University of Alberta

Abstract

Aiming to pursue studying enhanced oil recovery processes with an *ex-situ* produced emulsion as flooding agent, an improved core flooding experimental system was designed, constructed and commissioned. The developed system allows the use of not only emulsion, but also other flooding agents, including surfactants and polymers. The components of the experimental apparatus, including a biaxial core holder, a two-dimensional core holder, and effluent analysis system were re-designed to improve flow distribution, the packing process and reduce post-experimental analysis. To secure the conditions for experiments, custom software for system control and monitoring, and logging of all system parameters was developed. The limits and ways to improve the developed system were identified. An unconsolidated silica sand pack was chosen to represent the porous media on all experimental tests.

The initial experimental results with emulsion flooding explored the capability of the new apparatus and confirmed the efficiency of emulsion as a flooding agent during direct emulsion flooding or water flooding followed by emulsion flooding. Oil recovery was enhanced by 15 % of original oil in place in case of emulsion flooding followed by water flooding. From experimental results, it was hypothesised that emulsion moves through the sand pack with a piston-like flood front and

that an alternative technique to improve efficiency of emulsion flooding can be developed. This technique should also allow to reduce amount of emulsion used per percentage of oil recovery.

A flooding technique was proposed and established to improve the efficiency of emulsion flooding in reservoirs and reduce costs of flooding. The technique was named water-alternate-emulsion (WAE). Three different flooding ratios have been tested using a biaxial core holder. The experimental analysis showed that for 5:1 WAE flooding, the ultimate oil recovery could be up to 82 % at 0.3 PV of total emulsion injection. The analysis of physical properties of the effluent, such as viscosity, density and surface tension, revealed that alternate flooding does not affect on physical properties of liquids involved in flooding. Effluent analysis and examination of extracted sand packs after experiment completion reported that emulsion undergoes separation inside porous media during alternative flooding and moves with a post-like flood front during continuous injection. As a results, it blocks high-permeability zones and surfactant present in emulsion interacts with *in-situ* liquids. Pressure measurements identified that emulsion stimulates sand packs with internal pressure rise prior to water flooding.

Experimental flow visualization and pressure mapping analysis of emulsion flooding with horizontal and vertical wells was performed to provide additional understanding of internal processes. It was shown experimentally, that efficiency of emulsion flooding strongly depends on well configuration. The horizontal injection - horizontal production (HI-HP) configuration for injection and production well, based on data from effluent and image analysis, was found to be the most efficient for emulsion flooding. The flood front movement during emulsion flood-

ing process was estimated using code developed for image analysis. Experimental data presented in this research project suggests that stable emulsion flood front and stable pressure rise guarantees enhanced oil recovery during emulsion injection. In addition, oil drops present in an emulsion were observed with a microscope and it was hypothesised that emulsion has bimodal structure. Later it was confirmed with the membrane-base particle analysers.

As a results of this research study, emulsion flooding process was investigated experimentally. It was shown that emulsions can be used effectively to recover oil using different flooding techniques. Oil-in-water emulsion blocked highly permeable zones and redirecting following water flooding. Experimental results from multi-dimensional studies suggested that it is important to consider well configuration and physical parameters, such as pressure data, in a field trials. Collected results for the drop size distribution now can be considered in a future fundamental works for emulsion flooding process.

Preface

This thesis is original work by Aleksey Baldygin. Chapter 3 and 4 of this thesis have been published as A. Baldygin, D. S. Nobes, and S. K. Mitra, "A new laboratory core flooding experimental system", *Industrial & Engineering Chemistry Research*, DOI: 10.1021/ie501866e, 2014 and as A. Baldygin, D. S. Nobes, and S. K. Mitra, "Water-Alternate-Emulsion (WAE): A new technique for enhanced oil recovery",*Journal of Petroleum Science and Engineering*, DOI:10.1016/j.petrol.2014.06.021, 2014, respectively. Chapter 5 has been prepared for submissions as publication as A. Baldygin, D. S. Nobes, and S. K. Mitra, "Experimental pressure mapping and flow visualization of emulsion flooding with horizontal and vertical wells", *Journal of Petroleum Science and Engineering*, 2014. Appendix A-2 has been published as part of the conference paper as A. Baldygin, D. S. Nobes, and S. K. Mitra, "Oil recovery from porous media using emulsion", *Proceedings of the ASME 2014 International Mechanical Engineering Congress & Exposition*, 2014. The initial concept of the experimental system has been presented during the biennial CSME International Congress: Symposium on Advanced Energy Systems (CSME'12 - Symposium on AES) as A. Baldygin, D. S. Nobes, and S. K. Mitra, "Novel Technique for Core Flooding Experiments", 2012. The software with graphical user interface was developed myself and used to assist experiments in the current re-

search study. The design of core holders with appropriate drawing package was also developed myself. In addition, I was responsible for data collection and analysis as well as for manuscript preparation. Dr. David S. Nobes and Dr. Sushanta K. Mitra were the supervisory authors and contributed to manuscript edits. Emulsion used in experiments was provided by Quadrise Canada Inc..

Acknowledgements

I would like to thank my supervisor, Dr. David S. Nobes for believing in me in 2011 and giving me an opportunity to be part of PhD program at the Mechanical Engineering department. I am also thankful for the productive discussions that we had along my program. He gave me a passion to have attention on small details and provided continuous support during my program. I would also like to thank my co-supervisor, Dr. Sushanta K. Mitra for the time that he spend with me over weekends and helped me to improve my writing and thinking skills. His guidance and support over the last three years provided me an opportunity to do up-to-date level research.

My thanks and appreciation to Roger Marchand, Andrew Campbell, Rick Bubenko and other shop technicians who have provided me technical and engineering support whenever I needed it. I would also thank Rick Conrad for his expertise when I was setting up experimental set-up for the first time.

I would also like to thank my friends and colleagues: Anil Stephen, Prashant Waghmare, Orest Shardt, Lalit Pant, Arnab Guha, Sheng Tian, Amrit Bhinder, Reza Sabbagh and many others with whom I spent last three years. They have supported my research and my recreation time whenever I needed.

In addition, I would like to acknowledge Dr. Patrick Brunelle from Quadrise Canada Inc. for his valuable inputs and providing emulsion for experiments. Financial assistance from NSERC CRD (Grant No. CRDPJ 399500-10) is acknowledged here.

A sincere thank you to my wife Alexandra Komrakova and my little daughter Olivia Baldygin for their support, love and patience. Finally, a greatest thank you to my parents for providing me support during my whole live and believing that one day, I could be a PhD.

Chapter 1

Introduction

1.1 Motivation

For at least the next decade, fossil fuels, such as gas and oil will remain the dominant energy source (Dresselhaus and Thomas, 2001; Omrpublic.iea.org, 2014). Gas and oil are typically trapped inside the naturally formed pores in a geological formation (referred to porous media). The process of oil recovery can be divided into three stages. The first stage is called primary recovery and the efficiency of oil recovery at this stage is controlled by the geological formation. The primary stage typically allows recovery of 5-15 % of original oil in place (OOIP) (Tzimas et al., 2005). The second stage of oil recovery which is usually a form of water flooding, provides an additional 30-35 % (Green and Willhite, 1998). The final stage is tertiary recovery which has potential for high oil recovery ($\approx$ 80 - 90 %). The last two stages require the application of pressure to the system.

Different research groups are working on the improvement of current tertiary methods that include thermal recovery, surfactant/polymer flooding, emulsion flooding, and CO_2 injection (Liu et al., 2007; Asghari and Nakutnyy, 2008; Shen et al., 2009; Alvarado and Manrique, 2010; Hart, 2013; Hein et al., 2013). These methods

allowed to achieve record levels of oil production (92 million barrels/day (mb/d)) (Omrpublic.iea.org, 2014). Emulsion flooding is one of the improved oil recovery (IOR) and enhanced oil recovery (EOR) techniques used for oil recovery. Emulsion (oil-in-water or water-in-oil) produced *ex-situ* as a fuel source for industrial and commercial, utility, marine engines or boilers (www.altpetrol.com, 2014) can be used either during the secondary stage coupled with water flooding or as independent flooding during the tertiary stage. Process of residual oil emulsification has established itself as an efficient method for enhanced oil recovery (Speight, 2006). It can be used for recovering heavy crude oil with gravity from 5° to 20° API (Speight, 2006).

Heavy oil reserves in Canada exceed a trillion barrels (Adams, 1982) and it was estimated that only 8 - 9 % of the OOIP were recoverable (Adams, 1982) with available technologies on the market in 1982. Improved technologies allowed increased production up to 15 - 20% (Hein et al., 2013; Larter and Head, 2014). Steam-assisted gravity drainage (SAGD) and cyclic steam stimulation are used to recover heavy oil from thin reservoirs (Hart, 2013; Arhuoma et al., 2009). However, most heavy oil is available in the northern territories of Canada. In the case of shallow oil, thermal recovery can damage the environment (Qiu and Mamora, 2010). There is a possibility for high-pressure steam escaping to the surface with resulted damage to the ambient environment. In opposite, emulsion flooding technologies can already be used in proximity to the permafrost without possibility damaging a surface with a steam (Qiu and Mamora, 2010). However, there is a potential effect on nature from possible spills and usage of fresh water during oil production. These effects must be considered before attempting field trials.

Emulsions are mixtures of oil and water which can be obtained through the application of energy through mixing or friction (Schramm, 2006, p. 138). The essential parameters of emulsions are its type, *i.e.* water-in-oil (W/O) or oil-in-water (O/W), droplet size distribution (DSD), rheology (Newtonian or non-Newtonian fluid), and apparent density (ρ). It is of great importance to obtain these parameters during the production of the emulsion and keep them constant during its lifetime since they influence the efficiency of emulsion flooding (Wasan et al., 1978). The stability of the emulsion can be controlled by surfactant or by variation of DSD (Schramm, 2006, p. 138-139). Emulsion, which was used in this study, is a product of Quadrise Canada Inc. under brand name E^2EOR. Their technology allows to tailor parameters for any particular application, such as viscosity, hydrocarbon content, the drop size distribution, chemistry and stability.

