the first radial flow period corresponding to the penetrated section of the reservoir with a semi-log slope of 1.0 (that is, $0.5/\kappa$). As the pressure transient propagates into the non-penetrated section, the semi-log slope decreases before the pressure transient reaches the fluid front, when the semi-log slope increases because of the mobility contrast. Then, because the pressure transient responses at the wellbore are dominated by the aquifer, the semi-log slope decreases again and reaches a constant value of $0.5/\kappa_a$ before the effects of the outer boundaries of the reservoir and the aquifer are felt. In this particular case, the semi-log slope reaches a value of 0.5 when the transient pressure responses at the wellbore are dominated by the bottom-water zone, because the mobility-thickness ratio of the bottom-water zone, κ_a, equals 1.0. The aforementioned flow regimes and their sequences depend on a particular aquifer-reservoir system and the properties of the reservoir and the aquifer.

5.5 Conclusions

1. Bottom-water conditions, both finite and infinite, can be represented by the multi-layer composite reservoir model used in this study. The effects of mobility-thickness ratio of the penetrated section, crossflow parameters and the mobility-thickness ratio of the aquifer (for a finite aquifer) on transient pressure behaviour have been investigated.

2. The presence of the bottom-water zone is felt before the pseudosteady-state flow period occurs when the reservoir has a high vertical permeability. But if the vertical permeability is very small compared to the horizontal permeability, a brief pseudosteady-state flow period may be observed.

3. For a finite aquifer in a multi-layer, composite reservoir with closed outer boundary, the occurrence of various flow regimes and their sequences depend on the particular aquifer-reservoir system and its properties.

6.0 AN ANALYTICAL PRESSURE-TRANSIENT MODEL FOR COMPLEX RESERVOIR SCENARIOS

6.1 Introduction

Reservoir heterogeneity is usually described by layers and zones of different rock and/or fluid properties. When a secondary recovery method, such as steam-flooding, is applied, the reservoir resembles a composite reservoir. Because of reservoir heterogeneity and gravity override effects, the fluid front can have very complex shape. The presence of aquifers and gas caps can further complicate the situation. Numerous studies have been reported in the literature on layered and composite reservoirs. Gomes and Ambastha[1] have presented an extensive literature review on layered and composite reservoirs. These studies are limited in that they can not model the aforementioned complex situations analytically. This paper considers a multi-layer, composite reservoir with pseudosteady-state crossflow and presents a new and efficient model for the analytical treatment of such complex scenarios.

6.2 Model Description

In this study an n-layer, radial, composite reservoir as shown in Figure 6.1 has been considered. A symmetrically located well fully penetrates the reservoir. The well produces at a constant flow rate and pseudosteady-state formation crossflow is present between the layers. In Figure 6.1, the discontinuity boundary in each layer is represented by a vertical solid line. These discontinuity boundaries have been vertically extended across all the layers. As a result, depending on the total number of discontinuity boundaries and their locations, an n-layered reservoir may have m number of zones in each layer. Therefore, the reservoir is divided into n x m zones and each

127

zone may be identified by (i,j), in which i and j denote the zone and the layer, respectively. Each zone may have different rock and/or fluid properties, and can have a variable length in the radial direction, depending on the discontinuity boundary locations. In an actual reservoir, n x m zones of different rock and/or fluid properties may not be needed. In Figure 6.1, the shaded and non-shaded areas represent two different fluid and/or rock types. Each layer has only two different rock and/or fluid types separated by a discontinuity boundary. In each layer, the discontinuity boundary is placed at a different location to simulate a tilted-front discontinuity boundary for the reservoir and for this particular situation, m=n+1. Though layers of equal thicknesses throughout the reservoir are shown in Figure 6.1, non-uniform layer thicknesses are accounted for in the model presented in this paper.

The pseudosteady-state crossflow between layers within the reservoir is modelled as in the semi-permeable wall model proposed by Gao[2]. Thus, the crossflow resistance is assumed to be confined to the interlayer boundary and flow in each layer is horizontal. The upper boundary of the top layer and the lower boundary of the bottom layer are considered closed, when there is no aquifer or gas cap present. If an aquifer or a gas cap exists, crossflow across the bottom or top boundary should be considered. In the presence of an aquifer or a gas cap, the well is partially perforated to delay water or gas coning. Transient pressure responses for partially-penetrating wells can also be studied using the model discussed in this paper.

6.3 Solution Description

The diffusivity equations for all zones(i,j) in a cylindrical coordinate system has been considered. This system has been treated as a generalized eigenvalue system. From the boundary conditions of the various zones, a system of simultaneous, linear equations has been derived and solved to obtain transient pressure responses for each zone.

Details of this solution have been presented by Gomes and Ambastha[1]. A general solution for dimensionless pressure in Laplace space ($\bar{P}_{Di,j}$) for zone(i,j) has been obtained as:

$$\bar{P}_{Di,j} = \sum_{k=1}^{n} \left[A^k_i \, E^k_{i,j} \, K_0(\sigma^k_i r_D) + B^k_i \, E^k_{i,j} \, I_0(\sigma^k_i r_D) \right],$$ (6.1)

where σ^k_i and $E^k_{i,j}$ are the eigenvalues and the eigenvector, respectively, for Region i and Layer j. Constants A^k_i and B^k_i are to be determined from the boundary conditions. The boundary conditions are: the inner boundary condition (wellbore condition), the outer boundary condition, and the interface conditions, which are pressure and flowrate continuity conditions between zones. Equation (6.1) contains 2n x m constants to be evaluated from the boundary conditions. The variable r_D represents dimensionless radius. To evaluate the transient pressure response at the wellbore, the solution represented in Equation (6.1) is evaluated at $r_D = 1$. As discussed in Gomes and Ambastha[1], this new solution uses the eigenvalues and eigenvectors of the system and is computationally more efficient than other methods proposed in the literature.

6.4 Solution Algorithm

The computer program for the solution has been written in FORTRAN 77 and Appendix F shows the complete source code. The following logical sequence has been utilized in writing the source code:

Main Program: GENERAL

1. open output files to store results

2. read all the necessary input data from an input data file

3. call Subroutine TAB to compute front radii, if required

4. compute the average front radius, RDAV

5. non-dimensionalize the wellbore and front radii

6. compute transmissibilities, TS(i,j), and storativities, ST(i,j), of each zone

7. compute crossflow parameters, XA(i,j) and XB(i,j), of each zone

8. generate a set of time vectors, TD

9. call Subroutine INVERT to invert the results from Laplace space to real space

Subroutine INVERT

9.1 Subroutine Invert uses the Stehfest[3] algorithm to invert results from Laplace space to real space

9.2 call Subroutine LAP to compute results in Laplace space

Subroutine LAP

9.2.1 set up the coefficient matrices, A(j,j) and BB(j,j), and compute the eigenvalues and eigenvectors from the IMSL.Math Library[4]

9.2.2 set up the augmented matrices, AA(k,k) and B(k), from the boundary conditions and solve the resulting system of equations using the IMSL.Math Library[4]

9.2.3 compute the wellbore pressure and its derivative in Laplace space and transfer it to Subroutine INVERT

9.3 invert the pressure and the pressure derivative to real space and transfer it to the Main Program

10. compute the semi-log and Cartesian derivatives and generate buildup results

11. write and store the results in the Output files

The computational process involves repeated calculations of Bessel's functions. Very small and large arguments of Bessel's functions create an overflow problem during the computational process. This problem is overcome by using a dimensionless radius, r_D, based on the minimum front radius, instead of the wellbore radius, and by calculating

Bessel's functions in exponentiated form. Because of the exponentiation of Bessel's functions, equations obtained from the boundary conditions are multiplied by exponentiation factors, and if this is not corrected, the solution will generate erroneous results. During computation of the wellbore pressure, the results are divided by the corresponding exponentiation factors to reverse the exponentiation effects.

6.5 Model Validation

The new analytical solution has been validated by generating some well-known transient-pressure responses for various cases of homogeneous, composite, and layered reservoirs, which are subsets of the general solution developed. Results obtained from this solution have been compared against Agarwal et al.[5] type-curves for homogeneous reservoirs, Tariq and Ramey's[6] study on layered reservoirs, Eggenschwiler et al.[7] study on composite reservoirs, and Ambastha and Ramey's[8,9] study on two- and three-region, composite reservoirs. These comparisons have shown excellent matches of the results obtained from this new solution with those obtained from other studies. Gomes and Ambastha[1] have presented details of this validation. The model discussed in this paper is capable of generating transient pressure responses for partially-penetrating wells. A study regarding partially-penetrating wells using the model of this paper is presented in Gomes and Ambastha[10].

6.6 Reservoirs with Complex Front Shapes

One of the important advantages of this new analytical solution is its versatility in use. This new model can accommodate complex reservoir scenarios resulting from reservoir heterogeneity and from thermal recovery or other fluid injection operations. Figures 6.2 and 6.3 schematically show two reservoir situations where, because of the very high permeability contrast between layers, the shapes of the swept zones are complex or irregularly-shaped. These front shapes can not be described by a sharp front, or a tilted

131

front by specifying a front angle and a minimum front radius. Both reservoirs shown in Figures 6.2 and 6.3 consist of three layers. The non-shaded and the shaded areas represent the swept and the unswept regions, respectively. In Figure 6.2, Layer 2 has a very high permeability compared to the other layers and, thus, the swept front in Layer 2 propagates the maximum distance. In Figure 6.3, Layer 3 has a very high permeability, whereas Layer 2 has a very low permeability resulting in a complex front shape. Although, the swept fronts in Figures 6.2 and 6.3 have very different shapes, the swept zones in both these figures have equal swept volumes and minimum front radii. Thus, the two reservoirs have identical average front radii.

Figures 6.4 and 6.5 show the responses for the reservoirs described by Figures 6.2 and 6.3. Figure 6.4 shows the wellbore pressure responses with time. The line and the solid circles represent the responses corresponding to Figures 6.2 and 6.3, respectively. The two responses follow each other very closely. Figure 6.5 shows the corresponding semi-log pressure derivative responses. Figures 6.4 and 6.5 show that, when the minimum front radius and swept volume are equal, the transient pressure and pressure derivative responses are not very sensitive to the shape of the swept zones. This example represents one application of this new, multi-purpose pressure-transient model, which should become increasingly useful to the petroleum engineering community in the foreseeable future.

6.7 Summary

A computer program has been developed on the basis of an analytical solution to generate transient pressure responses for a multi-layer, composite reservoir with pseudosteady-state formation crossflow. This computer program can generate transient pressure responses for various complicated reservoir situations. The usefulness of the

132

computer program has been demonstrated by considering transient pressure behaviour for reservoirs with complex front shapes.

7.0 DISCUSSION, CONCLUSIONS, AND RECOMMENDATIONS

7.1 Discussion

In this study, an analytical solution for a multi-layer, composite reservoir with pseudosteady-state formation crossflow has been developed and validated. The new analytical solution is applicable for tilted or irregularly-shaped fluid fronts, multiple composite regions, and for closed, constant pressure and infinite outer boundary conditions. This new solution is computationally very efficient and requires solution of an order of magnitude fewer equations as compared to the other methods in the literature. The new solution is very versatile and can treat partially-penetrating wells subject to finite and infinite bottom-water conditions for well testing purposes.

In steam-flooding projects, because of the gravity override effect, the fluid front of the swept region is not vertical, but tilted or inclined. For tilted front reservoirs, this study shows that transient pressure responses are sensitive to the front shape. The time to the end of the first radial flow period and the responses for the transition flow period between the first and the second radial flow period are affected by the shape of the fluid front. This study shows that design equations for the end of the first radial flow period applicable for a sharp-front, single-layer reservoir are not adequate for tilted front reservoirs. Based on pressure derivative responses, modified design equations have been derived for the end of the first radial flow period and for the time to the maximum semi-log pressure derivative during the transition flow period. For tilted front cases and with sufficient mobility and storativity contrast between the swept and the unswept zones, this study shows that the pseudosteady-state (pss) flow period exists in some average sense and that pss analysis assuming a sharp front will result in considerable underestimation of the swept volume. A correction factor has been developed to correct the estimated swept volume from the pss analysis.

138

For reservoirs under bottom-water or gas-cap drives, the wells are partially-penetrated to avoid or delay water or gas production. For partially-penetrating wells in multi-layer reservoirs, this study has developed new analytical expressions for pseudoskin for both closed top and bottom boundaries and for bottom-water or gas cap conditions. These analytical expressions are simple and easy to use. The estimated pseudoskin factors are very close to the actual pseudoskin factors obtained from the complete analytical solution. These new analytical expressions are also applicable to the corresponding homogeneous and single-layer cases. For partially-penetrating wells in multi-layer reservoirs, time criteria have been derived for the end of the first radial flow period and for the beginning of the second radial flow period.

Many times, heavy-oil reservoirs undergoing steam-flooding are underlain by a bottom-water zone. Because of the gravity override effect, the fluid front is not vertical but tilted or inclined. Such reservoirs have been studied using the multi-layer composite reservoir model developed in this study. Both finite and infinite bottom-water conditions have been considered. A finite aquifer has been modelled as a layer of finite thickness having appropriate properties, and an infinite aquifer has been modelled as a constant-pressure boundary. The solution developed in this study can model adequately both finite and infinite bottom-water conditions for transient pressure analysis purposes. Both pressure and pressure derivative responses have been investigated to determine the effects of aquifer size, penetration ratio and the vertical permeability on wellbore responses. As the aquifer size increases, the response approaches that of an infinite aquifer. As expected, the presence of the bottom-water zone is felt before the pseudosteady-state flow period occurs when the reservoir has a very high vertical permeability. But when the vertical permeability (that is, the crossflow parameter) is small, a brief period of pseudosteady-state flow behaviour is observed for small penetration ratios and pseudosteady-state analysis, with some modification, may be possible.

7.2 Conclusions

In this study, the transient pressure behaviour of a multi-layer, composite reservoir has been investigated. To accommodate the gravity override effect, tilted and irregularly-shaped fluid fronts have been considered. The behaviour of partially-penetrating wells in reservoirs with finite and infinite bottom-water conditions has been investigated. Based on this study, the following has been concluded:

New Analytical Solution

1. A general analytical solution for transient pressure responses for an n-layered, composite reservoir with pseudosteady-state formation crossflow has been developed and validated.

2. The new analytical solution developed in this study is computationally more efficient and versatile in use than presently-available solutions in the literature.

3. The new analytical solution offers new possibilities to analyze more complicated well-testing scenarios than the possibilities offered by presently-available solutions.

Tilted Front Reservoirs

1. Design equations for the time to the end of the first radial flow period for a sharp-front reservoir are inadequate the tilted-front reservoirs. For tilted-front reservoirs, modified design equations have been developed for the time to the end of the first radial flow period, and for the time to the occurrence of the maximum semi-log slope during the transition flow period.

2. The deviation time method yields an estimate of the geometric mean of the minimum front radius and the average front radius of the swept region.

140

3. For inclined front reservoirs, pseudosteady-state (pss) occurs in some average sense and pss analysis results in a considerable underestimation of the swept volume.

4. A correction factor has been developed to estimate the correct swept volume from the pseudosteady-state analysis for situations where a tilted front is suspected.

5. For the cases considered in this study, thermal well test responses obtained from a crossflow system can be analyzed using a commingled system solution for a fully-penetrating well. However, crossflow must be taken into account for a proper analysis of thermal well test responses for partially-penetrating wells.

Partially-Penetrating Wells and Pseudoskin

1. Transient pressure responses and pseudoskin factors for a partially-penetrating well in a multi-layer reservoir can be studied analytically by a pseudosteady-state crossflow model.

2. Simplified expressions for pseudoskin factors have been derived for multi-layer reservoirs with or a without bottom-water or a gas-cap drive and pseudoskin factors can be estimated from these expressions with reasonable accuracy.

3. Times for the end of the radial flow period and the beginning of the pseudoradial flow period depend on the crossflow parameter and the mobility-thickness ratio of the open interval. Simplified expressions have been derived for these time criteria .

4. Pseudoskin factors obtained from this study have been compared with those obtained from other studies in the literature and these comparisons have shown good matches with most of the studies.

141

Composite Reservoirs Under Bottom-Water Conditions

1. Bottom-water conditions, both finite and infinite, can be represented by the multi-layer composite reservoir model used in this study. Effects of various parameters of the reservoir-aquifer system on transient pressure behaviour have been investigated.

2. The presence of the bottom-water zone is felt before the pseudosteady-state flow period occurs when the reservoir has a high vertical permeability. However, if the vertical permeability is very small compared to the horizontal permeability, a short pseudosteady-state flow period may be observed.

3. For a finite aquifer in a multi-layer, composite reservoir with a closed outer boundary, the occurrence of various flow regimes and their sequences depend on the particular reservoir-aquifer system and its properties.

Irregularly-Shaped Fronts

1. For irregularly-shaped fronts, when the minimum front radius and the swept volume are equal, pressure and pressure derivative responses are not very sensitive to the shape of the swept zones.

7.3 Recommendations

Future studies in multi-layer, composite reservoir should address the following:

1. Pressure falloff data for multi-layer, composite reservoirs with tilted and irregularly-shaped fluid fronts can be studied using this new analytical model.

2. The new analytical model can be used for automatic type-curve matching for complex reservoir scenarios.

142

3. Extension of this new model to multi-phase well-testing situations will make this model more general.

APPENDICES

Appendix A: Calculation of Layer Front Radii for Inclined Front Reservoirs (after Kiome[11])

This appendix describes the calculation procedure of various layer front radii for inclined front reservoirs (see Chapter 3) provided the minimum front radius (R_1), layer thicknesses (h_j), total number of layers (n), and the angle of inclination (θ) are known. An expression for the layer front radius has been obtained following the approach presented by Kiome[11].

Figure 3.2 shows the swept section of a two-layer composite reservoir. The parameters, R_1 and θ, are the minimum front radius and the angle of inclination, respectively. Layers are numbered from bottom to top. For Layer 1, line $R'_1 R'_2$ is drawn in such a way that the half-cylinder $ABCR_1$ and the cone frustrum $ABR'_1 R'_2$ have the same volume. The dotted line $R'_1 R'_2$ represents the inclined front, while line CR_1 represents the step approximation of the inclined front.