Emulsions can be used to decrease mobility of the injected fluids (extrusive liquid) or to block highly permeably zones (McAuliffe, 1973; Mandal et al., 2010a). Core flooding experiments can be used to provide information on the emulsion flooding process (Samanta et al., 2012; Moradi et al., 2014). The surfactant added to the emulsion reduces the interfacial tension of the produced fluid when it interacts within the porous media with oil (Kumar et al., 2010). Oil will be recovered first from small pores in water-wet reservoirs where these small pores are connected to each other and will create a highly permeable zone through which water can flow (Schramm, 2006, p. 268). This can be compared to the emulsion produced from crude oil which consists of the high viscous drops. These drops require higher critical pressure to squeeze and move through and out from the pore head. With known size of the pores, a designed emulsion can be produced with known drop

size distribution which is sized to block zones of high permeability and to resist the pressure of the injected fluid. Hence, injected liquids are forced to flow through the low permeable zone and recover additional oil.

Decker and Flock (1988) carried out experiments and showed that emulsions are efficient in emulsion blockage mechanism. Also, emulsions have viscosities higher compared to water and allow higher capillary numbers to be generated. Higher capillary numbers describe the presence of higher viscous forces in pores that allow mobilization of the oil drops in the porous media (Moradi et al., 2014). Mandal et al. (2010a) concluded that emulsion flooding is more efficient as a displace fluid compared to traditional water flooding because of improved mobility ratio as a result of increase in viscosity of the displacing fluid (emulsion). However, Cobos et al. (2009) pointed out that understanding of this process requires further pore-scale studies.

To move from pore-scale to macro-scale to investigate and understand how the emulsion phase interacts within the porous structures of the reservoir and the efficiency of this process, laboratory core flooding experiments are required. Laboratory core flooding experiments include investigation of reservoir parameters. Every newly introduced method for oil recovery requires testing experiments with different flow patterns, well configurations and field parameters. For instance, one dimensional (1D) core holders allow the study of linear flow patterns and obtain initial parameters, such as porosity, permeability, efficiency for oil recovery and set effective flow rates and can provide initial understanding for oil recovery mechanism during emulsion flooding (Hadia et al., 2007a). Mechanisms involved in emulsion flooding, the increase of the mobility of injected fluids or the blockage

of highly permeably zones, can be investigated with 1D core flooding experiments. Based on parameters obtained during 1D studies, such as pressure drop, the amount of oil recovered after induction emulsion into the system, it would be possible to investigate the mechanism of the emulsion for EOR.

Understanding of emulsion flooding process at the tertiary stage, its interaction with oil saturated porous media in multi-dimensional experimental studies has also been considered as another part of the research. A two dimensional (2D) core holder allow investigation of how the front of the flooding agent spreads through the porous media. A 2D core holder represents a sectional cut of a real reservoir. It is thin enough to assume that the flow is distributed in two directions only and there is no influence (flow) in the third direction. A 2D core holder highlights the effects of well configurations (Santosh et al., 2007, 2008) and strata (Chaudhari et al., 2011a) providing data on emulsion distribution in two direction and its interaction with the porous media. Based on obtained data, the type of emulsion can be specified. There is a significant number of studies showing how to increase oil recovery during water flooding by configuring wells in appropriate orientations (Chaudhari et al., 2011a; Bagci and Gumrah, 1992; Hadia et al., 2007b). Consequently, it is essential to study the dependency of wells configuration during emulsion flooding to determine their effect on the efficiency of recovery. Taking pictures from one side of the 2D visualization cell provide a map for oil, water and emulsion saturations and velocity of emulsion flood front. Another side of the core holder can be equipped with pressure sensors to provide pressure mapping analysis for the *in-situ* processes.

Core flooding experiments with emulsion flooding experiments have been performed by different research groups (Qiu and Mamora, 2010; D'Elia-S and Ferrer-

G, 1973; Walstra, 1993; Mandal et al., 2010b; Guillen et al., 2012; Kumar et al., 2012). A dominant part of these research studies have focused on ultimate oil recovery with an emulsion formed *in-situ* (D'Elia-S and Ferrer-G, 1973; Walstra, 1993; Kumar et al., 2012). Flooding agents (e.g., surfactant (Samanta et al., 2012; Kumar et al., 2012; Bryan and Kantzas, 2009; Krumrine and J.S., 1983)) present in injected fluids emulsify trapped residual oil and form *in-situ* emulsion. Only a limited number of studies are available for *ex-situ* produced emulsion (Moradi et al., 2014; Mandal et al., 2010b; Guillen et al., 2012; Qiu, 2010; Nogueira et al., 2013). Experimental setups for both types of emulsion followed a traditional design for core flooding studies.

During emulsion flooding experiments, multi-phase flows are present in the system and the experimental setup design has a significant influence from this. The amounts of injected and produced liquids have to be analyzed, as well as the pressure along the system has to be recorded. Emulsion has physical properties close to oil and water and conventional techniques for real-time effluent analysis, such as segregation method (Qiu and Mamora, 2010), use of visual cells or use of an ultra-sound separators (Boye et al., 2008) are not feasible. This leads to complex post-experimental analysis, such as Dean-Stark analysis, mass balance calculations with liquid-liquid separation to obtain amount for each phase collected from the system. Qiu and Mamora (2010) recently used these calculations and showed that around an additional 20 % of OOIP was recovered during emulsion flooding. Similar results were obtained by Mandal et al. (2010a). They, also, showed that additional 20 % of OOIP was recovered during emulsion flooding. The obtained numbers highlight the potential for emulsion flooding; however, the slow and com-

plicated post-experimental analysis slows down the progress of these types of studies. Thus, it is necessary to develop a system with on-line volume measurements of each phase.

During the past twenty years, control and measurement technologies have stepped forward and brought a wide range of new devices to the market. Their usage allows the development of a system to provide an extended range of measured parameters and improve experimental control. This allows the development of a system for core flooding studies. In order to avoid routine post-experimental procedures it may be possible to develop analysis equipment for the downstream effluent. This equipment would analyze the flow and coupled with data from upstream and downstream mass flow meters gives the values for recent drainage. Online information would potentially lead to the exploration of new regimes of three-phase relative permeability curves relevant to a particular EOR technique. Developing experimental setup to study enhance oil recovery considers as a part of the study, to provide facility for understanding emulsions' potential in oil recovery process.

1.2 Thesis objective

The main objective of this study is to contribute to the global understanding of emulsion flooding by studying the process of enhance oil recovery with emulsion as flooding agent. The aim is to investigate the technical feasibility of using emulsion as recovery agent and to develop efficient method for using in a field. Present study does not include an economical analysis of the emulsion flooding process and mainly focuses on efficiency. It is worth emphasizing that the results of this research can be used to develop theory for emulsion flooding using *ex-situ* produced

emulsion and to guide field engineers during field trials.

The reservoir is a region of porous medium with pores and capillaries. In order to efficiency recover the oil, it is necessary to understand what traps oil within the reservoir. Conditions of the reservoir after and during the first two recovery stages impact the parameters of tertiary oil stage. It is important to know these conditions and the physics behind them. The second chapter of this thesis focuses on understanding the conditions and the physics of emulsion flooding in porous media and provides required background.

A literature review of existing experimental systems and a review of current technologies is described in details in Chapter 3. Based on obtained results, a system has been designed, procured, constructed, commissioned, and initial experiments with emulsion flooding were carried out, details are available in Chapter 3. Also, as a result of performing routine experiments, the method for effluent analysis based on the data from a mass flow meter has been developed and tested. In addition, the traditional design of the biaxial core holder has been modified to reduce internal dead volumes during flooding and improve flow stability.

A hypothesis of alternative flooding technique efficiency is proposed and tested and compared to the the previously accomplished traditional floodings in Chapter 3. As a result of these experiments, water-alternate-emulsion (WAE) flooding technique has been established to enhance oil recovery. The optimal ratio for the emulsion and water slug during flooding has been outlined in Chapter 4. This chapter also outlines the internal interactions involved in emulsion flooding. The results and analysis from Chapter 3 and 4 have been published as two journal papers (Baldygin et al., 2014a,b). The initial concept of the experimental system

has been presented during conference in 2012 (Baldygin et al., 2012). Results from Chapter 4 has been also published as conference paper (Baldygin et al., 2014c).

The proposed hypothesis that efficiency of emulsion flooding from well configurations was studied using 2D core holder and resulted analysis presented in Chapter 5. It includes flood front analysis, the influence of well configurations, and pressure mapping during emulsion flooding for perforation of wells oriented either vertically or horizontally. For instance, vertical injection - vertical production (VI - VP), vertical injection - horizontal production (VI - HP), horizontal injection - horizontal production (HI - HP) well configuration are tested. The 2D core holder allowed flow visualization through a single transparent side of the holder and to collect pressure data using pressure ports on another side for future pressure mapping. Using inspectional analysis, results are interpreted for reservoirs, so that industry can estimate costs and prognoses effects from emulsion flooding on oil recovery.

Chapter 6 summaries the work that has been done in current research project and also provides recommendations for future studies that can be undertaken in a field of emulsion flooding.

Additional details about the 1D and 2D core holder design procedure are given in Appendix A-1. An error analysis for equipment involved during experiments and post-experimental procedures is included in Appendix A-2. A comparison between complete and incomplete 2D core flooding experiment is shown in Appendix A-3. Source codes which were used for image analysis and pressure mapping in Chapter 5 are given in Appendix A-4 and Appendix A-5, respectively. A complete set of drawings for core holders and software flow chart with source code are presented in Appendix A-6, Appendix A-7 and Appendix A-8, respectively.

Chapter 2

Oil recovery background

The physics of fluid flow through porous media has been studied for a long period of time. Porosity, permeability, relative permeability, capillary pressure, fluid saturations and mobility ratios need to be understood, as these parameters represent relevant rock properties (Darcy, 1856; Athy, 1930; Towler, 2002). Also, it is important to know the nature of oil and water content within the reservoir. In order to be consistent in the core flooding experiments with emulsions, understanding of physical properties and the type of emulsion in use should be considered. Parameters that influence the production of emulsions with distinct functional properties and experimental procedures that effect on results are discussed below.

2.1 Porosity of Sand Pack

Porosity (ϕ) of sand pack depends on a packing density. Total bulk volume (V) of the pack is a sum of grain volume (V_s) and pore volume (V_p). Pore volume indicates the amount of void space of the rock. Porosity can then be defined as (Athy, 1930):

$$\phi = \frac{V - V_s}{V} = \frac{V_p}{V} \tag{2.1}$$

Porosity plays an important role in core flooding experiments, as OOIP occupies only the pore volume. Also, it is important to indicate effective pore volume (V_{eff}), as void space (V_v) that is connected to each other forming flow channels (Towler, 2002; Edward W. Washburn, 1921). In general for experimental work it is important to be consistent in packing of the core by using sand with the same grain density (ρ_g) and grain size distribution from experiment to experiment in order to compare results. Once it is proved that output results are valid; sand can be replaced for future studies.

2.2 Permeability of Sand Pack

In 1859, Darcy performed experiments utilizing sand packs with different orientations (Dake, 1998, p. 100),(Darcy, 1856). The pressure loss was measured across the pack with known flow rate for the given fluid. Consider a general case when sand pack can be oriented either vertical or horizontal and pressure at the inlet and outlet is measured. Taking into account that sand pack can be offset from a reference ground level the following equations for hydraulic head can be written:

$$H_{in} = z_{in} + \frac{p_{in}}{\rho g} \tag{2.2}$$

$$H_{out} = z_{out} + \frac{p_{out}}{\rho g} \tag{2.3}$$

where H_{in} and H_{out} are hydraulic head at the inlet and outlet, respectively; z_{in} and z_{out} are elevations for porous media at the inlet and outlet, respectively; p_{in} and p_{out} water pressure measured by pressure sensors at the inlet and outlet, respectively.

Taking geometry and measured flow rates, Darcys equation is defined as:

$$Q = -K\frac{(H_2 - H_1)}{\Delta l} \cdot A \tag{2.4}$$

where K is the hydraulic conductivity, which depends on fluid and porous media, Δl is the length of porous media, A is the cross section of porous media and Q is discharge from the porous media. Dividing left and right parts of the equation by cross section area, the Darcy flux (q) can be defined as:

$$q = -K\frac{dH}{dl} \tag{2.5}$$

Hydraulic conductivity can differ for different sand packs. Consider a homogeneous porous media, where the hydraulic conductivity is constant throughout the sand pack such that $K(x, y, z) = C$. Otherwise, it is required to introduce a matrix for hydraulic conductivity for three axis, as:

$$\mathbf{K} = \begin{pmatrix} K_{xx} & K_{xy} & K_{xz} \\ K_{yx} & K_{yy} & K_{yz} \\ K_{zx} & K_{zy} & K_{zz} \end{pmatrix} \tag{2.6}$$

Consequently, for three dimensional porous media equation for Darcy flux in general form would be:

$$\bar{q} = -\begin{pmatrix} K_{xx} & K_{xy} & K_{xz} \\ K_{yx} & K_{yy} & K_{yz} \\ K_{zx} & K_{zy} & K_{zz} \end{pmatrix} \begin{pmatrix} \frac{\delta H}{\delta x} \\ \frac{\delta H}{\delta y} \\ \frac{\delta H}{\delta z} \end{pmatrix} \tag{2.7}$$

In the current studies, two different sand packs are used. A 1D horizontal pack with the assumption that there is no effect from gravity forces and a 2D pack with

the absence of penetration in the third direction. Also, the following assumptions for Darcys law are made:

- the media is homogeneous
- the fluid is incompressible
- the flow is single phase
- the flow is happening in isotropic media

Darcys law can also be written for 1D in x-direction in the following way:

$$q = -\mathbf{K}\frac{dH}{dx} \tag{2.8}$$

or

$$q = -\frac{kA}{\mu}\frac{dp}{dx} \tag{2.9}$$

where k is absolute permeability for the porous media. For 2D, the third components for z-direction vanishes:

$$\bar{q} = -\mathbf{K}\begin{pmatrix} \frac{dH}{dx} \\ \\ \frac{dH}{dy} \end{pmatrix} \tag{2.10}$$

The equations written above are valid for single phase flow only. However, it is possible to apply Darcys law to multiphase flow. To do this it is necessary to introduce a relative (k_r), effective (k_e) and phase permeabilities (k) (absolute) (Towler, 2002; Buckley and Leverett, 1941). Absolute permeability should be measured on samples which were saturated with a single phase using Darcys law for single phase which is defind as:

$$k_a = -\frac{q\mu}{A}\frac{dx}{dp} \tag{2.11}$$

where μ is the dynamic viscosity of the fluid. For instance, if the water occupies 100% of the pore volume, the measure permeability - k_{wa} is the absolute permeability to water. Same can be undertaken for other fluids, such as gas - k_{ga}, oil - k_{oa} or emulsion - k_{ea}.

An emulsion flooding experiment begins with a water saturated pack. Consequently, absolute permeability needs to be measured for pure water flooding through a water saturated sample. Once a new fluid is introduced to the system, effective permeabilities for each phase k_{we}, k_{oe}, k_{ee} would be designated. The values are going to be less than their absolute. The ratio of the effective permeability to the absolute permeability gives relative permeability, as follows:

$$k_{or} = \frac{k_{oe}}{k_{wa}}, \;\; k_{er} = \frac{k_{ee}}{k_{wa}}, \;\; \text{and} \;\; k_{wr} = \frac{k_{we}}{k_{wa}} \tag{2.12}$$

For instance for two-phase oil/water flow the relative permeability can be written as (Buckley and Leverett, 1941):

$$k_{or} = \frac{\left[\frac{q_o\mu_o}{A}\frac{dx}{dp}\right]_{S_w}}{\left[\frac{q_o\mu_o}{A}\frac{dx}{dp}\right]_{S_w=0}} = \frac{(q_o)_{S_w}}{(q_o)_{S_w=0}} \tag{2.13}$$

The error in values of relative permeabilities depends on selected absolute permeability. When three phase (e.g. water, oil and emulsion) flooding takes place, three phase relative permeability is in use. Direct experimental investigation of three phase relative permeability properties requires measuring the fluid saturation distribution along the length of the core. Advanced technologies are required to un-

dertake this. Instead of completing three phase relative permeability experiments, two sets of two phase experiments can be carried out (Stone, 1970, 1973). Two sets refer to the use of oil-water and oil-gas systems for oil, water and gas three-phase flooding. For emulsion flooding, it is an oil-water and oil-emulsion set. Based on obtained relative permeabilities, oil to water, k_{row}, in water system and oil to emulsion, k_{roe}, in emulsion system, oil relative permeability is determined for three-phase system using rough prediction as:

$$k_{ro} = k_{row} \cdot k_{roe} \tag{2.14}$$

In the future, in case of successful development of effluent analysis equipment, the simultaneous three phase flow takes place and using the obtained numbers for saturations, ternary diagrams (Corey et al., 1956) can be plotted. Wyllies correlations (Wyllie, 1961) can be taken into account to obtain an accurate results. Wyllie proposed equations for relative permeabilities in case of wetting and non wetting phases (Wyllie, 1961). Equations for water-wet system in case of cemented sandstone, vugular rock, or oolitic limestone can be possibly used in emulsion flooding considering an emulsion as a gas phase in equations.

2.3 Saturation

Fluid saturation is a ratio of the fluid volume that occupies the pore volume by a particular phase (water, oil or emulsion). Water saturation, S_w, is defined as:

$$S_w = \frac{V_w}{V_p} \tag{2.15}$$

where V_w is the pore volume occupied with water. This is also an important parameter that effects EOR performance. The number of saturations parameters present in the systems depends on the number of fluids present in the porous media. Thus, saturation of water, oil and emulsions take place in emulsion flooding named as S_w , S_o, S_e, respectively for water, oil and emulsion. The sum of the three equals to one such that:

$$S_w + S_o + S_e = \frac{V_w}{V_p} + \frac{V_o}{V_p} + \frac{V_e}{V_p} = 1 \tag{2.16}$$

During core flooding experiments, there are also several other important parameters, such as irreducible water saturation and saturation for immobile oil, to be determined as: S_{wi}, S_{or}. Irreducible water saturation is obtained during initial oil saturation process. It shows the amount of water that cannot be reduced further by displacing water with oil, displacing process. While, immobile oil shows the amount of oil that cannot be recovered from porous media at the end of oil recovery stages.

2.4 The physical Process of Oil Recovery

In order to understand the recovery process and why applied pressure is needed, consider single drop behavior in a pore as shown in Figure 2.1. The capillary force keeps oil inside the pores during secondary recovery. During secondary and tertiary recovery injected fluids are intended to overcome capillary pressure which is defined as using Young-Laplace equation:

$$P_c = \frac{2\gamma \cos\Theta}{r_{pore}} \tag{2.17}$$

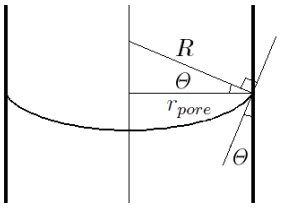

Figure 2.1: A schematic of the concept of a single pore with trapped oil (contact angle is less than 90°).

where γ - interfacial tension; Θ - contact angle; r_{pore} - is the pore radius, as defined in Figure 2.1

In the case of two pores located above the same free water level, capillary pressure, contact angle and interfacial tension will be the same. This means that for water-wet pores the amount of oil in percentage to pore size relation will be greater for large pores than for small pores (Schramm, 2006). Consequently, oil will tend to recover from small pores first for water-wet (Schramm, 2006, p. 269). The opposite situation is for oil-wet pores. Oil will tend to recover from large pores and the amount of oil is greater in small pores. A schematic of a single oil drop which is sitting on a pore is shown in Figure 2.2. In order to squeeze and move the drop through the pore (in other words recover the drop), pressure difference across the drop should be applied. (Nazzal and Wiesner, 1996) termed it as the critical pressure (P_{crit}) at which drop starts moving. From the Young-Laplace equation (capillary force) (Green and Willhite, 1998, p. 18), (Nazzal and Wiesner, 1996; Leverett, 1940), they derived:

$$P_{crit} = \left(\frac{2\gamma_{o/w}}{r^*}\right) - \left(\frac{2\gamma_{o/w}}{R^*}\right) \tag{2.18}$$

where r^* and R^* are radii shown in Figure 2.2 and $\gamma_{o/w}$ is the interfacial tension between two fluids, oil and water. Radius, r^* can be found from:

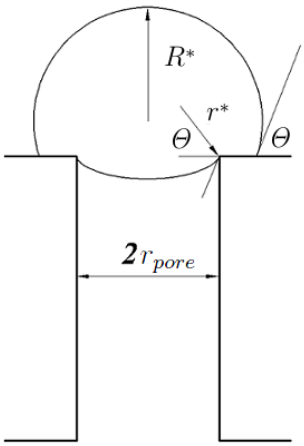

Figure 2.2: Oil drop is sitting on the throat of pore (following Nazzal et al. (Nazzal and Wiesner, 1996)).

$$r^* = r_{pore}/\cos\Theta \tag{2.19}$$

An advantage of using emulsion as an extrusive liquid is that it contains surfactants which reduce the interfacial tension between the two fluids. Thus, the critical pressure required for oil recovery is reduced and the amount of recovered oil increases.