Considering the half-cones OBR'_2 and OAR'_1,

$$\tan \theta = \frac{h'}{R'_1} = \frac{h' + h_1}{R'_2} = \frac{h_1}{R'_2 - R'_1} \tag{A.1}$$

Rearranging Equation (A.1) yields:

$$h' = R'_1 \tan \theta \tag{A.2}$$

$$R'_2 = R'_1 + h_1 \cot \theta \tag{A.3}$$

$$R'_2 = (h' + h_1) \cot \theta \tag{A.4}$$

The volume of the half cone frustrum $ABR'_1 R'_2$ is:

144

$$V_{cf} = \frac{1}{2} \cdot \frac{\pi}{3} \left[R'^2_2 (h' + h_1) - R'^2_1 h' \right]$$

(A.5)

Equations (A.1) and (A.5) yield:

$$V_{cf} = \frac{\pi}{6} \tan \theta \left[R'^3_2 - R'^3_1 \right]$$

(A.6)

Equating the volume of the half-cylinder $ABCR_1$ and the half-cone frustrum, V_{cf} yields:

$$R^2_1 = \frac{\tan \theta}{3 h_1} \left(R'^3_2 - R'^3_1 \right)$$

(A.7)

Making use of Equation (A.3) in Equation (A.7) yields:

$$R'^2_1 + (h_1 \cot \theta) R'_1 + \left[\frac{h^2_1 \cot^2 \theta}{3} - R^2_1 \right] = 0$$

(A.8)

For a specified minimum front radius R_1 and a front angle θ, it can be written:

$$R'_1 = \frac{-(h_1 \cot \theta) + \sqrt{(h_1 \cot \theta)^2 + 4 \left(R^2_1 - (h_1 \cot \theta)^2 / 3 \right)}}{2}$$

(A.9)

For any Layer j, Equation (A.9) can be written as:

$$R'_j = \frac{-(h_j \cot \theta) + \sqrt{(h_j \cot \theta)^2 + 4 \left(R^2_j - (h_j \cot \theta)^2 / 3 \right)}}{2}$$

(A.10)

For any Layer j, Equations (A.3) and (A.7) can be written as:

$$R'_{j+1} = R'_j + h_j \cot \theta$$

(A.11)

$$R_j = \sqrt{\frac{\tan \theta}{3 h_j} \left(R'^3_{j+1} - R'^3_j \right)}$$

(A.12)

For a particular Layer j with a layer thickness h_j, and with an angle of inclination θ, Equations (A.11) and (A.12) can be used to calculate the front radius R_j.

Appendix B: Defining an Average Radius for a Multi-layered, Composite Reservoir with an Inclined Front (after Kiome[11])

This appendix describes the calculation procedure of the average front radius for a tilted-front reservoir for Chapter 3. The swept volume of a multi-layer, composite reservoir with an inclined front can be represented by an equivalent swept volume in a single-layer, composite reservoir with a sharp front. This is done by equating the pore volume-compressibility products for the corresponding reservoirs. The expression for the average radius has been derived following Kiome's[11] approach.

Consider an n-layer, composite reservoir (Figure 3.1b) with a layer front radius R_j and swept volume storativity $(\phi c_t h)_j$, where j represents the layer number. Let the equivalent single-layer reservoir have a storativity of $(\phi c_t)_{eff}$ per unit reservoir thickness. Equating the storativity values for the two reservoirs gives:

$$\sum_{j=1}^{n} (\phi c_t h)_j = (\phi c_t)_{eff} \sum_{j=1}^{n} h_j$$

(B.1)

where h_j is the thickness of Layer j. Rearranging Equation (B.1) yields:

$$(\phi c_t)_{eff} = \sum_{j=1}^{n} (\phi c_t h)_j / h_t$$

(B.2)

where $h_t = \sum_{j=1}^{n} h_j$.

To obtain an appropriate definition of the average front radius, R_{avg}, the summation of the layer pore volume and the compressibility product for all the layers has to be equal to the pore volume-compressibility product of the single-layer system. Thus:

$$\sum_{j=1}^{n} (\phi c_t \pi R^2 h)_j = (\phi c_t)_{eff} \pi R_{avg}^2 h_t$$

(B.3)

Rearranging Equation (B.3) yields:

146

$$R_{avg}^2 = \frac{\sum\limits_{j=1}^{n} \left(\phi c_t R^2 h\right)_j}{\left(\phi c_t\right)_{eff} h_t} \tag{B.4}$$

Substituting for $(\phi c_t)_{eff}$ from Equation (B.2) into Equation (B.4) yields:

$$R_{avg} = \sqrt{\frac{\sum\limits_{j=1}^{n} \left(\phi c_t R^2 h\right)_j}{\sum\limits_{j=1}^{n} \left(\phi c_t h\right)_j}} \tag{B.5}$$

The transient-pressure responses of a multi-layer, composite reservoir can be compared with that of a single-layer, composite reservoir having equivalent reservoir properties. For example, transient-pressure responses of a multi-layer, composite reservoir having an inclined front with an average front radius of R_{avg} can be compared with that of a single-layer, composite reservoir having a sharp front located at R_{avg}. This definition of the average radiv: has been used in obtaining a correction factor for the estimation of the correct swept volume from the pseudosteady-state analysis. However, for this study, swept-region $\phi c_t h$ products for all layers are the same, and, thus, a simpler expression for R_{avg} is obtained from Equation (B.5) as:

$$R_{avg} = \sqrt{\sum\limits_{j=1}^{n} R_j^2/n} \tag{B.6}$$

Equation (B.6) describes R_{avg} as a root-mean-square front radius. Satman and Oskay[6] proposed the square root of the sum of the square of the nearest and the farthest distances to the front as the representative average front radius. Such an approximation is inadequate for reservoirs having more than two layers and for irregularly-shaped fronts.

147

Appendix C: Pseudoskin Factor for Closed Top and Bottom Boundaries

This appendix shows the derivation of the late-time pressure and the pseudoskin factor expressions when the top and the bottom boundaries are closed for multi-layer reservoirs. This pseudoskin expression has been discussed in Chapter 4.

Late-Time Behaviour of a Partially-Penetrating Well in a Two-layer Reservoir with Pseudosteady-State Crossflow.

Figure 4.1 schematically shows a two-layer, partially-penetrated reservoir. Layer 1 is penetrated and Layer 2 is closed at the wellbore. The upper boundary of Layer 2 and the lower boundary of Layer 1 are considered as closed boundaries. Pseudosteady-state crossflow is considered between the two layers. The problem is solved following the steps taken by Bourdet[20]. The diffusivity Equations for the two layers are:

$$\left(\frac{kh}{\mu}\right)_1 \left(\frac{\partial^2 p_1}{\partial r^2} + \frac{1}{r}\frac{\partial p_1}{\partial r}\right) = (\phi c_t h)_1 \frac{\partial p_1}{\partial t} + X_A(p_1 - p_2) \tag{C.1}$$

$$\left(\frac{kh}{\mu}\right)_2 \left(\frac{\partial^2 p_2}{\partial r^2} + \frac{1}{r}\frac{\partial p_2}{\partial r}\right) = (\phi c_t h)_2 \frac{\partial p_2}{\partial t} + X_A(p_2 - p_1) \tag{C.2}$$

Initial condition: $p_1 = p_2 = p_{in}$ (C.3)

Outer boundary condition: $\lim_{r \to \infty} p_1 = \lim_{r \to \infty} p_2 = p_{in}$ (C.4)

Inner boundary condition: Assuming Layer 1 is penetrated and Layer 2 is closed, and neglecting wellbore storage and skin yield:

$p_1 = p_w$ for $r = r_w$ (C.5)

$\left.\frac{\partial p_2}{\partial r}\right|_{r=r_w} = 0$ (C.6)

$$q = 2\pi \left(\frac{kh}{\mu}\right)_1 \left(r\frac{\partial p_1}{\partial r}\right)_{r=r_o} \qquad \text{(C.7)}$$

Dimensionless variables are defined as follows:

$$p_{D1,2} = \frac{2\pi}{q}\left(\overline{\frac{kh}{\mu}}\right)(p_{in} - p_{1,2}) \qquad \text{(C.8)}$$

$$t_D = \frac{\left(\overline{\frac{kh}{\mu}}\right)}{(\overline{\phi c_t h})} \frac{1}{r_w^2} \qquad \text{(C.9)}$$

$$\text{where, } \left(\overline{\frac{kh}{\mu}}\right) = \left(\frac{kh}{\mu}\right)_1 + \left(\frac{kh}{\mu}\right)_2, \text{ and} \qquad \text{(C.10)}$$

$$(\overline{\phi c_t h}) = (\phi c_t h)_1 + (\phi c_t h)_2 \qquad \text{(C.11)}$$

All other dimensionless parameters are defined in the Nomenclature.

The differential Equations and the boundary conditions can be written in dimensionless form as:

$$\kappa \nabla^2 p_{D1} = \omega \frac{\partial p_{D1}}{\partial t_D} + \lambda_A(p_{D1} - p_{D2}) \qquad \text{(C.12)}$$

$$(1 - \kappa) \nabla^2 p_{D2} = (1 - \omega)\frac{\partial p_{D2}}{\partial t_D} + \lambda_A(p_{D2} - p_{D1}) \qquad \text{(C.13)}$$

Initial condition: $\quad p_{D1}(r_D,0) = p_{D2}(r_D,0) = 0$ \qquad (C.14)

Outer boundary condition: $\quad \lim\limits_{r_D \to \infty} p_{D1} = \lim\limits_{r_D \to \infty} p_{D2} = 0$ \qquad (C.15)

Inner boundary condition: $\quad p_{D1}(1,t_D) = p_{wD}$ \qquad (C.16)

$$\left(\frac{\partial p_{D2}}{\partial r_D}\right)_{r_D=1} = 0 \qquad \text{(C.17)}$$

$$1 = -\kappa\left(\frac{\partial p_{D1}}{\partial r_D}\right)_{r_D=1} \qquad \text{(C.18)}$$

149

Taking the Laplace transform of Equations (C.12) through (C.18) yields:

$$\kappa \nabla^2 \bar{p}_{D1} = \omega f \, \bar{p}_{D1} + \lambda_A (\bar{p}_{D1} - \bar{p}_{D2}) \tag{C.19}$$

$$(1 - \kappa) \nabla^2 \bar{p}_{D2} = (1 - \omega) f \, \bar{p}_{D2} + \lambda_A (\bar{p}_{D2} - \bar{p}_{D1}) \tag{C.20}$$

Outer boundary condition: $\displaystyle \lim_{r_D \to \infty} \bar{p}_{D1} = \lim_{r_D \to \infty} \bar{p}_{D2} = 0 \tag{C.21}$

Inner boundary condition: $\bar{p}_{D1}(1, f) = \bar{p}_{wD} \tag{C.22}$

$$\left(\frac{\partial \bar{p}_{D2}}{\partial r_D} \right)_{r_D = 1} = 0 \tag{C.23}$$

$$\frac{1}{f} = - \kappa \left(\frac{\partial \bar{p}_{D1}}{\partial r_D} \right)_{r_D = 1} \tag{C.24}$$

Solutions of Equations (C.19) and (C.20) are modified Bessel's functions, $I_0(\sigma r_D)$ and $K_0(\sigma r_D)$, where σ is the eigenvalue of the system. For an infinite system, only the $K_0(\sigma r_D)$ function applies. Therefore,

$$\bar{p}_{D1} = A' K_0(\sigma r_D) \tag{C.25}$$

$$\bar{p}_{D2} = B' K_0(\sigma r_D) \tag{C.26}$$

Equations (C.19) and (C.20) together with Equations (C.25) and (C.26) yield:

$$\kappa \sigma^2 A' K_0(\sigma r_D) = \omega f \, A' K_0(\sigma r_D) + \lambda_A [A' K_0(\sigma r_D) - B' K_0(\sigma r_D)] \tag{C.27}$$

$$(1 - \kappa) \sigma^2 B' K_0(\sigma r_D) = (1 - \omega) f \, B' K_0(\sigma r_D) + \lambda_A [B' K_0(\sigma r_D) - A' K_0(\sigma r_D)] \tag{C.28}$$

Equations (C.27) and (C.28) reduce to:

$$\left[\kappa \sigma^2 - \omega f - \lambda_A \right] A' + \lambda_A B' = 0 \tag{C.29}$$

$$\lambda_A A' + \left[(1 - \kappa) \sigma^2 - (1 - \omega) f - \lambda_A \right] B' = 0 \tag{C.30}$$

150

Non-trivial solutions are possible, if the determinant is zero, that is,

$$(\kappa\sigma^2 - \omega l - \lambda_A)[(1-\kappa)\sigma^2 - (1-\omega)l - \lambda_A] - \lambda_A^2 = 0 \tag{C.31}$$

Equation (C.31) can be reorganized as:

$$\sigma^4 - \left[\frac{(1-\omega)l + \lambda_A}{1-\kappa} + \frac{\omega l + \lambda_A}{\kappa}\right]\sigma^2 + \frac{\left[\omega l (1-\omega) + \lambda_A\right]l}{\kappa(1-\kappa)} = 0 \tag{C.32}$$

This polynomial has two positive roots and they are:

$$\sigma_1^2 = \frac{1}{2}\left[\left(\frac{(1-\omega)l + \lambda_A}{1-\kappa} + \frac{\omega l + \lambda_A}{\kappa}\right) + \Delta\right] \tag{C.33}$$

$$\sigma_2^2 = \frac{1}{2}\left[\left(\frac{(1-\omega)l + \lambda_A}{1-\kappa} + \frac{\omega l + \lambda_A}{\kappa}\right) - \Delta\right] \tag{C.34}$$

where, $\Delta = \left[\left(\frac{(1-\omega)l + \lambda_A}{1-\kappa} - \frac{\omega l + \lambda_A}{\kappa}\right)^2 + \frac{4\lambda_A^2}{\kappa(1-\kappa)}\right]^{\frac{1}{2}}$ $\tag{C.35}$

Putting σ_1^2 and σ_2^2 from Equations (C.33) and (C.34), respectively, into Equation (C.30) and rearranging yield:

$$a_1 = \frac{A_1}{B_1} = 1 + \frac{1}{\lambda_A}\left[(1-\omega)l - (1-\kappa)\sigma_1^2\right] \tag{C.36}$$

$$a_2 = \frac{A_2}{B_2} = 1 + \frac{1}{\lambda_A}\left[(1-\omega)l - (1-\kappa)\sigma_2^2\right] \tag{C.37}$$

Putting $A_1 = a_1 B_1$ and $A_2 = a_2 B_2$ in Equations (C.25) and (C.26) yields:

$$\beta_{D1} = a_1 B_1 K_0(\sigma_1 r_D) + a_2 B_2 K_0(\sigma_2 r_D) \tag{C.38}$$

$$\beta_{D2} = B_1 K_0(\sigma_1 r_D) + B_2 K_0(\sigma_2 r_D) \tag{C.39}$$

Equations (C.38) and (C.39) together with Equations (C.22) and (C.23) yield:

151

$$B_1 = - \frac{B_2 \sigma_2 K_1(\sigma_2)}{\sigma_1 K_1(\sigma_1)} \qquad (C.40)$$

Equations (C.38) and (C.39) together with Equation (C.24) yields:

$$\frac{1}{\kappa l} = a_1 B_1 \sigma_1 K_1(\sigma_1) + a_2 B_2 \sigma_2 K_1(\sigma_2) \qquad (C.41)$$

Equations (C.40) and (C.41) yields:

$$B_1 = - \frac{1}{(a_2 - a_1) \kappa l \, \sigma_1 K_1(\sigma_1)} \qquad (C.42)$$

$$B_2 = \frac{1}{(a_2 - a_1) \kappa l \, \sigma_2 K_1(\sigma_2)} \qquad (C.43)$$

Now, Equation (C.38) becomes:

$$P_{wD} = - \frac{a_1 K_0(\sigma_1)}{(a_2 - a_1) \kappa l \, \sigma_1 K_1(\sigma_1)} + \frac{a_2 K_0(\sigma_2)}{(a_2 - a_1) \kappa l \, \sigma_2 K_1(\sigma_2)} \qquad (C.44)$$

Equation (C.44) represents the pressure transient responses of a partially-penetrating well in a two-layer reservoir in Laplace space and these responses are numerically inverted to real space using the Stehfest algorithm[x].

Late-Time Behaviour for a Partially-Penetrating Well with No Bottom-Water Zone or Gas Cap

At late time $t_D \to \infty$ and $l \to 0$, and Equations (C.33) through (C.37) become:

$$\lim_{l \to 0} \Delta = \lim_{l \to 0} \left[\left(\frac{\lambda_A}{1 - \kappa} + \frac{\lambda_A}{\kappa} \right)^2 + l[......] + l^2[.......] \right]^{\frac{1}{2}} = \frac{\lambda_A}{\kappa(1 - \kappa)} \qquad (C.45)$$

$$\lim_{l \to 0} \sigma_1^2 = \lim_{l \to 0} \left[\frac{\lambda_A}{1 - \kappa} + \frac{\lambda_A}{\kappa} + l[.......] + l^2[.......] \right] = \frac{\lambda_A}{\kappa(1 - \kappa)} \qquad (C.46)$$

$$\lim_{l \to 0} \sigma_2^2 = \lim_{l \to 0} \frac{1}{2} \left\{ \frac{1 - \omega}{1 - \kappa} + \frac{\omega}{\kappa} \cdot \frac{1 - \omega}{1 - \kappa} + \frac{\omega}{\kappa} \right\} = l \qquad (C.47)$$

152

Appendix E shows the simplification proposed in Equation (C.47) in detail.

$$\lim_{t \to 0} a_1 = \lim_{t \to 0} \left[1 + \frac{(1 - \omega)l - (1 - \kappa)\,\sigma_1^2}{\lambda_A} \right] = \frac{\kappa - 1}{\kappa} \tag{C.48}$$

$$\lim_{t \to 0} a_2 = \lim_{t \to 0} \left[1 + \frac{(1 - \omega)l - (1 - \kappa)\,\sigma_2^2}{\lambda_A} \right] = 1 \tag{C.49}$$

Using the late-time limits shown in Equations (C.45) through (C.49) , Equation (C.44) may be written as:

$$P_{wD} = \frac{(1 - \kappa)}{\kappa l} \; \frac{K_0 \left(\sqrt{\dfrac{\lambda_A}{\kappa(1 - \kappa)}} \right)}{\sqrt{\dfrac{\lambda_A}{\kappa(1 - \kappa)}} \; K_1 \left(\sqrt{\dfrac{\lambda_A}{\kappa(1 - \kappa)}} \right)} \; + \; \frac{K_0(\sqrt{l})}{l\sqrt{l} \; K_1(\sqrt{l})} \tag{C.50}$$

The first term in Equation (C.50) is a constant and it represents the additional pressure drop because of partial penetration, which is usually known as pseudoskin. The second term in Equation (C.50) represents the equivalent infinite, homogeneous reservoir response for the whole reservoir. So, for a two-layer reservoir, the expression for pseudoskin is:

$$s_p = \frac{(1 - \kappa)}{\kappa} \; \frac{K_0 \left(\sqrt{\dfrac{\lambda_A}{\kappa(1 - \kappa)}} \right)}{\sqrt{\dfrac{\lambda_A}{\kappa(1 - \kappa)}} \; K_1 \left(\sqrt{\dfrac{\lambda_A}{\kappa(1 - \kappa)}} \right)} \tag{C.51}$$

Equation (C.51) can be extended for a multi-layer reservoir by appropriately defining κ and λ_A :

$$s_p = \frac{(1 - \bar{\kappa})}{\bar{\kappa}} \; \frac{K_0 \left(\sqrt{\dfrac{\lambda_A}{\bar{\kappa}(1 - \bar{\kappa})}} \right)}{\sqrt{\dfrac{\lambda_A}{\bar{\kappa}(1 - \bar{\kappa})}} \; K_1 \left(\sqrt{\dfrac{\lambda_A}{\bar{\kappa}(1 - \bar{\kappa})}} \right)} \tag{C.52}$$

153

where, $\bar{\kappa}$ = Total mobility-thickness ratio of the open interval

$$\bar{\lambda}_A = \text{Total crossflow parameter}$$

Equation (C.52) is applicable for a multi-layer reservoir having any arbitrary number of layers making up the open interval and any arbitrary location of the open interval. In Equation (C.52), $\bar{\kappa}$ and $\bar{\lambda}_A$ are calculated by adding the individual layer mobility-thickness ratio of the open interval and by adding the lower and the upper boundary crossflow parameters, respectively. Irrespective of the number of layers in the reservoir, only two parameters are required to estimate the pseudoskin. A similar treatment for a reservoir subject to a gas-cap drive (or a bottom-water drive) is shown in Appendix D.