Another important parameter for oil recovery is the capillary number (Washburn, 1921) which describes the ratio of the viscous and interfacial forces in the form:

$$N_c = \frac{\eta v}{\gamma \phi} \tag{2.20}$$

where η is viscosity of displacing fluid; v is the velocity of the displacing fluid; ϕ is the porosity; and γ is the interfacial tension. At the beginning of a water flooding process, the capillary number can be around 10^{-6} (Schramm, 2006; Moore and Slobod, 2013). When residual oil mobilization begins the capillary number

would be around 10^{-5}. Typical chemical flooding, *e.g.* presence of surfactant in flood front, regime would lie into the range from 10^{-5} to 10^{-3}. The end of oil recovery brings the capillary number to range from 10^{-3} to 10^{-2}. Consequently the capillary number changes as the remaining percentage of oil inside reservoir is lowered (Schramm, 2006; Foulser et al., 1991). Romero et al. (2011) developed a network model of flow of oil-water emulsion through porous media. It was shown that during the process of emulsion flooding capillary number ranges from 10^{-6} to 10^{-2}.

The process of emulsion flow through sand is similar to the process of oil recovery. Emulsion is a mixture of droplets of one fluid in another. Similar physics can be applied for an emulsion with assumption that emulsion is a single phase fluid.

2.5 Mobility

Mobility can be derived as a ratio of relative permeability of a fluid to viscosity of the same fluid. Using the term mobility, defined as (Homsy, 1987):

$$M_{ro} \text{ for oil phase} = \frac{k_{ro}}{\mu_o} \tag{2.21}$$

$$M_{rw} \text{ for water phase} = \frac{k_{rw}}{\mu_w} \tag{2.22}$$

$$M_{re} \text{ for emulsion phase} = \frac{k_{re}}{\mu_e} \tag{2.23}$$

The mobility ratio is another important parameter defined as a ratio of oil mobility to water mobility for water-oil system:

$$\lambda = \frac{M_{ro}}{M_{rw}} \tag{2.24}$$

or as a ratio of oil mobility to emulsion mobility for emulsion-oil system:

$$\lambda = \frac{M_{ro}}{M_{re}} \tag{2.25}$$

If it is less than or equal to one, the process of oil recovery is characterized as "stable displacement" (Homsy, 1987; Schowalter, 1965). For mobility ratio greater than one, the process of oil recovery suffers from unstable displacement and other processes such as fingering can occur (Homsy, 1987; Schowalter, 1965). Mobility control is a key component for effectiveness of oil recovery. French et al. (1986) demonstrated that temperature and water dilution resistant emulsion with appropriate size can be formed and used for blocking mechanism. It allows to modify permeability of the porous media and improved mobility control. Hence, the mobility of emulsion can have a wide range and be matched for a given sand pack (Speight, 2006).

2.6 The Composition of the Fluids

The ultimate goal for core flooding experiments is scaling to the real reservoir. Results obtained in experiments should correlate to oil recovery in a field. Thus, it is important to take into account for the composition of oil and water and other important species content.

Fluid composition also affects oil recovery and emulsion stability. The water present in sandstone reservoirs has major cations and anions, such as Na+ and Cl- (Schmidt, 1973). Their content can vary with a depth with a rate of 30,000 mg/l Na+ per 1,000 ft and 45,000 mg/l Cl- per 1,000 ft down to 3,000 ft (Schmidt, 1973). Bagci et al. (2001a; 2001b) reported the results of brine flooding tests using a core flooding system and showed that brine composition affects oil recovery. The

increased amount of salt reduces the amount of recovered oil from reservoir oil. Higher pH can be achieved with lower salinity for brine composition. The pH level was stabilized at 7.2, 7.4 and 6.8 for 2 wt %, 5 wt % and 10 wt % $CaCl_2$, respectively after 1.0 pore volume of injection (Bagci et al., 2001a). Yildiz et al. (2013) identified that 16 % difference in an oil production can be as a result of using different brine compositions, e.g. Brine 1 (4 % NaCl + 0.5 % $CaCl_2$) is more efficient than Brine 2 (2 % $CaCl_2$). Also, in consolidated/unconsolidated limestone samples there may be a reduction in permeability when the critical salt concentration in brine is achieved (Bagci et al., 2001a).

The stability of emulsion also depends on fluid composition. Moradi et al. (2011) studied the stability of water-in-oil emulsion prepared with a crude oil and a synthetic reservoir water. It was shown that emulsion becomes unstable at higher salinity (1, 10 and 50 % water salinity values were examined). The base 100 % solution was a composition of NaCl, $CaCl_2$, Na_2SO_4, $MgSO_4$ and TDS.

2.7 Production of the Emulsion

The process of emulsion production is termed emulsification and contains different physical processes. Walstra (1993) divided the process into three main categories: deformation coupled with possible break up; adsorption and transportation of surfactant to newly developed droplets; and bouncing and merging of drops. For the petroleum industry, there are two options to create emulsions *in-situ*, inside the reservoir, or *ex-situ*, outside in a process facility. Direct injection of alkali/surfactant (AS) solution after water flooding into porous media can result in emulsion formation (Kumar et al., 2012). Salt concentration and alkali concentration affect emul-

sion formation (Kumar et al., 2012; Perles et al., 2012). Another method is to use higher velocities and more efficient emulsifiers to increase shear stresses *in-situ* and form emulsion (Sarma et al., 1998).

Outside process facilities can also be used to prepare emulsion using oil, water and surfactants. Warmed heavy oil can be added to hot water premixed with surfactant and mixed using an industrial mixer. Another way would be circulating the fluid through a jet at a set volume rate with a centrifugal pump outside of reservoir (McAuliffe, 1973). Another procedure, the aqueous-phase solution and oil-phase solution can be prepared separately and stirred using a homogenizer (Son et al., 2014).

During production, the emulsion can be specified to be stable or unstable. Stable emulsions have a constant drop size distribution, while unstable emulsion forms larger droplets. In the critical case, the two liquids can segregate and form creaming and generate flocculation (Schramm, 2006). In the case of drop size around 10-100 nm, drops are stable (Windhab et al., 2005; Binks, 1998); however for larger sizes coalescence can occur. Surfactants can be added into the mixture to reduce surface tension between oil and water to avoid droplet break-up for sizes in the range of 0.5 to 100 micrometers (Binks, 1998). In addition, McAuliffe (1973) pointed out that mineral surfaces, reservoir water salinities, and water hardness can break droplets. Mandal et al. (2010a) observed the influence of stirring speed of a three-blade propeller and time of mixing on a stability of emulsion. In the present studies, the emulsion is prepared prior to experiment with known drop size distribution viscosity, stability and water/oil ratio (WOR).

It is important to know and control the emulsion parameters. During emulsion

production, the energy input can indicate different emulsion properties. In order to connect the energy input to properties of the liquids, such as viscosity of the continuous phase and interfacial tensions, the Weber (*We*) number can be used and is defined as (Schramm, 2006, p. 59):

$$We = \frac{\eta_1 \dot{\gamma} R}{\gamma_{12}} \tag{2.26}$$

where η_1 the viscosity of the continuous phase; $\dot{\gamma}$ shear rate; R droplet radius and γ_{12} the interfacial tension. Values of *We* in laminar and turbulent flows are discussed in detail in (Walstra, 1993) and can be used during emulsion production. Dependence of *We* versus ratio of dispersed phase velocity and continuous phase velocity is shown in (Schramm, 2006).

The production an emulsion is not part of this project. However, understanding of this process is necessary for future reference during experiments. Quadrise Canada Corporation, a collaborator in the project supplied an emulsion for this project. Their emulsions manufactured under brand name E^2EOR are stable and flexible in parameters. Their technology allows to tailor parameters for any particular application, such as viscosity, hydrocarbon content, the drop size distribution, chemistry and stability. The drop size can be controlled within a few hundred nanometers to less than 10 μm. The amount of available emulsion was limited due to the closing down of the company in earlier 2012 resulted in a reduced number of experiments being carried out to test the hypothesis.

2.8 Scaling Analysis

Carrying out the experiments in the field can be expensive and sometimes is even impossible due to lack of the information about reservoir conditions. Core flooding experiments simulate reservoirs porous media with assumptions stated by researchers (similar to Darcys law assumptions). Based on the obtained results, the number of assumptions can be reduced to make the porous media closer to the reservoir conditions. During core flooding experiments different core holders are in use. Core holders can be 1D, 2D or even 3D. The experiments are performed using pre-set physical parameters. The ones obtained from experimental results should be presented in a way that makes them applicable to the actual field reservoir. Thus, these parameters and dimensions of a core holder have to be scaled from typical reservoir where the method being developed will be used. The dynamic and physical characteristics of the experiment and reservoir are required to be scaled up.