Appendix D: Pseudoskin Factor for a Gas-Cap Condition

This appendix shows the derivation of the late-time pressure and the pseudoskin factor expressions when the multi-layer reservoir is under an infinitely-large gas-cap drive. This pseudoskin expression has been discussed in Chapter 4.

Late-Time Behaviour of a Partially-Penetrated Well in a Two-layer Reservoir Subject to a Gas-Cap Drive.

Figure 4.2 schematically shows a two-layer, partially-penetrated reservoir subject to a gas-cap drive. The gas cap is assumed to be very large compared to the size of the reservoir and the boundary between the reservoir and the gas cap is considered to be at constant pressure. Layer 1 is penetrated and Layer 2 is closed at the wellbore. The upper boundary of Layer 2 is considered as a constant-pressure boundary because of gas cap, whereas the lower boundary of Layer 1 is considered as a closed boundary. Pseudosteady-state crossflow is considered between the two layers. The diffusivity Equations for the two layers are:

$$\left(\frac{kh}{\mu}\right)_1 \left(\frac{\partial^2 p_1}{\partial r^2} + \frac{1}{r}\frac{\partial p_1}{\partial r}\right) = (\phi c_t h)_1 \frac{\partial p_1}{\partial t} + X_A (p_1 - p_2) \tag{D.1}$$

$$\left(\frac{kh}{\mu}\right)_2 \left(\frac{\partial^2 p_2}{\partial r^2} + \frac{1}{r}\frac{\partial p_2}{\partial r}\right) = (\phi c_t h)_2 \frac{\partial p_2}{\partial t} + X_A (p_2 - p_1) + X_C (p_2 - p_{in}) \tag{D.2}$$

Inner and outer boundary conditions, and the initial condition are the same as in Appendix C. In dimensionless form, the differential equations and the boundary conditions can be written as:

$$\kappa \nabla^2 p_{D1} = \omega \frac{\partial p_{D1}}{\partial t_D} + \lambda_A (p_{D1} - p_{D2}) \tag{D.3}$$

$$(1 - \kappa) \nabla^2 p_{D2} = (1 - \omega)\frac{\partial p_{D2}}{\partial t_D} + \lambda_A (p_{D2} - p_{D1}) + \lambda_C \, p_{D2} \tag{D.4}$$

155

Initial condition: $p_{D1}(r_D,0) = p_{D2}(r_D,0) = 0$ (D.5)

Outer boundary condition: $\lim_{r_D \to \infty} p_{D1} = \lim_{r_D \to \infty} p_{D2} = 0$ (D.6)

Inner boundary condition: $p_{D1}(1,t_D) = p_{wD}$ (D.7)

$$\left(\frac{\partial p_{D2}}{\partial r_D}\right)_{r_D=1} = 0$$ (D.8)

$$1 = - \kappa \left(\frac{\partial p_{D1}}{\partial r_D}\right)_{r_D=1}$$ (D.9)

Following the same steps as in Appendix C, one can obtain:

$$\left[\kappa \sigma^2 - \omega l - \lambda_A\right]A + \lambda_A B = 0$$ (D.10)

$$\lambda_A A + \left[(1 - \kappa)\sigma^2 - (1 - \omega)l - \lambda_A - \lambda_C\right]B = 0$$ (D.11)

Non-trivial solutions are possible, if the determinant is zero, that is,

$$\left(\kappa\sigma^2 - \omega l - \lambda_A\right)\left[(1 - \kappa)\sigma^2 - (1 - \omega)l - \lambda_A - \lambda_C\right] - \lambda_A^2 = 0$$ (D.12)

Equation (D.12) can be reorganized as:

$$\sigma^4 - \left[\frac{(1-\omega)l + \lambda_A + \lambda_C}{1-\kappa} + \frac{\omega l + \lambda_A}{\kappa}\right]\sigma^2 + \frac{(\omega l + \lambda_A)\left[(1-\omega)l + \lambda_A + \lambda_C\right] - \lambda_A^2}{\kappa(1-\kappa)} = 0$$ (D.13)

This polynomial has two positive roots and these are:

$$\sigma_1^2 = \frac{1}{2}\left[\left(\frac{(1-\omega)l + \lambda_A + \lambda_C}{1-\kappa} + \frac{\omega l + \lambda_A}{\kappa}\right) + \Delta\right]$$ (D.14)

$$\sigma_2^2 = \frac{1}{2}\left[\left(\frac{(1-\omega)l + \lambda_A + \lambda_C}{1-\kappa} + \frac{\omega l + \lambda_A}{\kappa}\right) - \Delta\right]$$ (D.15)

156

$$\text{where, } \Delta = \left[\left(\frac{(1-\omega)/+\lambda_A+\lambda_C}{1-\kappa} + \frac{\omega/+\lambda_A}{\kappa}\right)^2 - \frac{4(\omega/+\lambda_A)[(1-\omega)/+\lambda_A+\lambda_C]-\lambda_A^2}{\kappa(1-\kappa)}\right]^{\frac{1}{2}}$$

(D.16)

Putting σ_1^2 and σ_2^2 from Equations (D.14) and (D.15), respectively, into Equation (D.11) and rearranging, one can write:

$$a_1 = \frac{A_1}{B_1} = 1 + \frac{\lambda_C}{\lambda_A} + \frac{1}{\lambda_A}[(1-\omega)/-(1-\kappa)\sigma_1^2]$$

(D.17)

$$a_2 = \frac{A_2}{B_2} = 1 + \frac{\lambda_C}{\lambda_A} + \frac{1}{\lambda_A}[(1-\omega)/-(1-\kappa)\sigma_2^2]$$

(D.18)

As in Appendix A, putting $A_1 = a_1 B_1$ and $A_2 = a_2 B_2$ in the solution yields:

$$\bar{p}_{D1} = a_1 B_1 K_0(\sigma_1 r_D) + a_2 B_2 K_0(\sigma_2 r_D)$$

(D.19)

$$\bar{p}_{D2} = B_1 K_0(\sigma_1 r_D) + B_2 K_0(\sigma_2 r_D)$$

(D.20)

Again, following the same steps as in Appendix C, one can obtain the expression for the wellbore pressure as:

$$\bar{p}_{wD} = -\frac{a_1 K_0(\sigma_1)}{(a_2-a_1)\kappa/\sigma_1 K_1(\sigma_1)} + \frac{a_2 K_0(\sigma_2)}{(a_2-a_1)\kappa/\sigma_2 K_1(\sigma_2)}$$

(D.21)

Equation (D.21) represents pressure transient responses in Laplace space of a partially-penetrating well in a two-layer reservoir subject to a gas-cap drive and these responses are numerically inverted to real space using the Stehfest Algorithm[*].

Late-Time Behaviour for a Partially-Penetrating Well Under a Gas-cap Drive

At late time $t_D \to \infty$ and $/ \to 0$, and Equations (D.14) through (D.18) become:

$$\lim_{l \to 0} \sigma_1^2 = \sigma_{1L}^2 = \frac{1}{2}\left[\frac{\lambda_A + \lambda_C}{1-\kappa} + \frac{\lambda_A}{\kappa} + \left(\left(\frac{\lambda_A + \lambda_C}{1-\kappa} + \frac{\lambda_A}{\kappa}\right)^2 - \frac{4\lambda_A\lambda_C}{(1-\kappa)\kappa}\right)^{\frac{1}{2}}\right] \qquad (D.22)$$

$$\lim_{l \to 0} \sigma_2^2 = \sigma_{2L}^2 = \frac{1}{2}\left[\frac{\lambda_A + \lambda_C}{1-\kappa} + \frac{\lambda_A}{\kappa} - \left(\left(\frac{\lambda_A + \lambda_C}{1-\kappa} + \frac{\lambda_A}{\kappa}\right)^2 - \frac{4\lambda_A\lambda_C}{(1-\kappa)\kappa}\right)^{\frac{1}{2}}\right] \qquad (D.23)$$

$$\lim_{l \to 0} \Delta = \left[\left(\frac{\lambda_A + \lambda_C}{1-\kappa} + \frac{\lambda_A}{\kappa}\right)^2 - \frac{4\lambda_A\lambda_C}{(1-\kappa)\kappa}\right]^{\frac{1}{2}} \qquad (D.24)$$

$$\lim_{l \to 0} a_1 = a_{1L} = 1 + \frac{\lambda_C}{\lambda_A} \cdot \frac{(1-\kappa)}{2\lambda_A}\left[\frac{\lambda_A + \lambda_C}{1-\kappa} + \frac{\lambda_A}{\kappa} + \left(\left(\frac{\lambda_A + \lambda_C}{1-\kappa} + \frac{\lambda_A}{\kappa}\right)^2 - \frac{4\lambda_A\lambda_C}{(1-\kappa)\kappa}\right)^{\frac{1}{2}}\right]$$
$$(D.25)$$

$$\lim_{l \to 0} a_2 = a_{2L} = 1 + \frac{\lambda_C}{\lambda_A} \cdot \frac{(1-\kappa)}{2\lambda_A}\left[\frac{\lambda_A + \lambda_C}{1-\kappa} + \frac{\lambda_A}{\kappa} - \left(\left(\frac{\lambda_A + \lambda_C}{1-\kappa} + \frac{\lambda_A}{\kappa}\right)^2 - \frac{4\lambda_A\lambda_C}{(1-\kappa)\kappa}\right)^{\frac{1}{2}}\right]$$
$$(D.26)$$

Using the late-time limits shown in Equations (D.22) through (D.26), Equation (D.21) may be written as:

$$\bar{P}_{wDFL} = -\frac{a_{1L}K_0(\sigma_{1L})}{(a_{2L} - a_{1L})\kappa/\sigma_{1L}K_1(\sigma_{1L})} + \frac{a_{2L}K_0(\sigma_{2L})}{(a_{2L} - a_{1L})\kappa/\sigma_{2L}K_1(\sigma_{2L})} \qquad (D.27)$$

Equation (D.27) denotes the limiting pressure drop in Laplace space for a partially-penetrating well subject to a gas-cap drive. Taking the inverse Laplace transform of Equation (D.27), one can obtain the corresponding pressure drop in the real space as:

$$P_{wDFL} = -\frac{a_{1L}K_0(\sigma_{1L})}{(a_{2L} - a_{1L})\kappa\sigma_{1L}K_1(\sigma_{1L})} + \frac{a_{2L}K_0(\sigma_{2L})}{(a_{2L} - a_{1L})\kappa\sigma_{2L}K_1(\sigma_{2L})} \qquad (D.28)$$

Performing the same treatment for a fully-penetrating well in a two-layer reservoir subject to a gas-cap drive, one can obtain:

$$P_{wDFL} = \frac{(a_{2L} - a_{1L})K_0(\sigma_{1L})\,K_0(\sigma_{2L})}{b_L} \qquad (D.29)$$

where,

$$b_L = (1 - a_{1L})(\kappa a_{2L} + 1 - \kappa)\sigma_{2L}K_0(\sigma_{1L})K_1(\sigma_{2L}) - (1 - a_{2L})(\kappa a_{1L} + 1 - \kappa)\sigma_{1L}K_0(\sigma_{2L})K_1(\sigma_{1L})$$

$$(D.30)$$

The difference between Equations (D.28) and (D.29) is the additional pressure drop because of the partial penetration of a two-layer reservoir subject to a gas-cap drive. Therefore, the expression for the pseudoskin for this case is:

$$s_p = \frac{a_{2L}K_0(\sigma_{2L})}{(a_{2L} - a_{1L})\kappa\sigma_{2L}K_1(\sigma_{2L})} - \frac{a_{1L}K_0(\sigma_{1L})}{(a_{2L} - a_{1L})\kappa\sigma_{1L}K_1(\sigma_{1L})} - \frac{(a_{2L} - a_{1L})K_0(\sigma_{1L})\,K_0(\sigma_{2L})}{b_L} \qquad (D.31)$$

Equation (D.31) estimates the pseudoskin in a two-layer, partially-penetrated reservoir subject to a gas-cap or a bottom-water drive. Equation (D.31) is also applicable for a multi-layer reservoir having any arbitrary number of layers making up the open interval and any arbitrary location of the open interval, provided κ and λ_A are calculated by adding the individual layer mobility-thickness ratio of the open interval and by adding the lower and the upper boundary crossflow parameters of the open interval, respectively. Parameter, λ_C, is the crossflow parameter between the reservoir and the gas cap or the bottom-water zone. Irrespective of the number of layers in the reservoir, only three parameters (κ, λ_A, λ_C) are required to estimate the pseudoskin factor.

Appendix E: Late-Time Approximation of σ_2^2

This appendix shows the simplification proposed in Equation (C.47) of Appendix C in detail.

From Appendix C,

$$\sigma_2^2 = \frac{1}{2}\left[\left(\frac{\lambda_A}{1-\kappa} + \frac{\lambda_A}{\kappa} + \left(\frac{1-\omega}{1-\kappa} + \frac{\omega}{\kappa} \right) l \right) \cdot \Delta \right] \tag{E.1}$$

and,

$$\lim_{l \to \infty} \Delta = \lim_{l \to \infty} \left[\left(\frac{(1-\omega)l + \lambda_A}{1-\kappa} - \frac{\omega l + \lambda_A}{\kappa} \right)^2 + \frac{4\lambda_A^2}{\kappa(1-\kappa)} \right]^{\frac{1}{2}} \tag{E.2}$$

Equation (E.2) can be written as:

$$\lim_{l \to \infty} \Delta = \lim_{l \to \infty} \left[\left(\frac{\lambda_A}{1-\kappa} - \frac{\lambda_A}{\kappa} \right)^2 \left\{ 1 + 2 \frac{\frac{1-\omega}{1-\kappa} \cdot \frac{\omega}{\kappa}}{\frac{\lambda_A}{1-\kappa} \cdot \frac{\lambda_A}{\kappa}} l + \left(\frac{\frac{1-\omega}{1-\kappa} \cdot \frac{\omega}{\kappa}}{\frac{\lambda_A}{1-\kappa} \cdot \frac{\lambda_A}{\kappa}} \right)^2 l^2 \right\} + \frac{4\lambda_A^2}{\kappa(1-\kappa)} \right]^{\frac{1}{2}} \tag{E.3}$$

Neglecting the term containing l^2 and rearranging Equation (E.3) yields:

$$\lim_{l \to \infty} \Delta = \lim_{l \to \infty} \left(\frac{\lambda_A}{1-\kappa} + \frac{\lambda_A}{\kappa} \right) \left[1 + \frac{\left(\frac{1-\omega}{1-\kappa} \cdot \frac{\omega}{\kappa} \right)\left(\frac{\lambda_A}{1-\kappa} \cdot \frac{\lambda_A}{\kappa} \right)}{\left(\frac{\lambda_A}{1-\kappa} + \frac{\lambda_A}{\kappa} \right)^2} 2l \right]^{\frac{1}{2}} \tag{E.4}$$

Expanding Equation (E.4) using the binomial theorem yields:

$$\lim_{l \to \infty} \Delta = \lim_{l \to \infty} \left(\frac{\lambda_A}{1-\kappa} + \frac{\lambda_A}{\kappa} \right) \left[1 + \frac{\left(\frac{1-\omega}{1-\kappa} \cdot \frac{\omega}{\kappa} \right)\left(\frac{\lambda_A}{1-\kappa} \cdot \frac{\lambda_A}{\kappa} \right)}{\left(\frac{\lambda_A}{1-\kappa} + \frac{\lambda_A}{\kappa} \right)^2} l - (\dots)l^2 + (\dots)l^3 \dots \right]$$

(E.5)

Neglecting the higher order terms in l in Equation (E.5) yields:

$$\Delta = \left[\frac{\lambda_A}{1-\kappa} + \frac{\lambda_A}{\kappa} + \left(\frac{1-\omega}{1-\kappa} \cdot \frac{\omega}{\kappa} \right) (2\kappa - 1) \gamma \right] \tag{E.6}$$

At late times, the reservoir behaves like a fully-penetrated, equivalent homogeneous system with s pseudoskin. Thus, at late time, $\kappa = \omega = 1$, and Equation (E.6) becomes:

$$\Delta = \left[\frac{\lambda_A}{1-\kappa} + \frac{\lambda_A}{\kappa} + \left(\frac{1-\omega}{1-\kappa} \cdot \frac{\omega}{\kappa} \right) \gamma \right] \tag{E.7}$$

Now, Equation (E.1) becomes:

$$\sigma_2^2 = \frac{\omega}{\kappa} l = l \tag{E.8}$$

Appendix F: Computer Program

This appendix shows the computer program for the analytical solution developed in this study. This computer program has been described in Chapter 6.

SOURCE CODE FOR THE PROGRAM: GENERAL

Appendix G: Published Paper From Chapter 2

This appendix shows the published paper from Chapter 2 of this study in *AOSTRA Journal of Research*, Volume 8, Number 2 , Spring 1992. This paper was originally presented as SPE 26049 at the 1993 SPE Western Regional Meeting, held in Anchorage, AK, May 26-28, 1993.

An Analytical Pressure-Transient Model for Multi-Layered, Composite Reservoirs With Pseudosteady-State Formation Crossflow

Edmond Gomes and Anil K. Ambastha*

Mining, Metallurgical, and Petroleum Engineering Department, University of Alberta, Edmonton, Alberta, Canada T6G 2G6. Received September 22, 1992; in revised form, May 4, 1993.

Abstract. Reservoir deposition occurs over geologic periods of time. Although reservoirs are assumed homogeneous for simplicity of analysis, most reservoirs are heterogeneous in nature. Some common forms of heterogeneity are the presence of layers and the presence of different zones of fluids and/or rocks in the formation.

In this study, a new analytical solution for multi-layered composite reservoirs with pseudosteady-state interlayer crossflow has been developed. Fluid flow in the reservoir has been treated as a generalized eigenvalue problem. The developed analytical solution for an *n*-layered composite reservoir is applicable for any irregularly-shaped discontinuity boundary, and for closed, constant-pressure and infinite outer boundary conditions. This new solution is computationally very efficient. Using eigenvalues and eigenvectors of the system, this method requires solution of an order-of-magnitude fewer simultaneous equations as compared to other methods proposed in the literature. This method is also very versatile and can handle multiple composite regions (more than two), and partially-penetrating wells subject to bottom-water and/or gas-cap drives for well testing purposes. This analytical model has been validated by comparing the results with those of some simple, well-known models in the well-testing literature. Solution methodology and future possibilities of the new solution are also discussed.

Keywords: Pressure-transient model/layered reservoirs/composite reservoirs/formation crossflow.

INTRODUCTION

Most reservoirs are heterogeneous in nature. The presence of layers and zones of different fluid and/or rocks is a common cause for reservoir heterogeneity. Figures 1a and 1b show a layered reservoir and a layered composite reservoir, respectively. The horizontal lines show the layering and the arrows show the presence of crossflow. The layers may be communicating or non-communicating. Formation crossflow is present when the layers are communicating. When the layers do not communicate with each other, except through the wellbore, then the reservoir is termed a "commingled reservoir." A layered, composite reservoir may result because of artificial as well as natural processes.

Enhanced oil recovery processes such as steam flooding, CO_2 flooding, in-situ combustion, tectonic movements, phase changes, acidizing, and temperature differences may cause a reservoir to behave as a composite reservoir. The tilted line in Figure 1b shows the discontinuity boundary or the fluid front. A layered, composite reservoir situation occurs when all or some of the layers have two or more regions of different rock and/or fluid properties.

Numerous studies have been reported in the literature on layered reservoirs and Table 1 lists relevant papers on layered reservoirs. One aspect in which the studies differ is the way they model crossflow between the layers. Formation crossflow has been modelled mainly by two methods: pseudosteady-state crossflow
Figure 1. (a) Layered reservoir with interlayer crossflow; (b) radial, layered composite reservoir with a tilted front.

and transient crossflow. Pseudosteady-state crossflow assumes that the resistance to crossflow is confined to the interlayer boundary and the flow is horizontal within each layer. This assumption reduces a two-dimensional problem to a one-dimensional problem. Transient crossflow utilizes the two-dimensional diffusivity equation for each layer. Table 1 also shows that, although numerous studies have appeared on layered reservoirs with formation crossflow, very little work has been reported for layered, composite reservoirs with formation crossflow. Responses of layered reservoirs may be summarized as follows: for commingled reservoirs, the time needed to reach pseudosteady-state is an order of magnitude higher than that for homogeneous reservoirs; semi-log analysis can be used to estimate the average permeability-thickness product and the skin effect; initially, a crossflow system and a commingled system have the same responses; then there is a transition period and, finally, the crossflow system behaves like an equivalent homogeneous system.

Satman [22] presented drawdown and buildup responses for a commingled, multi-layered composite reservoir. In his model, he considered different discontinuity boundary radii for different layers. He used the concept of a tilted front for layered composite reservoirs, because the fluid front would propagate at different rates in different layers. For enhanced recovery processes, such as steam flooding, Satman and Oskay [35] considered the discontinuity boundary as a tilted front to

account for the gravity override effect and modelled the reservoir as a multi-layered composite reservoir without crossflow. They concluded that the tilted front model is a better representation of the actual reservoir than the sharp-front model when the gravity override effect is present. Hatzignatiou et al. [45] presented a solution for interference pressure transient behaviour in a two-layered reservoir having pseudosteady-state formation crossflow and described a type-curve matching technique to estimate the reservoir parameters. Anbarci et al. [55] presented an analytical solution for a two-layer, composite reservoir. They included wellbore storage and skin, and considered pseudosteady-state crossflow between the layers. They conducted a limited sensitivity study and used a type-curve matching technique to locate the front location in a particular layer. The preceding discussion shows that a general solution for an n-layer composite reservoir with crossflow is yet to be developed. In this study, we present an analytical solution and its validation for multi-layered, composite reservoirs with formation crossflow. We also discuss the usefulness of this solution for future studies.

MODEL DEVELOPMENT

We consider an n-layer, radial, composite reservoir as shown in Figure 2. A symmetrically located well fully penetrates the reservoir. The well produces at a constant flow rate and pseudosteady-state formation crossflow is present between the layers. The problem is solved following the approach of Anbarci et al. [55]. In Figure 2, the discontinuity boundary in each layer is represented by a vertical solid line. These discontinuity boundaries have been vertically extended across all the

Figure 2. Schematic diagram of an n-layered composite reservoir in radial geometry with two different rock and/or fluid types in each layer.

layers. As a result, depending on the total number of discontinuity boundaries and their locations, an n-layer reservoir may have m number of regions in each layer. Therefore, the reservoir is divided into $n \times m$ zones and each zone may be identified by (i,j), in which i and j denote the region and the layer, respectively. Each zone may have different rock and/or fluid properties, and can have variable length in the radial direction depending on the discontinuity boundary locations. In an actual reservoir, we may not need $n \times m$ zones of different rock and/or fluid properties. In Figure 2, the shaded and non-shaded areas represent two different fluid and/or rock types. Each layer has only two different rock and/or fluid types separated by a discontinuity boundary. In each layer, the discontinuity boundary is placed at a different location to simulate a tilted-front discontinuity boundary for the reservoir and for this particular situation, $m = n + 1$. Layers are assumed to be of constant thicknesses throughout the reservoir.

The crossflow between layers within the reservoir is modelled as in the semi-permeable wall model proposed by Gao [29]. Thus, crossflow resistance is assumed to be confined to the interlayer boundary and flow in each layer is horizontal. It is also assumed that the upper boundary of the top layer and the lower boundary of the bottom layer are closed. Other assumptions for the development of the mathematical model are as follows:

1. Reservoir fluids are slightly compressible and have constant compressibility.
2. The effects of gravity and capillary forces are negligible.
3. The flow in the formation can be described by Darcy's law.
4. When a fluid crosses the boundary of its zone, it behaves as the fluid in the downstream side.

The flow equation for zone i,j can be written as:

$$(1)\quad \left(\frac{kh}{\mu}\right)_{i,j}\left(\frac{\partial^2 p_{i,j}}{\partial r^2}+\frac{1}{r}\frac{\partial p_{i,j}}{\partial r}\right)=\left(\phi c_t h\right)_{i,j}\frac{\partial p_{i,j}}{\partial t}$$

$$+X_{Ai,j}\left(p_{i,j}-p_{i,j+1}\right)+X_{Bi,j}\left(p_{i,j}-p_{i,j-1}\right)$$

where $X_{Ai,j}$ and $X_{Bi,j}$ are defined as follows:

$$(2)\quad X_{Ai,j}=\frac{2}{\left(\frac{h\mu}{k_v}\right)_{i,j}+\left(\frac{h\mu}{k_v}\right)_{i,j+1}}$$

$$(3)\quad X_{Bi,j}=\frac{2}{\left(\frac{h\mu}{k_v}\right)_{i,j}+\left(\frac{h\mu}{k_v}\right)_{i,j-1}}$$

$$(4)\quad X_{Bi,1}=0 \qquad\qquad \text{for } i=1,\dots m$$

$$(5)\quad X_{Ai,n}=0 \qquad\qquad \text{for } i=1,\dots m$$

Initial condition: We assume that initially all zones are at initial pressure and thus,

$$(6)\quad p_{i,j}(r,0)=p_{in} \qquad \text{for all } i \text{ and } j$$

Inner boundary condition:

$$(7)\quad p_{wf}=p_{1,j}(r_w,t)-s_j\left(r\frac{\partial p_{1,j}}{\partial r}\right)_{r_w} \qquad \text{for } j=1,\dots n$$

$$(8)\quad q=-C\frac{\partial p_{wf}}{\partial t}+2\pi r_w\sum_{j=1}^{n}\left(\frac{kh}{\mu}\right)_{1,j}\left(\frac{\partial p_{1,j}}{\partial r}\right)_{r_w}$$
$$\text{for } j=1,\dots n$$

Outer boundary conditions:
Infinitely large system:

$$(9)\quad p_{m,j}=p_{in} \qquad\qquad \text{for } r\to\infty \text{ and } j=1,n$$

Finite system with a constant pressure at the outer boundary:

$$(10)\quad p_{m,j}=p_{in} \qquad\qquad \text{for } r=r_{ej} \text{ and } j=1,\dots n$$

Finite system with a closed outer boundary:

$$(11)\quad \frac{\partial p_{m,j}}{\partial r}=0 \qquad\qquad \text{for } r=r_{ej} \text{ and } j=1,\dots n$$

The flow equations for different zones in the same layer are coupled using the following interface conditions defining pressure and flow rate continuity between these zones:

$$(12)\quad p_{i,j}=p_{i+1,j} \qquad \text{for } r=r_{ai} \text{ and } i=1,\dots m-1$$
$$\text{and } j=1,\dots n$$

$$(13)\ \frac{\partial p_{i,j}}{\partial r} = M_{i,j}\frac{\partial p_{i+1,j}}{\partial r} \quad \text{for } r = r_w \text{ and } i = 1, \ldots, m$$
$$\text{and } j = 1, \ldots, n$$

where,

$$(14)\ M_{i,j} = \frac{\left(\frac{kh}{\mu}\right)_{i+1,j}}{\left(\frac{kh}{\mu}\right)_{i,j}}$$

Let us introduce the following dimensionless variables:

$$(15)\ r_D = \frac{r}{r_w}$$

$$(16)\ p_{D_{i,j}} = \frac{2\pi}{q}\left(\frac{\overline{kh}}{\mu}\right)\left(p_{in} - p_{i,j}\right)$$

$$(17)\ p_{wD} = \frac{2\pi}{q}\left(\frac{\overline{kh}}{\mu}\right)\left(p_{in} - p_{wf}\right)$$

$$(18)\ t_D = \frac{t}{r_w^2}\frac{\left(\frac{\overline{kh}}{\mu}\right)}{\left(\overline{\phi c_t h}\right)},$$

where,

$$(19)\ \left(\frac{\overline{kh}}{\mu}\right) = \sum_{j=1}^{n}\left(\frac{kh}{\mu}\right)_{1,j},$$

$$(20)\ \left(\overline{\phi c_t h}\right) = \sum_{j=1}^{n}\left(\phi c_t h\right)_{1,j},$$

Expressing the flow equation and the boundary conditions in terms of dimensionless variables, we can write:

$$(21)\ \kappa_{i,j}\left(\frac{\partial^2 p_{D_{i,j}}}{\partial r_D^2} + \frac{1}{r_D}\frac{\partial p_{D_{i,j}}}{\partial r_D}\right) = \omega_{i,j}\frac{\partial p_{D_{i,j}}}{\partial t_D}$$
$$+ \lambda_{A_{i,j}}\left(p_{D_{i,j}} - p_{D_{i,j+1}}\right) + \lambda_{B_{i,j}}\left(p_{D_{i,j}} - p_{D_{i,j-1}}\right).$$

where,

$$(22)\ \kappa_{i,j} = \frac{\left(\frac{kh}{\mu}\right)_{i,j}}{\left(\frac{\overline{kh}}{\mu}\right)}$$

$$(23)\ \omega_{i,j} = \frac{\left(\phi c_t h\right)_{i,j}}{\left(\overline{\phi c_t h}\right)}$$

$$(24)\ \lambda_{A_{i,j}} = \frac{r_w^2}{\left(\frac{\overline{kh}}{\mu}\right)}X_{A_{i,j}}$$

$$(25)\ \lambda_{B_{i,j}} = \frac{r_w^2}{\left(\frac{\overline{kh}}{\mu}\right)}X_{B_{i,j}}$$

Initial condition:

$$(26)\ p_{D_{i,j}}(r_D,0) = 0, \quad \text{for all } i \text{ and } j$$

Inner boundary condition:

$$(27)\ p_{wD} = p_{D_{i,j}}\left(1,t_D\right) - s_j\left(\frac{\partial p_{D_{i,j}}}{\partial r_D}\right), \quad \text{for } j = 1, \ldots, n$$

$$(28)\ 1 = C_D\frac{\partial p_{wD}}{\partial t_D} - \sum_{j=1}^{n}\kappa_{1,j}\left(\frac{\partial p_{D_{i,j}}}{\partial r_D}\right).$$

Outer boundary conditions:
Infinitely large system:

$$(29)\ p_{D_{i,j}} = 0, \quad \text{for } r_D \to \infty \text{ and } j = 1, \ldots, n$$

Finite system with a constant pressure at the outer boundary:

$$(30)\ p_{D_{i,j}} = 0, \quad \text{for } r_D = r_{D_{ej}} \text{ and } j = 1, \ldots, n$$

Finite system with a closed outer boundary:

$$(31)\ \frac{\partial p_{D_{i,j}}}{\partial r_D} = 0, \quad \text{for } r_D = r_{D_{ej}} \text{ and } j = 1, \ldots, n$$

Interface conditions defining pressure and flow rate continuity between the zones of a layer:

$$(32)\ p_{\mathrm{D},j} = p_{\mathrm{D}i+1,j} \qquad \text{for } r_{\mathrm{D}} = r_{\mathrm{D}i}\ \text{and } i = 1, \dots m-1$$
$$\text{and } j = 1, \dots n$$

$$(33)\ \frac{\partial p_{\mathrm{D}i,j}}{\partial r_{\mathrm{D}}} = M_{i,j}\ \frac{\partial p_{\mathrm{D}i+1,j}}{\partial r_{\mathrm{D}}} \qquad \text{for } r_{\mathrm{D}} = r_{\mathrm{D}i}$$
$$\text{and } i = 1, \dots m-1$$
$$\text{and } j = 1, \dots n$$

The Laplace transformation of Eqs. (21), and (27) through (33), yields:

$$(34)\ \kappa_{i,j}\left(\frac{d^2\bar{p}_{\mathrm{D}i,j}}{dr_{\mathrm{D}}^2} + \frac{1}{r_{\mathrm{D}}}\ \frac{d\bar{p}_{\mathrm{D}i,j}}{dr_{\mathrm{D}}}\right) = \omega_{i,j}\ p_{\mathrm{D}i,j}\ l$$
$$+ \lambda_{Ai,j}\left(\bar{p}_{\mathrm{D}i,j} - \bar{p}_{\mathrm{D}i,j+1}\right) + \lambda_{Bi,j}\left(\bar{p}_{\mathrm{D}i,j} - \bar{p}_{\mathrm{D}i,j-1}\right).$$

Inner boundary condition:

$$(35)\ \bar{p}_{w\mathrm{D}} = \bar{p}_{\mathrm{D}1,j}\ (1,l) - s_j\left(\frac{d\bar{p}_{\mathrm{D}1,j}}{dr_{\mathrm{D}}}\right), \qquad \text{for } j = 1, \dots n$$

$$(36)\ \frac{1}{l} = C_{\mathrm{D}}\bar{p}_{w\mathrm{D}}\ l - \sum_{j=1}^{n} \kappa_{1,j}\left(\frac{d\bar{p}_{\mathrm{D}1,j}}{dr_{\mathrm{D}}}\right).$$

Outer boundary conditions:
Infinitely large system:

$$(37)\ \bar{p}_{\mathrm{D}m,j} = 0, \qquad \text{for } r_{\mathrm{D}} \to \infty \text{ and } j = 1, \dots n$$

Finite system with a constant pressure at the outer boundary:

$$(38)\ \bar{p}_{\mathrm{D}m,j} = 0, \qquad \text{for } r_{\mathrm{D}} = r_{\mathrm{D}ej}\ \text{and } j = 1, \dots n$$

Finite system with a closed outer boundary:

$$(39)\ \frac{d\bar{p}_{\mathrm{D}m,j}}{dr_{\mathrm{D}}} = 0, \qquad \text{for } r_{\mathrm{D}} = r_{\mathrm{D}ej}\ \text{and } j = 1, \dots n$$

Interface conditions defining pressure and flow rate continuity between the zones of a layer:

$$(40)\ \bar{p}_{\mathrm{D}i,j} = \bar{p}_{\mathrm{D}i+1,j} \qquad \text{for } r_{\mathrm{D}} = r_{\mathrm{D}i}\ \text{and } i = 1, \dots m-1$$
$$\text{and } j = 1, \dots n$$

$$(41)\ \frac{d\bar{p}_{\mathrm{D}i,j}}{dr_{\mathrm{D}}} = M_{i,j}\ \frac{d\bar{p}_{\mathrm{D}i+1,j}}{dr_{\mathrm{D}}} \qquad \text{for } r_{\mathrm{D}} = r_{\mathrm{D}i}$$
$$\text{and } i = 1, \dots m-1$$
$$\text{and } j = 1, \dots n$$

Eq. (34) has the form of a modified Bessel's equation. Let us assume a solution of the following form for Eq. (34):

$$(42)\ \bar{p}_{\mathrm{D}i,j} = A_{i,j}\ K_0\left(\sigma r_{\mathrm{D}}\right) + B_{i,j}\ I_0\left(\sigma r_{\mathrm{D}}\right)$$

Introducing Eq. (42) into the left-hand side of Eq. (34), we get:

$$(43)\ \kappa_{i,j}\left(\frac{d^2\bar{p}_{\mathrm{D}i,j}}{dr_{\mathrm{D}}^2} + \frac{1}{r_{\mathrm{D}}}\ \frac{d\bar{p}_{\mathrm{D}i,j}}{dr_{\mathrm{D}}}\right) = \kappa_{i,j}\sigma^2 p_{\mathrm{D}i,j}.$$

Substituting Eq. (43) into Eq. (34) results in the following general equation:

$$(44)\ \lambda_{Ai,j}\ \bar{p}_{\mathrm{D}i,j+1} + \left(\sigma^2\kappa_{i,j} - \omega_{i,j}\ l - \lambda_{Ai,j} - \lambda_{Bi,j}\right)\bar{p}_{\mathrm{D}i,j}$$
$$+ \lambda_{Bi,j}\ p_{\mathrm{D}i,j-1} = 0$$

Eq. (44) has the form of a generalized eigenvalue system. As pointed out by Ehlig-Economides and Joseph [1], Eq. (44) has a non-trivial solution (i.e., $p_{\mathrm{D}i,j} \neq 0$) if and only if its coefficient matrix is singular. Thus, the determinant of the coefficient matrix has to be zero. The coefficient matrix is an $n \times m$ by $n \times m$ tridiagonal matrix. The coefficient matrix can be divided into m smaller real-symmetric, positive-definitive tridiagonal matrices, where the σ^2 act as the eigenvalues, and these eigenvalues are always positive. The determinant of each of these matrices is an nth order polynomial in σ^2; and, from each determinant, n eigenvalues can be obtained. Now, a general solution for each zone can be written as:

$$(45)\ \bar{p}_{\mathrm{D}i,j} = \sum_{k=1}^{n}\left[A_{i,j}^k\ K_0\left(\sigma_i^k r_{\mathrm{D}}\right) + B_{i,j}^k\ I_0\left(\sigma_i^k r_{\mathrm{D}}\right)\right].$$