For instance, pressure and temperature are the same in both cases. However, the dimensions of the cells and flow rates of injected liquids are parameters for scaling procedure. In order to set the flow rate for the 1D core holder, the Willhite's scaling coefficient is used (Willhite, 1986). Empirical correlation for water flooding to estimate the stabilizing criteria has been developed using the dimensional analysis by Rapoport and Leas (1953). According to Bagci et al. (2001b, p. 90), "displacement data for linear floods were independent of length, rate of injection, and viscosity of the injected water when the numerical value of the scaling coefficient, $Lu_t\mu_w$, exceeded a critical value", which is given as

$$Lu_t\mu_w = 5.85 \times 10^{-9}N \tag{2.27}$$

where u_t - total Darcy velocity in linear displacement, m/D (ft/D); μ_w - water-phase viscosity, Pa·s; L - length of cell, m. In reservoir engineering, it is a common practice to use ft/D as a unit for the velocity of flood front. After determining all the variables with fixable units, the following equation was obtained:

$$q = \frac{0.00351 \cdot A}{L \cdot \mu_w}, \text{cm}^3/\text{min} \tag{2.28}$$

where d - diameter in 1D cell, cm; A - cross sectional area for 1D cell, cm^2. It was found that applicable flow rates for 1D core holder are within a range of 0.1 to 1 cm^3/min. For the 2D core holder it is within a range of 1 to 1.75 cm^3/min.

Chapter 3

A new laboratory core flooding experimental system [1]

3.1 Introduction

The oil and gas industry heavily relied on laboratory core flooding experiments, where a core pack, often unconsolidated sand particles (Santosh et al., 2007; Hadia et al., 2007b; Mandal et al., 2010b; Hadia et al., 2008a) or in some cases consolidated cores (sandstone and carbonate outcrops) (Hadia et al., 2007a; D'Elia-S and Ferrer-G, 1973; Hadia et al., 2012, 2008b), mimicking the porous natural reservoir, is traditionally flooded with an injection fluid and resultant output in terms of oil recovery is measured. Existing core flooding systems use this concept, which was introduced for the first time in early 1930's (Wyckoff and Botset, 1936). When the industry is exploring new options for flooding the existing oil fields abandoned after the primary recovery process (Tzimas et al., 2005), there is a need to produce more robust, automated system to reduce time associated with experimental and post-experimental analysis.

A critical solution is provided to this pressing need for the oil and gas indus-

[1] A version of this chapter has been published. A. Baldygin, D. S. Nobes, and S. K. Mitra, "A new laboratory core flooding experimental system", *Industrial & Engineering Chemistry Research*, DOI: 10.1021/ie501866e, 2014

try by providing a robust, versatile, precise and automated core flooding platform which can be tested for various types of reservoir conditions using some of the advancements in fluid controls and data processing and automation. For validation purposes for the developed system, initially experiments are conducted with water and paraffin oil only, water flooding. To anticipate the future performance of the core flooding system for potential enhanced oil recovery (EOR) studies, applicability of the system for flooding complex fluids, such as an emulsion, is also demonstrated here.

3.2 Traditional Core Flooding Systems

The traditional core flooding system, as described in the existing literature (Hadia et al., 2007a; Mandal et al., 2010b), has three main sections: the upstream, the core block, and the downstream. The upstream supplies relevant fluids (saturation and flooding agents) to the core block typically using syringe pumps and piston accumulators (PA) to provide a controlled flow rate. The core block contains the porous media and often simulates the reservoir conditions which could include overburden pressure and a thermal jacket to maintain reservoir temperature. The downstream collects the effluent from the core block by using fraction collectors (Nasralla et al., 2011) or two-/three-phase separators (Boye et al., 2008; Legowo and Pratomo, 1999), the analysis of such data often leads to the estimation of the efficiency of tested oil recovery method.

Components of the system are connected to a data acquisition module through which the user can communicate, which is referred here as a control module. Such experimental techniques work well for single phase fluids (such as water or oil)

and certain restricted two-phase systems (oil and water mixture as effluent from the production wells).

Table. 3.1 provides a summary of existing core flooding systems, used for academic research and industrial applications for research in oil and gas industry. It can be noted that most of the systems use syringe pumps coupled with piston accumulators (Samanta et al., 2012; Hadia et al., 2007b; Legowo and Pratomo, 1999; Nobakht et al., 2007) which limits the type of liquids that can possibly be injected into the core as the inner surface of the piston-cylinder assembly of the syringe pump is susceptible to corrosion. The piston accumulator size limits the volume of fluid that can be continuously injected during flooding experiments and *a priori* calculations need to be performed to determine the size and specification of the piston accumulator to undertake a given core flooding study.

Table. 3.1 also suggests that a fraction collector was used for the downstream section in significant amount of the core flooding systems, which resulted in discrete estimation of oil and water effluents for the recovery curves (Samanta et al., 2012; Hadia et al., 2007b; Mandal et al., 2010b). Also, post experimental analysis is required to analyze the fraction of each effluent phase collected in each tube (Mandal et al., 2010a; Hadia et al., 2007b) of the fraction collector. In some cases, an ultrasound separator has been used for the effluent collection and analysis (Legowo and Pratomo, 1999). It is an effective method for experiments with three-phase effluent fractions, where phases are distinctly different from each other. As an example, experiments which involve water/oil/gas flooding has three components that can be separated in effectively inside the column of the three-phase separator using ultrasound and later can be quantified by volume.

Table 3.1: Summary of existing core flooding systems used globally.

Author	Year	Upstream	Downstream	Used fluids

Ko et al.	2014	Syringe pump with PA	Fraction collector with centrifuge tubes	Brine, oil and surfactant

These traditional core flooding systems need to be modified in order to make it more versatile in terms of using a wide range of flooding fluids such as surfactants, polymers and emulsions. Often in such scenarios, to calculate the various fluid volume fractions in real-time is needed which requires the inclusion of modern fluid handling systems to increase the functionalities of traditional core flooding system.

3.3 Developed Core Flooding System

A core flooding apparatus has been designed and constructed by taking into account the potential challenges related to a traditional core flooding system and the availability of new technology. This is a further modification to the initial conceptual design reported earlier (Baldygin et al., 2012). A schematic of the system is shown in Figure 3.1. This schematic shows the layout for the core flooding system, which is divided into three sections: the upstream, the core block and the downstream. This schematic was developed using diagramming software (Microsoft Visio, Microsoft, Co.) with a set of standard diagram elements. The fluid lines, control and data transfer lines are shown to guide the reader through the fluid and data flow.

The upstream side of the system provides continuous injection of three different types of liquids. It consists of fluid holding containers (carboys), pumps, and mass flow meters. Three carboys (E-1,...,E-3) are directly connected to three dual piston pumps (Smartline 100, Wissenschaftliche Gerätebau Dr. Ing. Herbert KNAUER GmbH) through 6.35 mm (1/4 in.) stainless steel tubes. The precision and accuracy of the upstream pumps at 12 MPa and for flow rate of 1 ml/min are equal to $<$ 0.5 % and $<$ 1.0 %, respectively. These numbers are close to the flow accuracy of

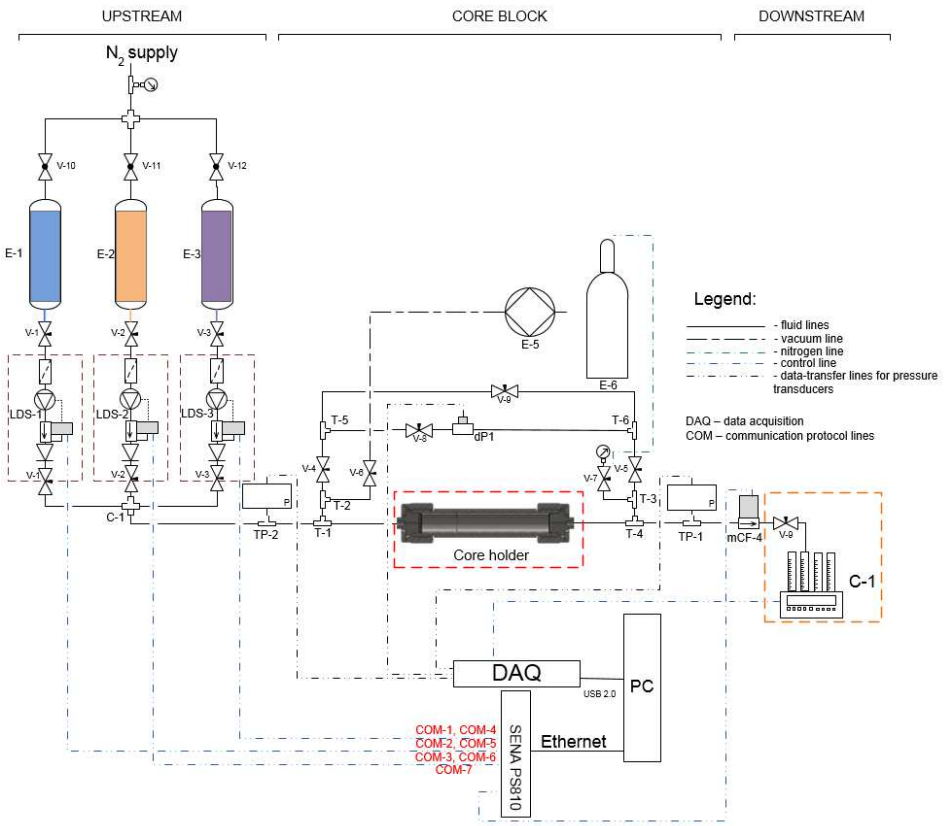

Figure 3.1: Schematic of the core flooding experimental apparatus.

a syringe pump. For example, 500D series pump (500D Teledyne Isco) has flow accuracy equal to 0.5 % of set point. In order to avoid cavitation at the inlet side of the pumps, the carboys are pressurized with nitrogen at 0.138 bar(g) (2 psig). Mass flow meters (M13, Bronkhorst Cori-Tech BV) are installed downstream of the pumps. Two of the mass flow meters are built of stainless steel, while one is made of Hastelloy to allow the use of salt (brine) water. According to the calibration certificates of the mass flow meters, the measurement error is $\pm$ 0.2% of the full-scale reading + 0.5 g/h. During the factory calibration procedure, density deviation was found to be 0.11 kg/m^3, -0.16 kg/m^3, -0.27 kg/m^3 and 0.01 kg/m^3 for water, oil, emulsion and downstream mass flow meter, respectively. The density measured using the three mass flow meters was compared with the one calculated using software (Bronkhorst High-Tech FLUIDAT©, Bronkhorst Cori-Tech BV) which defines physical properties of a fluid based on specific fluid temperature and pressure conditions with theoretical calculation methods. For example, with the water flow rate of 0.5 cm^3/min for half hour (approximate time to fill a single test tube at the fraction collector) the error is $\pm$ 0.28 ml considering density of water at experimental conditions. Together with the pumps are coupled to check valves, they form the liquid dosage systems (LDS-1,...,LDS-3), which can keep constant mass/volume flow rate at a pre-set pressure.