Constants $A_{i,j}^k$ and $B_{i,j}^k$ can be split into two parts as follows:

$$(46)\ A_{i,j}^{k} = E_{i,j}^{k}\, A_{i}^{k}$$

$$(47)\ B_{i,j}^{k} = E_{i,j}^{k}\, B_{i}^{k}$$

where $E_{i,j}^{k}$ is the eigenvector for region i, and this eigenvector can be calculated from Eq. (44). Constants A_{k}^{i} and B_{k}^{i} are to be determined from the boundary conditions. Now, a general solution for region i and layer j becomes:

$$(48)\ p_{D,j} = \sum_{k=1}^{n}\left[A_{i}^{k}\, E_{i,j}^{k}\, K_{0}\!\left(\sigma_{i}^{k}\, r_{D}\right) + B_{i}^{k}\, E_{i,j}^{k}\, I_{0}\!\left(\sigma_{i}^{k}\, r_{D}\right)\right].$$

Eq. (48) contains $2n \times m$ constants to be evaluated from the boundary conditions. For the inner boundary condition, without considering wellbore storage, we can write:

$$(49)\ \bar{p}_{wD} = \sum_{k=1}^{n}\left[\left(A_{1}^{k}\, E_{1,j}^{k}\, K_{0}\!\left(\sigma_{1}^{k}\right) + B_{1}^{k}\, E_{1,j}^{k}\, I_{0}\!\left(\sigma_{1}^{k}\right)\right)\right.$$
$$\left. + s_{j}\,\sigma_{1}^{k}\!\left(A_{1}^{k}\, E_{1,j}^{k}\, K_{1}\!\left(\sigma_{1}^{k}\right) - B_{1}^{k}\, E_{1,j}^{k}\, I_{1}\!\left(\sigma_{1}^{k}\right)\right)\right]$$

for $j = 1, \ldots n$

$$(50)\ \frac{1}{s} = \sum_{j=1}^{n} \kappa_{1,j} \sum_{k=1}^{n} \sigma_{1}^{k}\left[A_{1}^{k}\, E_{1,j}^{k}\, K_{1}\!\left(\sigma_{1}^{k}\right)\right.$$
$$\left. - B_{1}^{k}\, E_{1,j}^{k}\, I_{1}\!\left(\sigma_{1}^{k}\right)\right] \qquad \text{for } j = 1, \ldots n$$

For an infinite outer boundary condition, we can write:

$$(51)\ \sum_{k=1}^{n}\left[A_{m}^{k}\, E_{m,j}^{k}\, K_{0}\!\left(\sigma_{m}^{k}\, r_{D}\right) + B_{m}^{k}\, E_{m,j}^{k}\, I_{0}\!\left(\sigma_{m}^{k}\, r_{D}\right)\right] = 0$$

for $r_{D} \to \infty$ and $j = 1, \ldots n$

In order that the pressure be bounded, we can write:

$$(52)\ \sum_{k=1}^{n} B_{m}^{k} = 0 \qquad \text{for } j = 1, \ldots n$$

A constant pressure outer boundary condition yields:

$$(53)\ \sum_{k=1}^{n}\left[A_{m}^{k}\, E_{m,j}^{k}\, K_{0}\!\left(\sigma_{m}^{k}\, r_{De,j}\right)\right.$$
$$\left. + B_{m}^{k}\, E_{m,j}^{k}\, I_{0}\!\left(\sigma_{m}^{k}\, r_{De,j}\right)\right] = 0$$

for $j = 1, \ldots n$

A no flow outer boundary condition yields:

$$(54)\ \sum_{k=1}^{n}\left[A_{m}^{k}\, E_{m,j}^{k}\, K_{1}\!\left(\sigma_{m}^{k}\, r_{De,j}\right)\right.$$
$$\left. + B_{m}^{k}\, E_{m,j}^{k}\, I_{1}\!\left(\sigma_{m}^{k}\, r_{De,j}\right)\right] = 0$$

for $j = 1, \ldots n$

The interface conditions defining pressure and flow rate continuity yield:

$$(55)\ \sum_{k=1}^{n}\left[A_{i}^{k}\, E_{i,j}^{k}\, K_{0}\!\left(\sigma_{i}^{k}\, r_{Dai}\right) + B_{i}^{k}\, E_{i,j}^{k}\, I_{0}\!\left(\sigma_{i}^{k}\, r_{Dai}\right)\right]$$
$$= \sum_{k=1}^{n}\left[A_{i+1}^{k}\, E_{i+1,j}^{k}\, K_{0}\!\left(\sigma_{i+1}^{k}\, r_{Dai}\right)\right.$$
$$\left. + B_{i+1}^{k}\, E_{i+1,j}^{k}\, I_{0}\!\left(\sigma_{i+1}^{k}\, r_{Dai}\right)\right]$$

for $j = 1, \ldots n$ and $i = 1, \ldots m - 1$

$$(56)\ \sum_{k=1}^{n}\left[A_{i}^{k}\, E_{i,j}^{k}\, K_{1}\!\left(\sigma_{i}^{k}\, r_{Dai}\right) - B_{i}^{k}\, E_{i,j}^{k}\, I_{1}\!\left(\sigma_{i}^{k}\, r_{Dai}\right)\right]$$
$$= \sum_{k=1}^{n}\left[A_{i+1}^{k}\, E_{i+1,j}^{k}\, K_{1}\!\left(\sigma_{i+1}^{k}\, r_{Dai}\right)\right.$$
$$\left. - B_{i+1}^{k}\, E_{i+1,j}^{k}\, I_{1}\!\left(\sigma_{i+1}^{k}\, r_{Dai}\right)\right]$$

for $j = 1, \ldots n$ and $i = 1, \ldots m - 1$

Eqs. (47) through (56) give a total of $2n \times m$ simultaneous equations which can be solved to find $2n \times m$ values of the coefficients A_{i}^{k} and B_{i}^{k}.

Thus, the preceding solution models transient fluid flow in an n-layer, composite reservoir with pseudo-steady-state crossflow. This new solution uses the eigenvalues and eigenvectors of the system and is computationally more efficient than other methods proposed in the literature. For example, for a 5-layer,

composite reservoir ($m = 6$), this new solution requires the solution of only 60 simultaneous equations, whereas the method proposed by Anbarci et al. [55] requires the solution of 300 simultaneous equations to solve the same problem. By assigning a constant-pressure boundary at the top or at the bottom, this new solution can include a gas cap or a bottom-water drive, respectively. This new solution is also capable of treating any irregularly shaped fluid front by dividing the reservoir into a number of mathematical layers.

To include a bottom-water drive, the lower boundary of the bottom layer is considered as a constant-pressure boundary. Mathematically, the vertical permeability of the bottom-water zone is considered infinite and Eq. (4) is modified as follows:

$$(4a)\ X_{Bi,1} = \frac{2}{\left(\frac{h\mu}{k_v}\right)_{i,1}} \qquad \text{for } i = 1, \dots\, m$$

Also, in the diffusivity equation for layer $j = 1$, $p_{i,j-1}$ is replaced by the initial pressure, p_{in}. Similarly, to include a gas-cap drive, the upper boundary of the top layer is considered as a constant-pressure boundary, and the vertical permeability of the gas-cap zone is considered infinite. Therefore, Eq. (5) is modified as follows:

$$(5a)\ X_{Ai,n} = \frac{2}{\left(\frac{h\mu}{k_v}\right)_{i,n}} \qquad \text{for } i = 1, \dots\, m$$

Also, in the diffusivity equation for layer $j = n$, $p_{i,j+1}$ is replaced by the initial pressure, p_{in}.

For a partially penetrating well, the inner boundary condition needs some modification. Both Eqs. (7) and (8) are considered to apply only for layers penetrated by the well. For layers that are not open to flow to the wellbore, the inner boundary condition can be written as:

$$(8a)\ \frac{\partial p_{i,j}}{\partial r} = 0, \qquad \text{for } r = r_w \text{ and } j = \text{layers not open}$$
to flow to the wellbore

For a partially penetrating well, Eqs. (7), (8) and (8a) together describe the inner boundary condition.

SOLUTION METHODOLOGY

The following steps were utilized to solve Eq. (48) at any region i and layer j:

1. From Eq. (44), eigenvalues and eigenvectors were calculated using an appropriate subroutine from the IMSL Math/Library [60].
2. From the boundary conditions, $2n \times m$ simultaneous equations were set up and then solved using Gauss' elimination routine from the IMSL Math/Library [60] for the constants A_i^k and B_i^k.
3. Dimensionless pressure in Laplace space is calculated using Eq. (48) and then numerically inverted using the Stehfest algorithm [61].
4. The wellbore storage effect is included using the following well known relationship:

$$(57)\ \bar{p}_{wD} = \frac{1}{C_D l^2 + \frac{1}{(\bar{p}_{wD})_{C_D = 0}}}$$

The computation process involves repeated calculation of Bessel's functions. Very small and large arguments of Bessel's functions create an overflow problem during the computational process. This problem is overcome by using a dimensionless radius, r_D, based on the minimum front radius, r_{a1}, instead of the wellbore radius, and by calculating Bessel's functions in exponentiated form.

MODEL VALIDATION

The new analytical solution was validated by generating some well-known pressure transient responses for various cases of homogeneous, composite, and layered reservoirs, which are subsets of the general solution developed. Figure 3 shows a comparison of results generated by the new analytical solution with an Agarwal et al. [62] type-curve for homogeneous reservoirs. Homogeneous reservoir responses were generated by setting identical reservoir properties for each of the layers of a two-layer reservoir and by setting very high crossflow parameters. The responses were generated for different wellbore storage and skin effects. Figure 3 shows a successful match between the two solutions. Figure 4 shows a comparison of the responses of this study with Tariq and Ramey's solution [19] for a two-layer, commingled reservoir with a closed outer boundary. Commingled layered reservoir responses
Figure 3. Comparison of this study with Agarwal et al.'s [62] solution for a homogeneous reservoir.

Figure 4. Comparison of this study with Tariq and Ramey's [19] solution for a two-layer reservoir with closed outer boundary.

were generated by setting different layer properties for each layer and assigning very small crossflow parameters. Figure 4 shows a very good match between the two results for different wellbore storage effects. Figure 5 shows a comparison of responses of this study with the Eggenschwiler et al. [63] solution for a single-layer, two-region composite reservoir. In the model, a single-layer, composite reservoir is obtained by dividing a two-layer reservoir into two regions and setting different properties for them. In each region, the layers are assigned identical fluid and rock properties and a very high crossflow parameter. The responses were
Figure 5. Comparison of this study with Eggenschwiler et al.'s [63] solution for a two-region composite reservoir.

generated for different mobility ratios and Figure 5 shows a good match between the two solutions. Figure 6 shows a comparison of the results of this study with Ambastha and Ramey's [64] pressure derivative solution for a single-layer, two-region, composite reservoir. Again, Figure 6 shows a good match between the two solutions. One important aspect of the new solution is its versatility. Figure 7 shows a comparison of this study with Ambastha and Ramey's solution [65] for a three-region composite reservoir. The three-region composite reservoir response was generated by dividing a two-

Figure 6. Comparison of this study with Ambastha and Ramey's [64] study for a two-region, composite reservoir.
Figure 7. Comparison of this study with Ambastha and Ramey's [65] study for an infinitely large, three-region, composite reservoir.

layer reservoir into three regions and setting different fluid properties for each region. The layers were assigned identical fluid and rock properties in each region and very high crossflow parameters. Figure 7 shows pressure derivative responses for different mobility ratios between zones one and two, and the responses show a good match between the two solutions.

Figure 8 shows the effect of crossflow on pressure transient responses for a two-layer reservoir. The upper and the lower straight lines represent commingled and homogeneous reservoir responses, respectively. Initially, the reservoir behaves like a commingled reservoir. Then, depending on the crossflow parameter λ, there is a transition period during which the crossflow effect becomes important and the responses change from
Figure 8. Effect of crossflow on wellbore pressure for a two-layer reservoir.

those for a commingled reservoir to those for a homogeneous reservoir. At late time, the reservoir behaves like an equivalent homogeneous system. The transition from commingled reservoir behaviour to homogeneous reservoir behaviour depends on the crossflow parameter. The higher the crossflow parameter, the earlier the transition occurs. The above observation is consistent with layered reservoir behaviour reported in the literature.

Figure 9 shows the pressure drawdown responses of a partially penetrating well in a two-layer reservoir subject to bottom-water drive. The upper layer is open to flow and the lower layer is closed. For a penetration ratio of 0.5, the two curves show the responses for two different crossflow parameters. Both curves show radial flow characteristics until the effect of the constant-pressure boundary becomes dominant. Similar observations have been made by Streltsova-Adams [66] and Buhidma and Raghavan [67]. For a lower crossflow parameter, it takes a longer time for the constant pressure boundary to have a dominant effect on the pressure drawdown responses.

Figure 9. Pressure drawdown response of a partially penetrating well in a two-layer reservoir subject to bottom-water drive.

FUTURE POSSIBILITIES

In this study, a general analytical solution for an n-layer composite reservoir with pseudosteady-state interlayer crossflow has been developed and validated. Formation crossflow has been modelled as pseudo-steady-state interlayer crossflow. This method is very general and computationally efficient. This method has

certain advantages over the finite-difference method in that this method does not have a numerical dispersion problem and rounding off error like the finite-difference method.

A reservoir undergoing a thermal recovery process has been idealized as a single-layer, composite reservoir for a long time [63,64,68-71]. This new model can be used to analyze more general scenarios of heterogeneous reservoirs undergoing thermal recovery processes. Effects of gravity override or underride, viscous fingering, etc., on a discontinuity boundary can be treated as a tilted or any other irregularly shaped front and its effects on pressure transient responses can be studied. Pressure transient analysis of both drawdown and buildup tests can be studied with this model.

This new model can also accommodate the situation where each layer has a different outer boundary distance, r_{ej}. This can be done by vertically extending the outer boundary of each layer, the same way as has been done for the discontinuity boundaries. This will create some mathematical zones (which do not exist) which will be taken care of by assigning very small horizontal and vertical permeabilities to them.

Another possibility is to use automated type-curve matching to analyze rate and pressure measurements from different layers of layered, composite reservoirs. The effect of a gas cap or bottom-water has been included by properly specifying pressure and semi-permeabilities at the appropriate boundary to yield a constant-pressure boundary at the top or bottom, respectively. Transient pressure responses of a partially penetrating well in a layered reservoir subject to the effects of a bottom-water and/or a gas cap can be investigated with this model. The proposed analytical solution may also lead to new and/or improved methods for analyzing well test data from multi-layered, composite reservoirs with formation crossflow. Efforts are underway to develop some simplified type-curves for the system under study.

CONCLUSIONS

1. A general analytical solution for pressure transient responses for an n-layer, composite reservoir with pseudosteady-state interlayer crossflow has been developed and validated.

2. The new analytical solution developed in this study is a more efficient and versatile solution than presently available solutions in the literature.

3. The new analytical solution of this study offers new

possibilities to analyze more complicated well-testing scenarios than the possibilities offered by presently available solutions.

NOMENCLATURE

A_j^k	=	Constant in Eq. (46)
B_j^k	=	Constant in Eq. (47)
C	=	Wellbore storage coefficient, m^3/Pa
C_D	=	Dimensionless wellbore storage
c_t	=	Total system compressibility, Pa^{-1}
E_{ij}^k	=	Eigenvector for the region i
F_s	=	Storativity ratio, $(\phi c_t)_1/(\phi c_t)_2$
F_{s12}	=	Storativity ratio between region 1 and 2 for a 3-region reservoir, $(\phi c_t)_1/(\phi c_t)_2$
F_{s13}	=	Storativity ratio between region 1 and 3 for a 3-region reservoir, $(\phi c_t)_1/(\phi c_t)_3$
h	=	Formation thickness, m
k	=	Permeability, m^2
l	=	Laplace variable
M	=	Mobility ratio, $(k/\mu)_1/(k/\mu)_2$
M_{12}	=	Mobility ratio between region 1 and 2 for a 3-region reservoir, $(k/\mu)_1/(k/\mu)_2$
M_{13}	=	Mobility ratio between region 1 and 3 for a 3-region reservoir, $(k/\mu)_1/(k/\mu)_3$
M_{ij}	=	Mobility ratio between zone i,j and $i+1,j$
p	=	Pressure, Pa
p_{in}	=	Initial pressure, Pa
p_{wf}	=	wellbore flowing pressure, Pa
p_D	=	Dimensionless pressure
p_{wD}	=	Dimensionless wellbore pressure
q	=	Flow rate, $m^3 s^{-1}$
r	=	Radial distance, m
r_D	=	Dimensionless radial distance
r_a	=	Radial front distance, m
r_{ai}	=	Minimum radial front distance, m
r_{ai}	=	Radial front distance located between regions i and $i+1$, m
r_{ej}	=	Outer boundary distance of layer j, m

R_{D1} = Dimensionless front radius for region 1 for a 3-region reservoir, r_{a1}/r_w

R_{D2} = Dimensionless front radius for region 2 for a 3-region reservoir, r_{a2}/r_w

s = Wellbore skin effect

s_j = Wellbore skin effect for layer j

t = Time, sec

t_D = Dimensionless time

t_{RD} = Dimensionless time based on radial front distance, r_a, $K(kh)_1/r_a^2(\mu\phi c_t h)_1$

t_{RD1} = Dimensionless time based on radial front distance, r_{a1}, $K(kh)_1/r_{a1}^2(\mu\phi c_t h)_1$

$X_{A,j}$ = Semi-permeability of the zone i,j between layer j and $j+1$

$X_{B,j}$ = Semi-permeability of the zone i,j between layer j and $j-1$

GREEK SYMBOLS

σ_i^k = Eigenvalues for the region i

$\kappa_{i,j}$ = Defined by Eq. (22)

θ = Front angle, degrees

∂ = Partial

λ = Crossflow parameter for a two-layered reservoir,

$$\frac{2r_w^2}{\left[\left(\frac{h\mu}{k_v}\right)_1 + \left(\frac{h\mu}{k_v}\right)_2\right]\left(\frac{\overline{kh}}{\mu}\right)}$$

$\lambda_{A,j}$ = Defined by Eq. (24)

$\lambda_{B,j}$ = Defined by Eq. (25)

μ = Viscosity

ω = Relative storativity, $(\phi c_t h)_1/(\phi c_t h)_2$

$\omega_{i,j}$ = Defined by Eq. (23)

ϕ = Porosity

Abstract

Many times, oil reservoirs are accompanied by bottom-water zones and/or gas caps, and these reservoirs are produced using partially-penetrating wells. An extra pressure drop occurs around such wells during production because of partial penetration. Several correlations have been presented in the literature to estimate pseudoskin for a partially-penetrating well located in either a homogeneous or a layered reservoir with closed top and bottom boundaries. This study aims to develop new analytical expressions for pseudoskin for partially-penetrating wells in multi-layered reservoirs with both closed top and bottom boundaries, and with bottom water zones and/or gas caps. A pseudosteady-state interlayer crossflow has been assumed in this study.