There are three LDS in the current configuration to deliver water, oil and emulsion into the core block as needed. The LDS system can work simultaneously if it is needed for certain experimental conditions. In addition, the upstream has open access to refill the carboys to allow continuous injection of liquids for lengthy experimental runs. There is no need to stop an ongoing experimental run for refilling

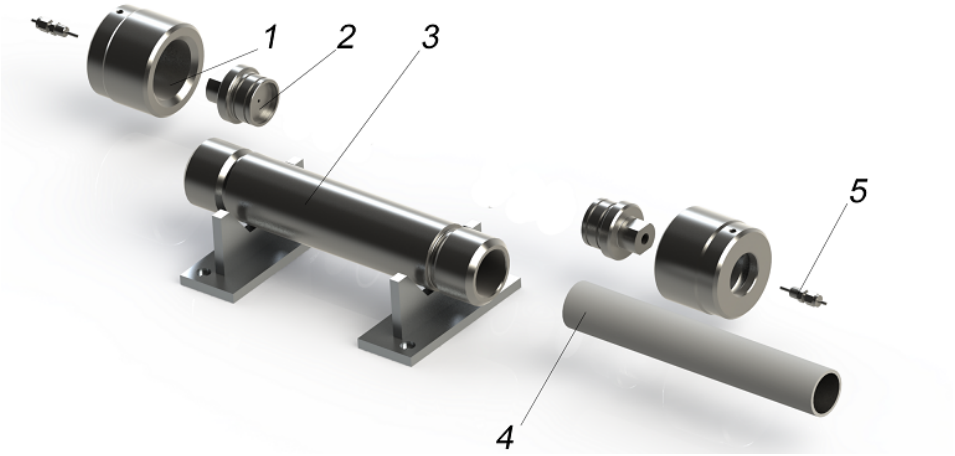

Figure 3.2: Exploded view of the core holder (1 - cap, 2 - end plug's body, 3 - body, 4 - internal surface, 5 - fitting 1/8 NPT to 3.175 mm (1/8 in.) tube).

purpose, which is a shortcoming in case of a traditional system with piston accumulators at the upstream side.

The core block consists of the core holder, in which the porous medium is usually packed which can be sand pack or samples, inline pressure sensors and differential pressure sensors. A biaxial horizontal core holder, shown in Figure 3.2, is used for containing and packing the medium. The core holder, shown here, is designed to perform one-dimensional core flooding experiments. However, any other two-dimensional (Santosh et al., 2007) or three-dimensional (Hadia et al., 2007b, 2008a) core holders, as and when available, can be plugged into the system through appropriate connections to 3.175 mm (1/8 in) stainless steel tube. The dimensions of the core holder used here as an example are: length: 284 mm (11.18 in) and diameter : 38.1 mm (1.5 in). This design incorporates minimal fluid leakage between the inner surface of the coreholder and the sand pack. At the same time, it also reduces the dead volumes at the inlet and outlet sides of the sand pack due to the modified entrance region, shown in Figure 3.3. The entrance region incorporates

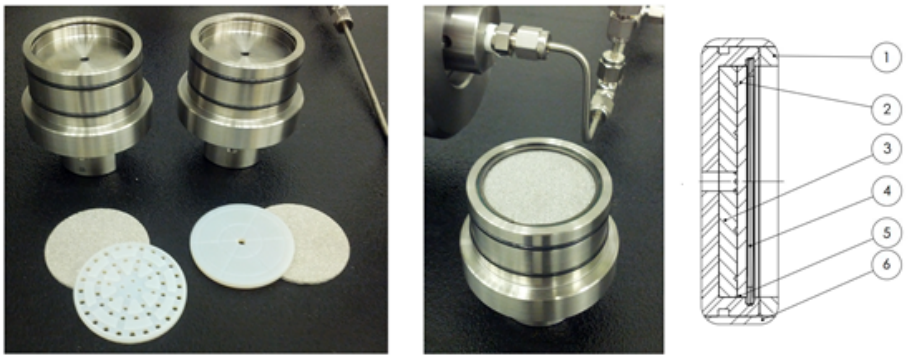

Figure 3.3: End plugs of the biaxial core holder. (a) - isometric view of end plugs; (b) - end plug assembled; (c) - cross section view of single end plug (1 - sandblasted internal surface, 2 - stainless steel filter, 3 - 3D-printed plate, 4 - strain ring, 5 - end plug's body, 6 - core holder's body

modifications to the patents of Stanley (1984; 1985). It combines the geometrical configurations of both patents and thereby replaces/modifies the distribution plates as per current needs. A sand-blasted plastic tube is installed inside the core holder to prevent such fluid leakage. The distribution plugs, located at the two ends of the core holder, have built-in stainless steel media with mesh size of 40 μm and 1.59 mm (1/16 in.) thickness and distribution plate printed using a 3D printing. This combination redistributes the liquid across the cross-section and reduces dead volumes.

The design for the distribution plates was optimized by performing separate simulation using commercial software (SolidWorks Simulations, Dassault Systemes SolidWorks, Corp.). In total, nine different configurations have been analyzed as a combination of three configurations for the end plug, which are shown in Figure 3.4, and four configurations for the distribution system, which are shown in Figure 3.5. Design of the end plugs shown in Figure 3.4 (b) and (c) bases on industry standard available in a core holders from two main manufactures (Core Laborato-

ries (www.corelab.com, 2014a,b) and CORETEST Systems Inc. (www.coretest.com, 2014)). Stainless steel filter, shown in Figure 3.5 (c), forms artificial porous media after perforated plate, shown in Figure 3.5, and helps additionally redistribute liquid before it goes into a sand pack. In addition, it provides sand control in a core holder. The cap with 9 holes, shown in Figure 3.5 (d) has internal thread and can be installed only on end plug with channels for flow redistribution. Thread allows to change orientation for holes with respect to the open channels and twist flow internally.

Figure 3.5: Variation of sub-components for end plug (a) perforated plate, single hole; (b) perforated plate, four entrance holes; (c) 40 micron stainless steel filter made of 316L SS; (d) cap with 9 holes and channels.

A comparison of the flow distribution between traditionally used and improved configuration is shown in Figure 3.6. The color map represents internal velocity through the cross section of the sand pack. Once the configuration was finalized particular attention was given to the size of the holes in the radial direction (Stanley, 1984). It was optimized to guarantee uniform flow distribution through the porous medium with known range of permeability and porosity.

For pressure monitoring, there are three pressure sensors (FP2000 series, Honeywell International Inc.), TP-2, TP-1 and dP-1, to measure the inlet pressure at the upstream, the outlet pressure at the downstream, and differential pressure across the porous media.

The downstream section has an effluent management system which allows it to quantify different fractions of effluents removed from the core block. The mass

Figure 3.6: The horizontal velocity component distribution in the axial cross-section of the core holder obtained with different configurations of end plugs.

fraction of each component needed to be calculated to estimate the amount of oil recovered, which is often the ultimate goal for such core flooding system. The effluent management system has a mass flow meter and a fraction collector (CF-2, Spectrum Laboratories, Inc.). The fraction collector uses graded test tubes with 15 ml volume each. The error in a measuring volume of liquid collected in a test tube (430055, Cole-Parmer Canada Inc.), used for checking the effluent fraction data, is $\pm$ 0.25 ml. Since this error would be accumulated from sample to sample, the cumulative error in the oil production is around 6.5 ml (estimated based on expected number of test tubes in 1D experiments). The error bars incorporated for each data point in the recovery curves represent the error in measurements. Complete error analysis can be found in Appendix A-2. The mass flow meter (M13, Bronkhorst Cori-Tech BV) has the same specifications as that used for water flow, installed in LDS-1. The mass flow meter provides the flexibility to deal with effluents having different densities and it allows automatic evaluation of volumes of different effluent phases, the details of which are described later.

The experimental setup can be pressurized with nitrogen, E-6, and tested for leakage using soap-water, usually undertaken without the porous sand pack in place.

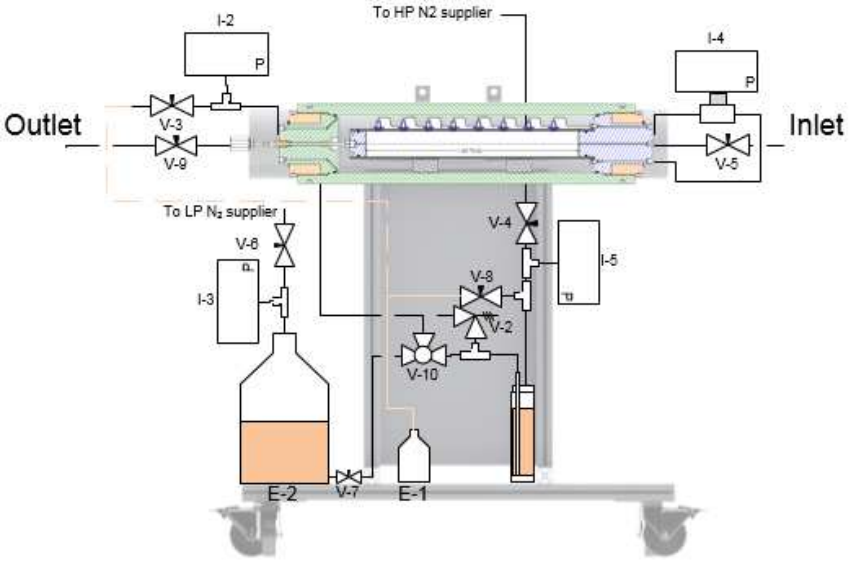
3.3.1 Core Flooding System Flexibility

The advantage of the developed system is that it is designed as a ”plug-and-play” modular system. There is a possibility for further modification of the core block, which is only limited by the specification of the upstream pumps. The region highlighted with red dashed square in Figure 3.1 can be replaced with the sub-system, described in Figure 3.7(a), quite readily, or with a 2D core holder, used for experi-

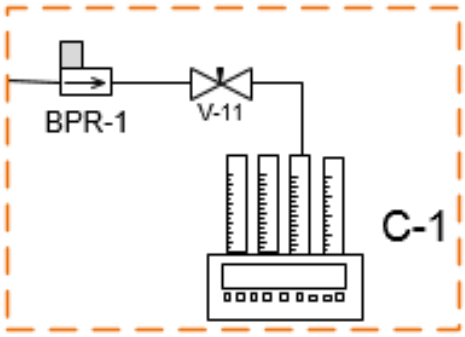
ments in Chapter 5.

Example of the subsystem, proposed in Figure 3.7(a), has a Hassler core holder (www.corelab.com, 2014b) which allows the core to be maintained with a confining pressure up to 10,000 psi, to use actual cores previously extracted from reservoirs (outcrops) and to measure pressure drop across the core using eight tap-points. The confining pressure in the present configuration can be maintained using a high pres-sure N_2 line. This further can be replaced with either high pressure hand pump or a syringe pump. The temperature inside the core (or along its outer surface) can be measured using any of the eight tap-points of core's sleeve via thermocouples installed through the ports located on the end plug with appropriate pressure sealed feedthroughs (Series WF, Spectite Inc.). In order to maintain the temperature of the core block similar to reservoir conditions, the core holder can be placed inside an environmental chamber or an ultra-thin heat sheets can be mounted at the outer sur-face of the core holder covered with fiberglass pipe insulation. The chamber allows to maintain temperature up to 200 °C, whereas the heat sheets allow to maintain temperature up to 100 °C. The temperature can be controlled via programmable temperature PID controller with feedback from one or more thermocouples.

Similarly, the downstream section can be also modified to satisfy the requirements for the inline pressure. For example, a digital back pressure regulator (EL-PRESS P-712CV, Bronkhorst Cori-Tech BV) can be installed between downstream mass flow meter and fraction collector, as shown in Figure 3.7(b). It would allow to set the back pressure up to 103.4 bar(g) (1500 psig). These modifications to the core block and downstream section of the core flooding developed allow end-users to obtain the required parameters to mimic desired reservoir conditions.



(a) Core block



(b) Downstream section

Figure 3.7: Schematics of the further updates to the developed system.

3.3.2 Core Flooding System Limitations

One of the limitations of the current system is that the produced water cannot be separated from the emulsion and re-injected back to the core block as a flooding fluid for further oil recovery. In order to utilize such produced water back into the flooding system, it would be required to install additional components at the downstream to separate emulsion, paraffin oil and water. Such separation of oil/water emulsion can be done using traditional membranes (Chen et al., 2009) or more recently through the use of microfluidics devices (Fidalgo et al., 2008).

3.3.3 Remote Control

In order to minimize human intervention and have robust control on the experiment, software with a graphical user interface (GUI) was created for the entire system using a commercial environment (LabWindows CVI, National Instruments Inc.). This software allows user to control and track different components during the experiment, save data and analyze various experimental conditions. A commercial data acquisition (DAQ) system (cDAQ-9172, National Instruments Corp.) with onboard control modules for pressure sensors and fraction collector is used for data acquisition. In addition, the mass flow meters and pumps are connected to a universal eight port device server (PS 810, Sena Technologies, Inc.) which transfers and receives signals from personal computer (PC) through an ethernet network.

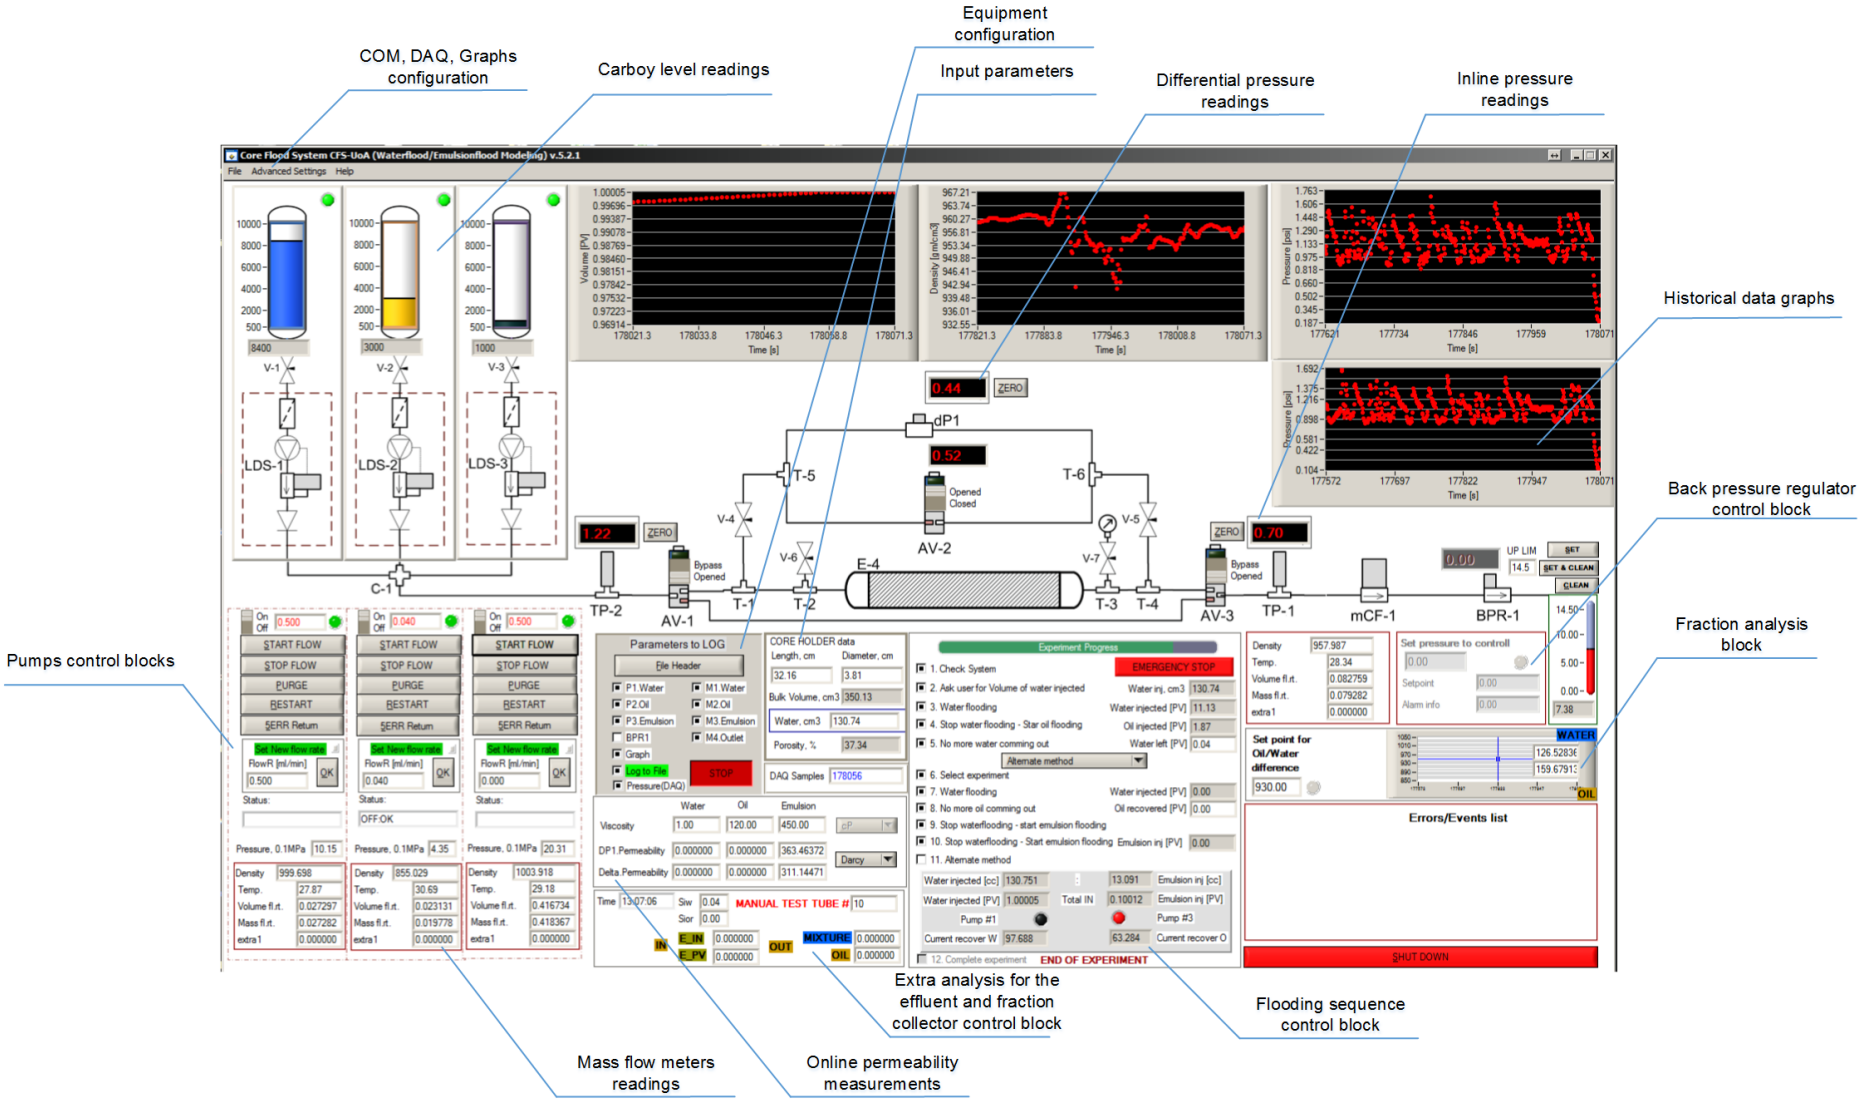


Figure 3.8: A graphical user interface to perform automation for the core flooding system.