These new analytical expressions are simple and easy to use. Evaluation of pseudoskin using these expressions requires a knowledge of two parameters when the top and the bottom boundaries are closed, and three parameters in the presence of a bottom-water zone or a gas cap, regardless of the number of layers. The estimated pseudoskin is very close to the actual pseudoskin obtained from the complete analytical solution. These new analytical expressions are also applicable to the corresponding homogeneous and single-layered cases. The estimated pseudoskin values have been compared with those estimated by other researchers. Effects of the open interval location, the presence of bottom-water zone and/or gas cap, and the layer refinement on pseudoskin have also been studied.

Introduction

Reservoir deposition occurs over geologic period of time and, because of this, many reservoirs are layered instead of homogeneous. Oil reservoirs are often accompanied by a bottom-water zone and/or a gas cap. In such situations, wells are completed over a fraction of the productive zone to delay water and/or gas coning. These wells are known as partially-penetrating wells. Because of partial penetration, pressure transient responses show additional pressure drop in comparison to the pressure drop for a fully-penetrating well. This additional pressure drop is referred to as pseudoskin. Partially-penetrating wells have their own characteristic responses which, if not properly evaluated, may lead to errors in the interpretation of well-test data. The purpose of this paper is to study the pressure transient responses and pseudoskin factor in a partially-penetrated, multi-layered reservoir with or without a bottom-water zone or a gas cap.

Muskat[1] studied partially-penetrating wells in single-layered reservoirs under steady-state conditions using the method of images and estimated productivity loss because of partial penetration. Nisle[2] presented buildup pressure transient responses for a partially-penetrating well in a single-layered homogeneous reservoir. He considered a partially-penetrating well in an infinite slab and used the method of images to solve the problem. He observed two different straight lines for early and late time pressure buildup responses and used ratio of the slopes of these two straight lines to estimate penetration ratio. Brons and Marting[3] observed three sequences in pressure transient responses of a partially-penetrating well in a single-layered isotropic reservoir: a radial flow period with a slope corresponding to open interval thickness, a transition period, and a pseudoradial flow period with a slope corresponding to total formation thickness. They presented an empirical expression for pseudoskin factor, s_p. But they did not consider the variation in the horizontal and the

vertical permeabilities when defining dimensionless wellbore thickness and their pseudoskin factor had to be numerically evaluated.

Bilhartz and Ramey[4] used a 2-D finite-difference model to study wellbore storage and skin effects in a single-layered, partially-penetrated reservoir. They concluded that radial flow period and transition to pseudoradial flow period may be masked in the presence of significant wellbore storage. They extended Brons and Marting[3] pseudoskin expression for anisotropic reservoirs and discussed methods to estimate horizontal and vertical permeabilities.

Streltsova-Adams[5] used Laplace and Hankel transformations to solve partial-penetration problem in a single-layered reservoir and derived an expression for pseudoskin factor in terms of infinite sine and cosine series. She considered the presence of a gas cap as a constant-pressure boundary in her solution. She investigated the effect of open interval (penetrated portion) location on pseudoskin factor and concluded that pseudoskin factor is minimum for centrally-located open intervals, other parameters remaining unchanged. She also observed that for a reservoir with a gas cap, the pseudoskin factor is lower than that for a reservoir with no gas cap, when the open interval is adjacent to the constant-pressure boundary. Buhidma and Raghavan[6] studied drawdown and buildup behaviour of a partially-penetrating well in a square reservoir subject to bottom-water drive. Using Green's function for solution, they concluded that under bottom-water drive, pseudoradial flow does not exist and pseudoskin factor can not be calculated by the methods presented by Brons and Marting[3] and other researchers. Although pseudoradial flow period does not exist under bottom-water or gas-cap drive, the expression for pseudoskin developed in this study can be used to estimate the pseudoskin factor under these reservoir conditions.

Using a 2-D finite-difference simulator, Reynolds et al.[7] graphically presented the pressure transient responses of a partially-penetrated, two-layered reservoir. Analyzing the steady-state analytical solution, they identified the correlating parameters and then obtained a correlation for pseudoskin factor by regressional analysis. They also concluded that using different layers for different fluid regions, a multi-phase flow system can be approximated by a layered, single-phase flow system.

Papatzacos[8] used the method of images to solve partial-penetration problem for a single-layered, homogeneous reservoir and derived an expression for pseudoskin factor in terms of dimensionless open interval, its location and dimensionless wellbore radius.

Olarewaju and Lee[9] studied buildup pressure behaviour of a partially-penetrating well in a two-layered reservoir with closed top and bottom boundaries. Of the two layers they considered, one layer is open to flow and the other layer is closed. In the closed layer, they considered flow only in the vertical direction, neglecting the radial component of the flow, which may limit the applicability of their model. Olarewaju and Lee[9] considered crossflow as a time-dependent source term for the open layer based on the vertical flow component for the closed layer. By regressional analysis, they developed a series of expressions correlating the pseudoskin factor with the penetration ratio for various k_z/k_r values.

Using a numerical simulator, Yeh and Reynolds[10] presented some type-curves for partially-penetrated, multi-layered reservoirs with transient crossflow. Using the same numerical model, Yeh and Reynolds[11] graphically presented pseudoskin factors for a partially-penetrated, multi-layered reservoir. Using regressional analysis, they obtained an expression for pseudoskin factor.

Vrbik[12] derived a simplified approximate expression for a single-layered, homogeneous reservoir in terms of three correlating parameters which are related to dimensionless open interval length, its location and dimensionless wellbore radius. Ding and Reynolds[13] extended Papatzacos[8] expression for pseudoskin for a single-layered reservoir to that for a multi-layered reservoir and reported good match with simulated results.

Shah and Thambynayagam[14] presented an analytical solution for a two-layered, partially-penetrated reservoir by successive application of Laplace and Hankel transformations. They considered transient crossflow between the two layers and the presence of a gas-cap drive. They presented some pressure transient responses for fully- and partially-penetrating wells and did not study the pseudoskin factor because of the partial penetration.

Table 1 summarizes most of the studies[1-19] conducted on partially-penetrated reservoirs and pseudoskin factor. Table 1 shows that most of the studies considered single-layered reservoirs and only a limited number of studies have focussed on partially-penetrating, multi-layered reservoirs. Partially-penetrated, multi-layered reservoir problem has been studied either by using a numerical simulator with graphical presentation of pressure transient responses and pseudoskin values (Yeh and Reynolds[10,11]), or by extending the single-layered expression of pseudoskin to multi-layered case by redefining some parameters (Ding and Reynolds[13]). Table 1 also shows that very few studies have been conducted for a partially-penetrated reservoir subject to a bottom-water or a gas-cap drive.

This study attempts to give some new insights in understanding partially-penetrated, multi-layered reservoirs and covers both pressure transient responses and pseudoskin factors in situations when the top and bottom boundaries are closed and when one of the boundaries is at a constant pressure because of a bottom-water or a gas-cap drive.

Pseudoskin Factor Expression for a Partially-Penetrated Reservoir with Closed Top and Bottom Boundaries

Figure 1 schematically shows a two-layered, partially-penetrated reservoir. In this study, the layers are numbered from bottom to top. Thus, layer 1 is always the bottom-most layer. In Figure 1, layer 1 is penetrated and layer 2 is closed at the wellbore. The upper boundary of the layer 2 and the lower boundary of the layer 1 are considered as closed boundaries. Pseudo-steady-state crossflow is considered between the two layers. Appendix A shows a detailed derivation of the pressure transient solution and late-time limiting solution for this case. From the late-time limiting solution, we obtain the expression for pseudoskin as:

$$s_b = \frac{(1-\kappa)}{\kappa} \frac{K_0\left(\sqrt{\frac{\lambda_A}{\kappa(1-\kappa)}}\right)}{\sqrt{\frac{\lambda_A}{\kappa(1-\kappa)}} \, K_1\left(\sqrt{\frac{\lambda_A}{\kappa(1-\kappa)}}\right)} \qquad (1)$$

where s_b denotes the pseudoskin, and λ_A and κ denote dimensionless crossflow parameter and mobility-thickness ratio of the open interval, respectively. Equation (1) can be extended for a multi-layered reservoir by appropriately defining λ_A and κ as:

$$s_b = \frac{(1-\bar{\kappa})}{\bar{\kappa}} \frac{K_0\left(\sqrt{\frac{\lambda_A}{\bar{\kappa}(1-\bar{\kappa})}}\right)}{\sqrt{\frac{\lambda_A}{\bar{\kappa}(1-\bar{\kappa})}} \, K_1\left(\sqrt{\frac{\lambda_A}{\bar{\kappa}(1-\bar{\kappa})}}\right)} \qquad (2)$$

where, $\bar{\kappa}$ = total mobility-thickness ratio of the open interval

λ_A = average crossflow parameter

Equation (2) is applicable for a multi-layered reservoir having any arbitrary number of layers consisting the open interval and any arbitrary location of the open interval. In equation (2), $\bar{\kappa}$ and λ_A are calculated by adding the individual layer mobility-thickness ratio of the open interval, and by adding the bottom and the top boundary crossflow parameters of the open interval, respectively. For multi-layered reservoirs, instead of considering crossflow parameters of each and every layer, only top and bottom boundary crossflow parameters of the open interval are considered in defining the average crossflow parameter. This was done because equation (2) gives better results with an average crossflow parameter defined in this manner, rather than with an average crossflow parameter, which considers the crossflow parameters of each and every layer. Similar observation is made by Ding and Reynolds[13] in defining the average vertical permeability. Irrespective of the number of layers in the reservoir, only two parameters (i.e., $\bar{\kappa}$ and λ_A) are required to estimate the pseudoskin using equation (2).

For a single-layered, anisotropic reservoir, the mobility-thickness ratio, κ, and the crossflow parameter, λ_A, reduce to the penetration ratio (b) and $2b^2/h_D{}^2$, respectively. With these simplifications, equation (1) reduces to:

$$s_b = \frac{h_D}{\sqrt{2}} (1-b) \frac{K_0\left(\sqrt{\frac{2b}{h_D^2(1-b)}}\right)}{K_1\left(\sqrt{\frac{2b}{h_D^2(1-b)}}\right)} \qquad (3)$$

where, $h_D = \frac{h}{r_w} \sqrt{\frac{k_r}{k_z}}$ \qquad (4)

Equation (3) estimates pseudoskin factor for a single-layered, anisotropic reservoir with closed top and bottom boundaries.

Equation (3) is also applicable for homogeneous reservoirs with an appropriate change (i.e., $k = k_v$) in the definition of h_D.

Pseudoskin Factor Expression for a Partially-Penetrated Reservoir Subject to a Gas-Cap or a Bottom-Water Drive

Figure 2 schematically shows a two-layered, partially-penetrated reservoir subject to a gas-cap drive. Layer 1 is penetrated and layer 2 is closed at the wellbore. The upper boundary of the layer 2 is considered as a constant-pressure boundary because of the gas cap, whereas the lower boundary of the layer 1 is considered as a closed boundary. Pseudosteady-state crossflow is considered between the two layers. Appendix B shows a detailed derivation of the pressure transient solution and late-time limiting solution. From late-time limiting solution, we obtain the pseudoskin expression as:

$$s_b = \frac{a_2 \, K_0(\sigma_2)}{(a_2 - a_H)\sigma_2 \, K_1(\sigma_2)} - \frac{a_H \, K_0(\sigma_H)}{(a_2 - a_H)\sigma_H \, K_1(\sigma_H)}$$

$$- \frac{(a_2 - a_H) \, K_0(\sigma_H) \, K_0(\sigma_2)}{b_L} \qquad (5)$$

where s_b denotes the pseudoskin factor, and σ_H, σ_2, a_L, a_2, and b_L are late-time limiting values defined by the equations (B.22) through (B.26) and (B.30) in Appendix B. The variable, λ_C, in the equations (B.22) through (B.26), is the crossflow parameter between the reservoir and the gas cap and this parameter is required to calculate the late-time limiting values in equation (5). Equation (5) estimates the pseudoskin in a two-layered, partially-penetrated reservoir subject to a gas-cap or a bottom-water drive. Equation (5) is also applicable for a multi-layered reservoir having any arbitrary number of layers representing the open interval and any arbitrary location of the open interval, provided $\bar{\kappa}$ and λ_A are calculated by adding the individual layer mobility-thickness ratio of the open interval, and by adding the top and the bottom boundary crossflow parameters of the open interval, respectively. Irrespective of the number of layers in the reservoir, only three parameters (i.e., $\bar{\kappa}$, λ_A and λ_C) are required to estimate the pseudoskin. An effort was made to simplify equation (5) for a single-layered reservoir without much success.

Accuracy of Pseudoskin Factor Expressions

For multi-layered reservoirs, Table 2 compares the estimated pseudoskin using the simplified expressions of equations (2) and (5), with those calculated using the actual analytical solutions. Layered reservoirs of 2, 3 and 5 layers are considered. Various cases of reservoir configuration in Table 2 are explained in Table 3. In Table 2, for a particular reservoir, s_{AC} denotes the actual or 'correct' pseudoskin from the analytical solution of Gomes and Ambastha[20], which is the late-time dimensionless pressure difference between the response of the partially-penetrating well and that of the fully-penetrating well at a particular time, whereas s_{GA} denotes the estimated pseudoskin using the simplified expressions of equations (2) and (5). For different values of open

interval mobility-thickness ratio ($\bar{\kappa}$) and crossflow parameter ($\bar{\lambda}_A$) and for different open interval locations, pseudoskin factors are estimated for layered reservoirs having different number of layers. For both the closed top and bottom boundaries and the bottom-water zone, Table 2 shows excellent match between the estimated and the actual pseudoskins for all different cases considered.

Comparison with Reference 3

Figure 3 compares the pseudoskin factors estimated from equation (3) of this study with those from Figure 2 of Brons and Marting[3] study for a single-layered, homogeneous reservoir. Figure 3 shows that, except for small penetration ratios (b < 0.3), the pseudoskin factors estimated from equation (3) are very close to those estimated from Brons and Marting[3] study. The difference between the two pseudoskin values increases with the decrease in penetration ratios. Also, pseudoskin factors calculated from equation (3) are consistently higher than those of Brons and Marting[3] study. The reason for the differences in pseudoskin values may be the difference in crossflow modelling in the two studies.

Comparison with References 11 and 13

Table 4 compares the pseudoskin factors estimated from this study with those estimated from Yeh and Reynolds[11] and Ding and Reynolds[13] studies. Various cases in Table 4 refer to different data sets. Cases in Table 4 are not related to cases in Table 3. Table 4 shows data for a three-layered reservoir with closed top and bottom boundaries and with layer 3 open to flow. These data are taken from Ding and Reynolds[13] study. In Table 4, s_{YR} and s_{DR} denote the pseudoskin obtained from Yeh and Reynolds[11] study and Ding and Reynolds[13] study, respectively. Table 4 shows consistently close comparison of the pseudoskins of this study with those of Ding and Reynolds[13] study, and of Yeh and Reynolds[11] study. Ding and Reynolds[13] reported good match between their pseudoskin and that obtained from the numerical simulator. In most cases, pseudoskin factors obtained from the analytical solution as well as from the the simplified expression developed in this study are observed to be greater than those obtained from Ding and Reynolds[13] study, and from Yeh and Reynolds[11] study. This is probably because of the pseudosteady state crossflow assumption in the development of the analytical model of this study. Significance of this assumption is that the resistance to vertical flow is assumed to be limited in the interlayer area instead of uniformly dispersed in the vertical direction. This pseudosteady state crossflow assumption is more applicable when shale streaks are present in the interlayer area.

Development of New Time Criteria and Comparison with Reference 4

Figure 4 shows the effect of crossflow parameter, λ_A, on pressure derivative responses of a two-layered reservoir with different open interval mobility-thickness ratio, κ. The crossflow parameter (λ_A) has been varied between 0.5×10^{-5} and 0.5×10^{-7}, and the

mobility-thickness ratio (κ) has been varied between 0.25 and 0.75. For all values of the crossflow parameter and the mobility-thickness ratio, the early time responses show radial flow behaviour with a constant semi-log slope of $0.5/\kappa$. At very early time, the semi-log slopes are slightly lower than their constant value because of the numerical errors introduced in solving the system of equations. After some time, the responses show a transition from the radial flow behaviour, and the time at which the transition occurs is a strong function of the crossflow parameter and the mobility-thickness ratio. At late time, all responses show pseudoradial flow behaviour with a semi-log slope of 0.5. Again, the time to the beginning of the pseudoradial flow is a function of the crossflow parameter and the mobility-thickness ratio. The higher the crossflow parameters are, the sooner the radial flow period ends and the sooner the pseudoradial flow period begins. The lower the mobility-thickness ratio is, the earlier the radial flow period ends and the later the pseudoradial flow period begins. Analysis of the pressure derivative responses shown in Figure 4 results in the following criteria for the end of the radial flow period and the beginning of the pseudoradial (second radial) flow period as:

$$t_{D1} = 0.0196 \, \kappa^2/\lambda_A \qquad (6)$$

$$t_{D2} = 0.658 \, / \left(\lambda_A \sqrt{\kappa} \right) \qquad (7)$$

Equations (6) and (7) describe the times by which the semi-log pressure derivatives are within 5% of the correct slope values. Equations (6) and (7) have been extended for reservoirs having more than two layers by replacing λ_A and κ by $\bar{\lambda}_A$ and $\bar{\kappa}$, respectively, and have been tested to be applicable for three-layered and five-layered reservoirs.

Bilhartz and Ramey[4] used a 2-D finite-difference model to study the pressure transient responses of a partially-penetrating well with wellbore storage and skin effects. Based on an analysis of pressure responses, they developed the time criteria for the end of radial flow and the beginning of the pseudoradial flow periods as follow:

$$t_{D1} = 0.02 \, h_D^2 \qquad (8)$$

$$t_{D2} = h_D^2 \left(\frac{h}{h_w \pi} \right)^2 \left[\ln \left(\frac{2}{\pi} \sin \left(\frac{\pi h_w}{h} \right) \cos \left(\frac{\pi h_z}{2h} \right) \cos \left(\frac{3 \pi h_z}{4h} \right) \right) \cdot \ln (0.02) \right] \qquad (9)$$

where, h_D is defined by equation (4).

For a single-layered reservoir, equations (6) and (7) degenerate to the following form:

$$t_{D1} = 0.0196 \, h_D^2 \qquad (10)$$

$$t_{D2} = 0.329 \, \frac{h_D}{b^{0.5}} \qquad (11)$$

The time for the end of the first radial flow period given by equation (10) is about half of that given by equation (8). Thus, the first radial flow period ends earlier as predicted by equation (10) than by equation (8). For a single-layered reservoir, equation (11) estimates the time for the beginning of the second radial flow period, $t_{D2} = 837,500$ with a crossflow parameter $\lambda_A = 1.11 \times 10^{-6}$ and a penetration ratio of 0.5. For the same data, equation (9) estimates $t_{D2} = 196,500$. Analysis with some more values of crossflow parameter and penetration ratio showed that the time for the beginning of the second radial flow period estimated from equation (11) is approximately 2 to 4 times greater than those estimated from equation (9). Thus, according to the time criteria obtained in this study, the first radial flow period ends earlier and the second radial flow period begins later than the times predicted by Bilhartz and Ramey's[4] correlations. Some of the differences in these time criteria may be attributed to different ways of modelling the crossflow in these two studies. However, a smaller t_{D1} and a larger t_{D2} based on pressure derivative responses (equations (10) and (11)) than those based on pressure responses (equations (8) and (9)) are consistent with the general observations regarding time criteria based on pressure and pressure derivative responses presented by Ambastha[21].

Figure 5 compares the correlations for the time to the beginning of the second radial flow period from this study (equation 11) and that from Bilhartz and Ramey[4] study (equation 9) for a single-layered reservoir. Equation (9) is not applicable for all penetration ratios. Equation (9) becomes meaningless for $b \geq 2/3$ because $\cos(3\pi b/4 b)$ becomes zero or negative. However, computationally, equation (9) is applicable for $b < 0.64$, because beyond this penetration ratio, t_{D2} becomes negative. To the best of our knowledge, this limitation of equation (9) has not been pointed out in the literature. But equation (11) has been derived for $0.1 \leq b \leq 0.5$ and for h_D between 100 and 10,000. Although there is no mathematical or computational limitation to equation (11), t_{D2} value calculated at $b = 1$ becomes physically meaningless. When $b = 1$, all t_{D2} values should coincide with the time to the beginning of radial flow period for a fully-penetrated, single-layered reservoir, which does not happen with equation (11).

Figure 6 compares the pressure transient responses from this study with those from Figure 3 of Bilhartz and Ramey[4] study. Figure 6 graphs dimensionless wellbore pressure against dimensionless time for penetration ratios of 0.25 and 0.5. Initially, the responses show a straight line corresponding to the first radial flow period with a semi-log slope of 0.5h. After the first radial flow period, there is a transition period after which, the responses again show straight lines corresponding to the second radial (pseudoradial) flow period with a slope of 0.5. Since pseudoskin factors obtained from this study are slightly higher than those obtained from Bilhartz and Ramey[4] study, pressure responses for the second radial flow period are slightly higher than those of Bilhartz and Ramey[4]. For the penetration ratios of 0.25 and 0.5, pseudoskin factors obtained from this study are 19.4 and 5.98, respectively, whereas those obtained from Bilhartz and Ramey[4] study are 17.53 and 5.47, respectively. Thus, the pseudoskin factors obtained from the two studies are very close.

Effects of Gas-Cap (or Bottom-Water) Drive on Pseudoskin and Comparison with Reference 5

Table 5 shows the effects of gas cap on pseudoskin factor for a three-layered reservoir with $k_1 = k_2 = k_3 = 4.9344 \times 10^{-14}$ m^2 and with $h = 200$ m. The various cases of reservoir configuration in Table 5 are explained in Table 3. Cases 1 and 2 show pseudoskins when there is no gas cap and cases 3 and 4 show pseudoskins when the reservoir is subject to a gas-cap drive. In the absence of the gas cap, pseudoskin is lower when the open interval is away from the top or the bottom boundary than when the open interval is located adjacent to the top or the bottom boundary. This happens because the crossflow parameter, λ_A, is higher when the open interval is away from the top or bottom boundary. But case 3 shows that when the gas cap is present, pseudoskin is smaller when the open interval is adjacent to the constant-pressure boundary than when the open interval is away from the constant-pressure boundary. This happens because when the open interval is adjacent to the constant-pressure boundary, the wellbore pressure stabilizes faster than when the open interval is away from the constant-pressure boundary. Similar observations were also made by Streltsova-Adams[5]. The above observations are also valid for the corresponding cases when the reservoir is accompanied by a bottom-water zone.

Figure 7 compares the pseudoskin factors from this study with those from Streltsova-Adams[5] study for a partially-penetrating well in a reservoir subject to a gas-cap drive. Gas-oil contact has been modelled as a constant pressure boundary in both studies. Figure 7 compares pseudoskin factors with those from Figure 9 of Streltsova-Adams[5] study. The solid lines in Figure 7 show the pseudoskin factors estimated from equation (5) of this study for various penetration ratios and under gas-cap condition. Streltsova-Adams[5] estimated the pseudoskin by taking the difference between the late-time pressure responses of a partially-penetrating well and a fully-penetrating well in a particular reservoir. Figure 7 shows very close comparison of the pseudoskin factors estimated from this study with those from Streltsova-Adams[5] study, except for very small penetration ratios ($b < 0.3$). Pseudoskin factors estimated from this study are slightly higher than those obtained from Streltsova-Adams[5] study. This is likely due to the different ways of modelling the crossflow in the two studies.

Comparison with Reference 9

Figure 8 shows a comparison of the pseudoskin factors obtained from equation (1) of this study with those obtained from Figure 8 of Olarewaju and Lee[9] study. Figure 8 graphs the pseudoskin factors against various penetration ratios for a two-layered reservoir with layer two open to flow and layer one closed. Figure 8 shows that the pseudoskin factors obtained from this study are significantly higher (more than double) than those obtained from Olarewaju and Lee[9] study. The reason for this may be the assumption that Olarewaju and Lee[9] made in developing their model. They assumed that there is no radial flow component in the closed layer (i.e., layer one). Because of this assumption, fluid particles travel shorter distances and only vertically to move from the closed layer to the open layer (layer two). If there were radial

flow component in the closed layer, fluid particles would have travelled longer distances to move from the closed layer to the open layer and this would have caused higher pressure drops, i.e., higher pseudoskin factors. Thus, neglecting the radial flow component in the closed layer may not be a satisfactory assumption while studying pressure transient responses for partially-penetrating wells.

Effect of Layer Refinement on Pseudoskin Factor

Table 6 shows the effects of layer refinement on pseudoskin factor. For a particular reservoir thickness and open interval, the reservoir is divided into a number of mathematical layers to study the effects of layer refinement on pseudoskin factor. In Table 6, cases 1 through 3 represent a reservoir height of 30 m with an open interval thickness of 10 m, and cases 4 through 6 represent a reservoir thickness of 100 m with an open interval thickness of 20 m, respectively. For both reservoir thicknesses of 30 m and 100 m, the open interval is considered as a single layer, and the closed interval of the reservoir is divided into 1, 2 and 4 layers. The results in Table 6 show a small decrease in pseudoskin factor as the number of mathematical layers increases and this decrease in pseudoskin factor is greater when the reservoir thickness is larger. But the value of pseudoskin factor stabilizes as the number of mathematical layers is further increased. This layer refinement effect occurs because of the pseudosteady-state crossflow assumption. The layer refinement effect has also been observed by Larsen[22].

Conclusions

1. Pressure transient responses and pseudoskin factors for a partially-penetrated, multi-layered reservoir can be analytically studied by a pseudosteady-state crossflow model.

2. Simplified expressions for pseudoskin factor have been derived for a partially-penetrated, multi-layered reservoir with or without a bottom-water or a gas-cap drive and pseudoskin factors can be estimated from these expressions with reasonable accuracy.

3. Times for the end of the radial flow period and the beginning of the pseudoradial flow period depend on the crossflow parameter and the mobility-thickness ratio of the open interval. Simplified expressions have been derived for these time criteria.

4. Pseudoskin factors obtained from this study have been compared with those obtained from other studies in the literature and these comparisons have shown good matches with most of the studies.

Appendix A

Late Time Behaviour of a Partially-Penetrating Well in a Two-layered Reservoir with Pseudosteady-State Crossflow.

Figure 1 schematically shows a two-layered, partially-penetrated reservoir. Layer 1 is penetrated and layer 2 is closed at the wellbore. The upper boundary of the layer 2 and the lower boundary of the layer 1 are considered as closed boundaries. Pseudosteady-state crossflow is considered between the two layers. The problem is solved following the steps taken by Bourdet[23]. The diffusivity equations for the two layers are:

$$\left(\frac{kh}{\mu}\right)_1\left(\frac{\partial^2 p_1}{\partial r^2}+\frac{1}{r}\frac{\partial p_1}{\partial r}\right)=(\phi c_t h)_1\frac{\partial p_1}{\partial t}+\chi_d(p_1-p_2) \tag{A.1}$$

$$\left(\frac{kh}{\mu}\right)_2\left(\frac{\partial^2 p_2}{\partial r^2}+\frac{1}{r}\frac{\partial p_2}{\partial r}\right)=(\phi c_t h)_2\frac{\partial p_2}{\partial t}+\chi_d(p_2-p_1) \tag{A.2}$$

Initial condition: $p_1=p_2=p_{in}$ $\hspace{2cm}$ (A.3)

Outer boundary condition: $\lim_{r\to\infty} p_1=\lim_{r\to\infty} p_2=p_{in}$ $\hspace{1cm}$ (A.4)

Inner boundary condition: Assuming layer 1 is penetrated and layer 2 is closed, and neglecting wellbore storage and skin, we can write:

$p_1=p_w$ $\hspace{1cm}$ for $r=r_w$ $\hspace{2cm}$ (A.5)

$$\left(\frac{\partial p_2}{\partial r}\right)_{r=r_w}=0 \tag{A.6}$$

$$q=2\pi\left(\frac{kh}{\mu}\right)_1\left(r\frac{\partial p_1}{\partial r}\right)_{r=r_w} \tag{A.7}$$

We define the following dimensionless variables:

$$p_{D1,2}=\frac{2\pi}{q}\left(\frac{\overline{kh}}{\mu}\right)(p_{in}-p_{1,2}) \tag{A.8}$$

$$t_D=\frac{\left(\frac{\overline{kh}}{\mu}\right)}{\left(\overline{\phi c_t h}\right)}\frac{t}{r_w^2} \tag{A.9}$$

where, $\left(\dfrac{\overline{kh}}{\mu}\right)=\left(\dfrac{kh}{\mu}\right)_1+\left(\dfrac{kh}{\mu}\right)_2$, and $\hspace{1cm}$ (A.10)

$$\left(\overline{\phi c_t h}\right)=(\phi c_t h)_1+(\phi c_t h)_2 \tag{A.11}$$

All other dimensionless parameters are defined in the Nomenclature

The differential equations and the boundary conditions can be written in a dimensionless form as:

$$\kappa\nabla^2 p_{D1}=\omega\frac{\partial p_{D1}}{\partial t_D}+\lambda_d(p_{D1}-p_{D2}) \tag{A.12}$$

$$(1-\kappa)\nabla^2 p_{D2}=(1-\omega)\frac{\partial p_{D2}}{\partial t_D}+\lambda_d(p_{D2}-p_{D1}) \tag{A.13}$$

Initial condition: $p_{D1}(r_D,0)=p_{D2}(r_D,0)=0$ $\hspace{1cm}$ (A.14)

Outer boundary condition: $\lim_{r_D\to\infty} p_{D1}=\lim_{r_D\to\infty} p_{D2}=0$ $\hspace{0.5cm}$ (A.15)

Inner boundary condition: $\hspace{2cm} p_{D1}(1,t_D)=p_{wD}$ $\hspace{1cm}$ (A.16)

$$\left(\frac{\partial p_{D2}}{\partial r_D}\right)_{r_D=1}=0 \tag{A.17}$$

$$1=-\kappa\left(\frac{\partial p_{D1}}{\partial r_D}\right)_{r_D=1} \tag{A.18}$$

Taking Laplace transformation of equations (A.12) through (A.18) yields:

$$\kappa\nabla^2\overline{p}_{D1}=\omega s\overline{p}_{D1}+\lambda_d(\overline{p}_{D1}-\overline{p}_{D2}) \tag{A.19}$$

$$(1-\kappa)\nabla^2\overline{p}_{D2}=(1-\omega)s\overline{p}_{D2}+\lambda_d(\overline{p}_{D2}-\overline{p}_{D1}) \tag{A.20}$$

Outer boundary condition: $\lim_{r_D \to \infty} \bar{p}_{D1} = \lim_{r_D \to \infty} \bar{p}_{D2} = 0$ (A.21)

Inner boundary condition: $\bar{p}_{D1}(1,t) = \bar{p}_{wD}$ (A.22)

$$\left(\frac{\partial \bar{p}_{D2}}{\partial r_D}\right)_{r_D=1} = 0 \quad (A.23)$$

$$\frac{1}{t} = -\kappa \left(\frac{\partial \bar{p}_{D1}}{\partial r_D}\right)_{r_D=1} \quad (A.24)$$

Solutions of equations (A.19) and (A.20) are modified Bessel's functions, $I_0(\sigma r_D)$ and $K_0(\sigma r_D)$, where σ is the eigenvalue of the system. For an infinite system, only $K_0(\sigma r_D)$ function applies. Therefore,

$$\bar{p}_{D1} = AK_0(\sigma r_D) \quad (A.25)$$

$$\bar{p}_{D2} = BK_0(\sigma r_D) \quad (A.26)$$

Equations (A.19) and (A.20) together with equations (A.25) and (A.26) yield:

$$\omega \sigma^2 AK_0(\sigma r_D) = \omega AK_0(\sigma r_D) + \lambda_A[AK_0(\sigma r_D) - BK_0(\sigma r_D)] \quad (A.27)$$

$$(1-\kappa)\sigma^2 BK_0(\sigma r_D) = (1-\omega)BK_0(\sigma r_D) + \lambda_A[BK_0(\sigma r_D) - AK_0(\sigma r_D)] \quad (A.28)$$

Equations (A.27) and (A.28) reduce to:

$$\left[\omega\sigma^2 - \omega - \lambda_A\right]A + \lambda_A B = 0 \quad (A.29)$$

$$\lambda_A A + \left[(1-\kappa)\sigma^2 - (1-\omega) - \lambda_A\right]B = 0 \quad (A.30)$$

Non-trivial solutions are possible, if the determinant is zero, i.e.,

$$\left(\omega\sigma^2 - \omega - \lambda_A\right)\left[(1-\kappa)\sigma^2 - (1-\omega) - \lambda_A\right] - \lambda_A^2 = 0 \quad (A.31)$$

Equation (A.31) can be reorganized as:

$$\sigma^4 - \left[\frac{(1-\omega)\omega + \lambda_A}{1-\kappa} + \frac{\omega + \lambda_A}{\kappa}\right]\sigma^2 + \frac{\omega(1-\omega) + \lambda_A}{\kappa(1-\kappa)} = 0 \quad (A.32)$$

This polynomial has two positive roots and they are:

$$\sigma_1^2 = \frac{1}{2}\left[\left(\frac{(1-\omega)\omega + \lambda_A}{1-\kappa} + \frac{\omega + \lambda_A}{\kappa}\right) + \Delta\right] \quad (A.33)$$

$$\sigma_2^2 = \frac{1}{2}\left[\left(\frac{(1-\omega)\omega + \lambda_A}{1-\kappa} + \frac{\omega + \lambda_A}{\kappa}\right) - \Delta\right] \quad (A.34)$$

where, $\Delta = \left[\left(\frac{(1-\omega)\omega + \lambda_A}{1-\kappa} - \frac{\omega + \lambda_A}{\kappa}\right)^2 + \frac{4\lambda_A^2}{\kappa(1-\kappa)}\right]^{\frac{1}{2}}$ (A.35)

Putting σ_1^2 and σ_2^2 from equations (A.33) and (A.34), respectively, in equation (A.30) and rearranging, we can write:

$$a_1 = \frac{A_1}{B_1} = 1 + \frac{1}{\lambda_A}\left[(1-\omega)/ - (1-\kappa)\sigma_1^2\right] \quad (A.36)$$

$$a_2 = \frac{A_2}{B_2} = 1 + \frac{1}{\lambda_A}\left[(1-\omega)/ - (1-\kappa)\sigma_2^2\right] \quad (A.37)$$

Putting $A_1 = a_1 B_1$ and $A_2 = a_2 B_2$ in equations (A.25) and (A.26) yield:

$$\bar{p}_{D1} = a_1 B_1 K_0(\sigma_1 r_D) + a_2 B_2 K_0(\sigma_2 r_D) \quad (A.38)$$

$$\bar{p}_{D2} = B_1 K_0(\sigma_1 r_D) + B_2 K_0(\sigma_2 r_D) \quad (A.39)$$

Equations (A.38) and (A.39) together with equations (A.22) and (A.23) yield:

$$B_1 = -\frac{B_2\sigma_2 K_1(\sigma_2)}{\sigma_1 K_1(\sigma_1)} \quad (A.40)$$

Equations (A.38) and (A.39) together with equation (A.24) yield:

$$\frac{1}{\kappa t} = a_1 B_1 \sigma_1 K_1(\sigma_1) + a_2 B_2 \sigma_2 K_1(\sigma_2) \quad (A.41)$$

From equations (A.40) and (A.41), we get:

$$B_1 = -\frac{1}{(a_2 - a_1)\kappa t \sigma_1 K_1(\sigma_1)} \quad (A.42)$$

$$B_2 = \frac{1}{(a_2 - a_1)\kappa t \sigma_2 K_1(\sigma_2)} \quad (A.43)$$

Now, equation (A.38) becomes:

$$\bar{p}_{wD} = -\frac{a_1 K_0(\sigma_1)}{(a_2 - a_1)\kappa t \sigma_1 K_1(\sigma_1)} + \frac{a_2 K_0(\sigma_2)}{(a_2 - a_1)\kappa t \sigma_2 K_1(\sigma_2)} \quad (A.44)$$

Equation (A.44) represents pressure transient response of a partially-penetrating well in a two-layered reservoir in Laplace space and these responses are numerically inverted to real space using the Stehfest algorithm[34].

Late Time Behaviour for a Partially-penetrating Well with No Bottom-Water Zone or Gas Cap

At late time $t_D \rightarrow \infty$ and $I \rightarrow 0$, and equations (A.33) through (A.37) become:

$$\lim_{I \rightarrow 0} \Delta = \lim_{I \rightarrow 0} \left[\left(\frac{\lambda_A}{1-\kappa} + \frac{\lambda_A}{\kappa} \right)^2 + I (\ldots) + I^2 (\ldots) \right]^{\frac{1}{2}} = \frac{\lambda_A}{\kappa(1-\kappa)}$$

(A.45)

$$\lim_{I \rightarrow 0} \sigma_1^2 = \lim_{I \rightarrow 0} \left[\frac{\lambda_A}{1-\kappa} + \frac{\lambda_A}{\kappa} + I(\ldots) + I^2(\ldots) \right] = \frac{\lambda_A}{\kappa(1-\kappa)}$$

(A.46)

$$\lim_{I \rightarrow 0} \sigma_2^2 = \lim_{I \rightarrow 0} \frac{1}{2} \left\{ \frac{1-\omega}{1-\kappa} + \frac{\omega}{\kappa} \cdot \frac{1-\omega}{1-\kappa} + \frac{\omega}{\kappa} \right\} = I$$

(A.47)

Appendix C shows the simplification proposed in equation (A.47) in detail.

$$\lim_{I \rightarrow 0} a_1 = \lim_{I \rightarrow 0} \left[1 + \frac{(1-\omega)I - (1-\kappa)\sigma_1^2}{\lambda_A} \right] = \frac{\kappa-1}{\kappa}$$

(A.48)

$$\lim_{I \rightarrow 0} a_2 = \lim_{I \rightarrow 0} \left[1 + \frac{(1-\omega)I - (1-\kappa)\sigma_2^2}{\lambda_A} \right] = 1$$

(A.49)

Using the late-time limits shown in equations (A.45) through (A.49), equation (A.44) may be written as:

$$\bar{s}_p = \frac{(1-\kappa)}{\kappa} \frac{K_1\left(\sqrt{\frac{\lambda_A}{\kappa(1-\kappa)}}\right)}{\sqrt{\frac{\lambda_A}{\kappa(1-\kappa)}} K_1\left(\sqrt{\frac{\lambda_A}{\kappa(1-\kappa)}}\right)} + \frac{K_0(\sqrt{I})}{I\sqrt{I} K_1(\sqrt{I})}$$

(A.50)

The first term in equation (A.50) is a constant and it represents the additional pressure drop because of partial penetration, which is usually known as pseudoskin. The second term in equation (A.50) represents the equivalent infinite, homogeneous reservoir

response for the whole reservoir. So, for a two-layered reservoir, the expression for pseudoskin is:

$$\bar{s}_p = \frac{(1-\kappa)}{\kappa} \frac{K_1\left(\sqrt{\frac{\lambda_A}{\kappa(1-\kappa)}}\right)}{\sqrt{\frac{\lambda_A}{\kappa(1-\kappa)}} K_1\left(\sqrt{\frac{\lambda_A}{\kappa(1-\kappa)}}\right)}$$

(A.51)

Equation (A.51) can be extended for a multi-layered reservoir by appropriately defining κ and λ_A:

$$\bar{s}_p = \frac{(1-\bar{\kappa})}{\bar{\kappa}} \frac{K_1\left(\sqrt{\frac{\bar{\lambda}_A}{\bar{\kappa}(1-\bar{\kappa})}}\right)}{\sqrt{\frac{\bar{\lambda}_A}{\bar{\kappa}(1-\bar{\kappa})}} K_1\left(\sqrt{\frac{\bar{\lambda}_A}{\bar{\kappa}(1-\bar{\kappa})}}\right)}$$

(A.52)

where, $\bar{\kappa}$ = total mobility-thickness ratio of the open interval

$\bar{\lambda}_A$ = total crossflow parameter

Equation (A.52) is applicable for a multi-layered reservoir having any arbitrary number of layers consisting the open interval and any arbitrary location of the open interval. In equation (A.52), $\bar{\kappa}$ and $\bar{\lambda}_A$ are calculated by adding the individual layer mobility-thickness ratio of the open interval and by adding the lower and the upper boundary crossflow parameters, respectively. Irrespective of the number of layers in the reservoir, only two parameters are required to estimate the pseudoskin. A similar treatment for a reservoir subject to a gas-cap drive (or a bottom-water drive) is shown in Appendix B.

Appendix B

Late Time Behaviour of a Partially-Penetrated Well in a Two-layered Reservoir Subject to a Gas-Cap Drive.

Figure 2 schematically shows a two-layered, partially-penetrated reservoir subject to a gas-cap drive. Layer 1 is penetrated and layer 2 is closed at the wellbore. The upper boundary of the layer 2 is considered as a constant-pressure boundary because of gas cap, whereas the lower boundary of the layer 1 is considered as a closed boundary. Pseudosteady-state crossflow is considered between the two layers. The diffusivity equations for the two layers are:

$$\left(\frac{kh}{\mu}\right)_1 \left(\frac{\partial^2 p_1}{\partial r^2} + \frac{1}{r}\frac{\partial p_1}{\partial r}\right) = (\phi c_t h)_1 \frac{\partial p_1}{\partial t} + X_1(p_1 - p_2)$$

(B.1)

$$\left(\frac{kh}{\mu}\right)_2 \left(\frac{\partial^2 p_2}{\partial r^2} + \frac{1}{r}\frac{\partial p_2}{\partial r}\right) = (\phi c_t h)_2 \frac{\partial p_2}{\partial t} + X_2(p_2 - p_1) + X_3(p_3 - p_2)$$

(B.2)

Inner and outer boundary conditions, and initial condition are the same as in Appendix A. In dimensionless form, the differential equations and the boundary conditions can be written as:

$$\kappa \nabla^2 p_{D1} = \omega \frac{\partial p_{D1}}{\partial t_D} + \lambda_A (p_{D1} - p_{D2}) \qquad \text{(B.3)}$$

$$(1 - \kappa) \nabla^2 p_{D2} = (1 - \omega)\frac{\partial p_{D2}}{\partial t_D} + \lambda_A (p_{D2} - p_{D1}) + \lambda_C \, p_{D2} \qquad \text{(B.4)}$$

Initial condition: $p_{D1}(r_D,0) = p_{D2}(r_D,0) = 0$ (B.5)

Outer boundary condition: $\lim_{r_D \to \infty} p_{D1} = \lim_{r_D \to \infty} p_{D2} = 0$ (B.6)

Inner boundary condition: $p_{D1}(1,t_D) = p_{wD}$ (B.7)

$$\left(\frac{\partial p_{D2}}{\partial r_D}\right)_{r_D=1} = 0 \qquad \text{(B.8)}$$

$$1 = -\kappa \left(\frac{\partial p_{D1}}{\partial r_D}\right)_{r_D=1} \qquad \text{(B.9)}$$

Following the same steps as in Appendix A, we can obtain:

$$\left[\omega \sigma^2 - \omega f - \lambda_A\right]A + \lambda_A B = 0 \qquad \text{(B.10)}$$

$$\lambda_A A + \left[(1 - \kappa)\sigma^2 - (1 - \omega)f - \lambda_A - \lambda_C\right]B = 0 \qquad \text{(B.11)}$$

Non-trivial solutions are possible, if the determinant is zero, i.e.,

$$\left(\omega \sigma^2 - \omega f - \lambda_A\right)\left[(1 - \kappa)\sigma^2 - (1 - \omega)f - \lambda_A - \lambda_C\right] - \lambda_A^2 = 0 \qquad \text{(B.12)}$$

Equation (B.12) can be reorganized as:

$$\sigma^4 - \left[\frac{(1-\omega)f + \lambda_A + \lambda_C}{1-\kappa} + \frac{\omega f + \lambda_A}{\kappa}\right]\sigma^2 +$$
$$\frac{(\omega f + \lambda_A)\left[(1-\omega)f + \lambda_A + \lambda_C\right] - \lambda_A^2}{\kappa(1-\kappa)} = 0 \qquad \text{(B.13)}$$

This polynomial has two positive roots and these are:

$$\sigma_1^2 = \frac{1}{2}\left[\left(\frac{(1-\omega)f + \lambda_A + \lambda_C}{1-\kappa} + \frac{\omega f + \lambda_A}{\kappa}\right) + \Delta\right] \qquad \text{(B.14)}$$

$$\sigma_2^2 = \frac{1}{2}\left[\left(\frac{(1-\omega)f + \lambda_A + \lambda_C}{1-\kappa} + \frac{\omega f + \lambda_A}{\kappa}\right) - \Delta\right] \qquad \text{(B.15)}$$

where, $\Delta =$

$$\left[\left(\frac{(1-\omega)f + \lambda_A + \lambda_C}{1-\kappa} + \frac{\omega f + \lambda_A}{\kappa}\right)^2 - \frac{4(\omega f + \lambda_A)\left[(1-\omega)f + \lambda_A + \lambda_C\right] - \lambda_A^2}{\kappa(1-\kappa)}\right]^{\frac{1}{2}}$$

(B.16)

Putting σ_1^2 and σ_2^2 from equations (B.14) and (B.15), respectively, in equation (B.11) and rearranging, we can write:

$$a_1 = \frac{A_1}{B_1} = 1 + \frac{\lambda_C}{\lambda_A} + \frac{1}{\lambda_A}\left[(1 - \omega)f - (1 - \kappa)\sigma_1^2\right] \qquad \text{(B.17)}$$

$$a_2 = \frac{A_2}{B_2} = 1 + \frac{\lambda_C}{\lambda_A} + \frac{1}{\lambda_A}\left[(1 - \omega)f - (1 - \kappa)\sigma_2^2\right] \qquad \text{(B.18)}$$

As in Appendix A, putting $A_1 = a_1 B_1$ and $A_2 = a_2 B_2$ in the solution yields:

$$\bar{p}_{D1} = a_1 B_1 K_0(\sigma_1 r_D) + a_2 B_2 K_0(\sigma_2 r_D) \qquad \text{(B.19)}$$

$$\bar{p}_{D2} = B_1 K_0(\sigma_1 r_D) + B_2 K_0(\sigma_2 r_D) \qquad \text{(B.20)}$$

Again, following the same steps as in Appendix A, we obtain the expression for the wellbore pressure as:

$$\bar{p}_{wD} = \frac{a_1 K_0(\sigma_1)}{(a_2 - a_1)\kappa f \sigma_1 K_1(\sigma_1)} + \frac{a_2 K_0(\sigma_2)}{(a_2 - a_1)\kappa f \sigma_2 K_1(\sigma_2)} \qquad \text{(B.21)}$$

Equation (B.21) represents pressure transient responses in Laplace space of a partially-penetrating well in a two-layered reservoir subject to a gas-cap drive and these responses are numerically inverted to real space using the Stehfest Algorithm[26].

Late Time Behaviour for a Partially-penetrating Well Under a Gas-cap Drive

At late time $t_D \to \infty$ and $f \to 0$, and equations (B.14) through (B.18) become:

$$\lim_{f \to 0} \sigma_1^2 = \sigma_{1L}^2 = \frac{1}{2}\left[\frac{\lambda_A + \lambda_C}{1-\kappa} + \frac{\lambda_A}{\kappa} + \left(\left(\frac{\lambda_A + \lambda_C}{1-\kappa} + \frac{\lambda_A}{\kappa}\right)^2 - \frac{4\lambda_A \lambda_C}{(1-\kappa)\kappa}\right)^{\frac{1}{2}}\right]$$

(B.22)

$$\lim_{f \to 0} \sigma_2^2 = \sigma_{2L}^2 = \frac{1}{2}\left[\frac{\lambda_A + \lambda_C}{1-\kappa} + \frac{\lambda_A}{\kappa} - \left(\left(\frac{\lambda_A + \lambda_C}{1-\kappa} + \frac{\lambda_A}{\kappa}\right)^2 - \frac{4\lambda_A \lambda_C}{(1-\kappa)\kappa}\right)^{\frac{1}{2}}\right]$$

(B.23)

$$\lim_{t \to 0} \Delta = \left[\left(\frac{\lambda_A + \lambda_C}{1 - \kappa} + \frac{\lambda_A}{\kappa} \right)^2 - \frac{4\lambda_A\lambda_C}{(1 - \kappa)\kappa} \right]^{\frac{1}{2}} \qquad (B.24)$$

$$\lim_{t \to 0} a_1 = a_{1L} = 1 + \frac{\lambda_C}{\lambda_A}$$

$$\cdot \frac{(1 - \kappa)}{2\lambda_A} \left[\frac{\lambda_A + \lambda_C}{1 - \kappa} + \frac{\lambda_A}{\kappa} + \left\{ \left(\frac{\lambda_A + \lambda_C}{1 - \kappa} + \frac{\lambda_A}{\kappa} \right)^2 - \frac{4\lambda_A\lambda_C}{(1 - \kappa)\kappa} \right\}^{\frac{1}{2}} \right] \qquad (B.25)$$

$$\lim_{t \to 0} a_2 = a_{2L} = 1 + \frac{\lambda_C}{\lambda_A}$$

$$\cdot \frac{(1 - \kappa)}{2\lambda_A} \left[\frac{\lambda_A + \lambda_C}{1 - \kappa} + \frac{\lambda_A}{\kappa} - \left\{ \left(\frac{\lambda_A + \lambda_C}{1 - \kappa} + \frac{\lambda_A}{\kappa} \right)^2 - \frac{4\lambda_A\lambda_C}{(1 - \kappa)\kappa} \right\}^{\frac{1}{2}} \right] \qquad (B.26)$$

Using the late-time limits shown in equations (B.22) through (B.26), equation (B.21) may be written as:

$$\bar{p}_{wDL} = - \frac{a_{1L} K_0(\sigma_{1L})}{(a_{2L} - a_{1L})\kappa/\sigma_{1L} K_1(\sigma_{1L})} + \frac{a_{2L} K_0(\sigma_{2L})}{(a_{2L} - a_{1L})\kappa/\sigma_{2L} K_1(\sigma_{2L})} \qquad (B.27)$$

Equation (B.27) denotes the limiting pressure drop in Laplace space for a partially-penetrating well subject to a gas-cap drive. Taking inverse Laplace transformation of equation (B.27), we obtain the corresponding pressure drop in the real space as:

$$p_{wDL} = - \frac{a_{1L} K_0(\sigma_{1L})}{(a_{2L} - a_{1L})\kappa\sigma_{1L} K_1(\sigma_{1L})} + \frac{a_{2L} K_0(\sigma_{2L})}{(a_{2L} - a_{1L})\kappa\sigma_{2L} K_1(\sigma_{2L})} \qquad (B.28)$$

Performing the same treatment for a fully-penetrating well in a two-layered reservoir subject to a gas-cap drive, we obtain:

$$p_{wDL} = \frac{(a_{2L} - a_{1L}) K_0(\sigma_{1L}) K_0(\sigma_{2L})}{b_L} \qquad (B.29)$$

where,

$$b_L = (1 - a_{1L})(\kappa\sigma_{2L} + 1 - \kappa)\sigma_{2L} K_0(\sigma_{1L}) K_1(\sigma_{2L})$$
$$\cdot (1 - a_{2L})(\kappa\sigma_{1L} + 1 - \kappa)\sigma_{1L} K_0(\sigma_{2L}) K_1(\sigma_{1L}) \qquad (B.30)$$

Difference between equations (B.28) and (B.29) is the additional pressure drop because of the partial penetration of a two-layered reservoir subject to a gas-cap drive. Therefore, the expression for pseudoskin for this case is:

$$s_p = \frac{a_{2L} K_0(\sigma_{2L})}{(a_{2L} - a_{1L})\kappa\sigma_{2L} K_1(\sigma_{2L})} - \frac{a_{1L} K_0(\sigma_{1L})}{(a_{2L} - a_{1L})\kappa\sigma_{1L} K_1(\sigma_{1L})}$$

$$- \frac{(a_{2L} - a_{1L}) K_0(\sigma_{1L}) K_0(\sigma_{2L})}{b_L} \qquad (B.31)$$

Equation (B.31) estimates the pseudoskin in a two-layered, partially-penetrated reservoir subject to a gas-cap or a bottom-water drive. Equation (B.31) is also applicable for a multi-layered reservoir having any arbitrary number of layers consisting the open interval and any arbitrary location of the open interval, provided κ and λ_A are calculated by adding the individual layer mobility-thickness ratio of the open interval and by adding the lower and the upper boundary crossflow parameters of the open interval, respectively. Parameter, λ_C, is the crossflow parameter between the reservoir and the gas cap or the bottom-water zone. Irrespective of the number of layers in the reservoir, only three parameters (κ, λ_A, λ_C) are required to estimate the pseudoskin factor.

Appendix C
Late Time Approximation of σ_2^2

From Appendix A,

$$\sigma_2^2 = \frac{1}{2} \left[\left(\frac{\lambda_A}{1 - \kappa} + \frac{\lambda_A}{\kappa} + \left(\frac{1 - \omega}{1 - \kappa} + \frac{\omega}{\kappa} \right) l \right) - \Delta \right] \qquad (C.1)$$

and,

$$\lim_{t \to \infty} \Delta = \lim_{t \to \infty} \left[\left(\frac{(1 - \omega)l + \lambda_A}{1 - \kappa} - \frac{\omega l + \lambda_A}{\kappa} \right)^2 + \frac{4\lambda_A^2}{\kappa(1 - \kappa)} \right]^{\frac{1}{2}} \qquad (C.2)$$

Equation (C.2) can be written as

$$\lim_{t \to \infty} \Delta$$

$$= \lim_{t \to \infty} \left[\left(\frac{\lambda_A}{1 - \kappa} - \frac{\lambda_A}{\kappa} \right)^2 \left\{ 1 + 2 \frac{\frac{1 - \omega}{1 - \kappa} - \frac{\omega}{\kappa}}{\frac{\lambda_A}{1 - \kappa} - \frac{\lambda_A}{\kappa}} l + \left(\frac{\frac{1 - \omega}{1 - \kappa} - \frac{\omega}{\kappa}}{\frac{\lambda_A}{1 - \kappa} - \frac{\lambda_A}{\kappa}} \right)^2 l^2 \right\} + \frac{4\lambda_A^2}{\kappa(1 - \kappa)} \right]^{\frac{1}{2}}$$

$$(C.3)$$

Neglecting the term containing l^2 and rearranging equation (C.3) yields:

$$\lim_{t \to \infty} \Delta = \lim_{t \to \infty} \left(\frac{\lambda_A}{1 - \kappa} + \frac{\lambda_A}{\kappa} \right) \left[1 + \frac{\left(\frac{1 - \omega}{1 - \kappa} - \frac{\omega}{\kappa} \right)\left(\frac{\lambda_A}{1 - \kappa} - \frac{\lambda_A}{\kappa} \right)}{\left(\frac{\lambda_A}{1 - \kappa} + \frac{\lambda_A}{\kappa} \right)^2} 2l \right]^{\frac{1}{2}} \qquad (C.4)$$

Expanding equation (C.4) using the binomial theorem yields:

$$\lim_{t \to \infty} \left(\frac{\lambda_A}{1 - \kappa} + \frac{\lambda_A}{\kappa} \right) \left[1 + \frac{\left(\frac{1 - \omega}{1 - \kappa} - \frac{\omega}{\kappa} \right)\left(\frac{\lambda_A}{1 - \kappa} - \frac{\lambda_A}{\kappa} \right)}{\left(\frac{\lambda_A}{1 - \kappa} + \frac{\lambda_A}{\kappa} \right)^2} l + (\cdots)l^2 + (\cdots)l^3 \cdots \right]$$

$$(C.5)$$

Neglecting the higher order terms in t in equation (C.5) yields

$$A \left[\frac{\lambda_A}{t} + \frac{\lambda_A}{\kappa} + \left(\frac{1}{t} - \frac{\omega}{\kappa} - \frac{\omega}{\kappa} \right)(2\kappa - 1) \right] \qquad (C.6)$$

At late time, the reservoir behaves like a fully-penetrated, equivalent homogeneous system with a pseudoskin. Thus, at late time, $\kappa = \omega = 1$, and equation (C.6) becomes

$$A \left[\frac{\lambda_A}{t} + \frac{\lambda_A}{\kappa} + \left(\frac{1}{t} - \frac{\omega}{\kappa} - \frac{\omega}{\kappa} \right) t \right] \qquad (C.7)$$

Now, equation (C.1) becomes

$$\sigma_i' = \frac{\omega_i}{\kappa} t - t \qquad (C.8)$$