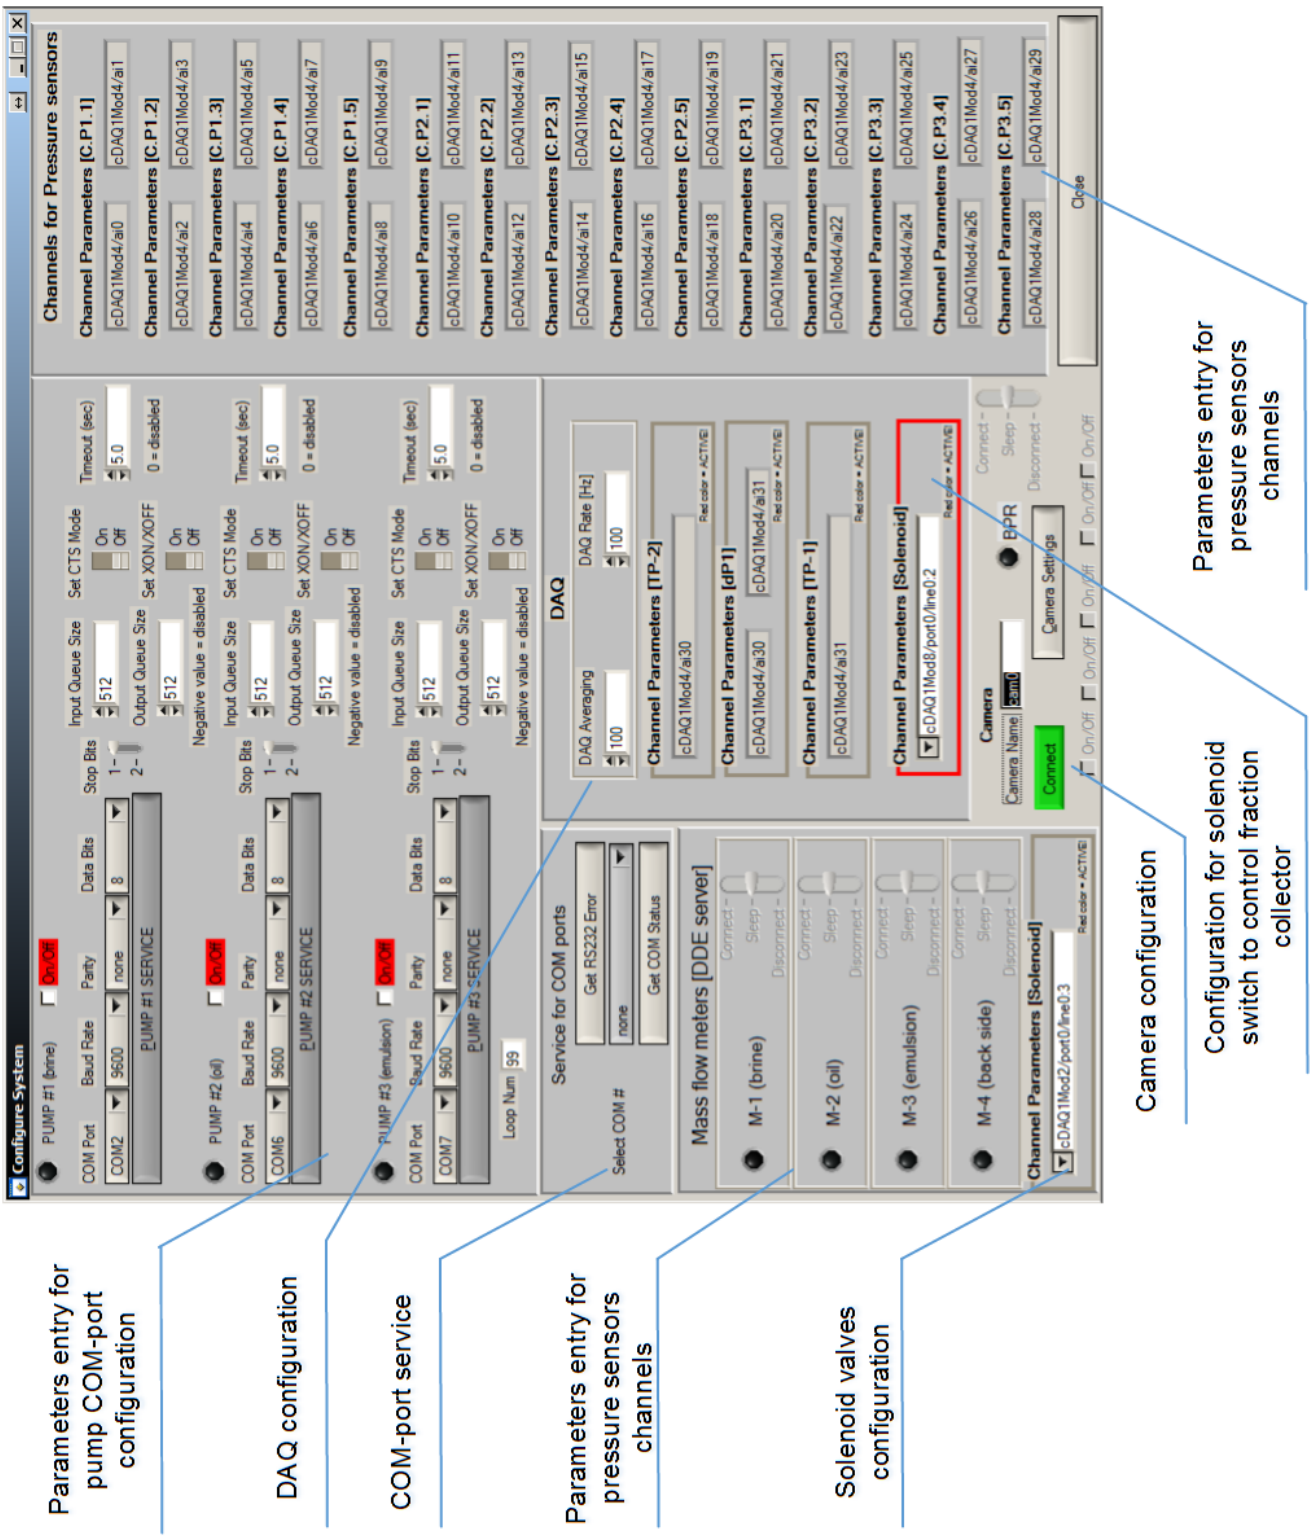

Figure 3.9: A graphical user interface to perform configuration for the core flooding system.

The developed GUI interface is shown in Figure 3.8. Similar to the experimental setup, it can be divided into three sub-sections: the upstream, the core block and the downstream. There are components for controlling different processes of experiment, load/save configuration parameters, saving data, monitor effluent properties, pressure and other parameters involved in each run. The developed software allows to monitor system in real time. There is a possibility to run experiments in "auto" operating mode using the developed logical structure. Figure 3.9 shows the GUI which was developed to configure individual components of the system.

3.4 Materials and Specifications

Using the developed core flooding system, both traditional core flooding using water as a flooding agent (secondary recovery process) and emulsion flooding using *ex-situ* produced emulsion (enhanced oil recovery) were performed. In this section, the details of different materials used during this experimental validation process for the core flooding system along with standard data extraction in the form of porosity and permeability of the core pack used for each flooding experiment are provided.

During 1D core flooding experiments, the injection rate was set at 0.5 cm^3/min. The core flooding temperature was at the room temperature of 22°C for all experiments. Distilled water (DI) produced from a water purification system (PURELAB Ultra, Elga Labwater, LLC) was used for the water flooding to obtain and to maintain initial water saturation. Paraffin oil (CAS Number 8012-95-1, Sigma-Aldrich Co. LLC) with viscosity of 130 mPa·s at 25°C and density of 868 kg/m^3, measured by the mass flow meter (M13, Bronkhorst Cori-Tech BV), was used for oil saturation processes. The *ex-situ* emulsion used in this study was oil-in-water (70.75

wt% oil and 29.25 wt% water with average oil drop size of 2.46 micron. The stable emulsion was made of heavy-oil, which is distinctly different than the resident oil (paraffin oil) in the sand pack. Density and viscosity of the emulsion are 1014 kg/m^3 and 495 mPa·s at 100 s^{-1} shear rate at 25°C (Patrick Brunelle (Quadrise Canada Corp.), 2012), respectively. Since the chosen emulsion is heavier than water and oil, it can be hypothesised that the downstream mass flow meter can detect each phase separately. By setting reference points for density of each phase in the developed software and using on-line measurements from the mass flow meter, fluid fraction-tracking software can be developed. Hence, the system can be further modified to eliminate the need for test tubes.

For each experiment, the sand (dry water-wet silica sand from Ottawa IL sand deposit with US sieve size# 10 (100-140), 53-251 μm) was weighted prior to the packing inside the core holder. The mass of the sand used for each pack was recorded to be 557 gm and was consistent from experiment to experiment with 1.5 % of deviation. The procedure for packing the core was as follows. The sand with a known mass was packed inside the void volume of the core holder (324 cm^3) using a vibration table (VP-181, FMC Technologies) with the vibrator controller (Syntron Power Pulse AC, FMC Technologies) set at maximum level. The core holder with one opened end, containing the inner plastic tube, was placed vertically on the vibration table. The sand was poured inside the core holder continuously up to the top of the internal tube. The core holder was kept for 5 minutes on a powered table to let the sand settle and form a dense medium. A rod with diameter equal to the internal diameter of the plastic tube was used to compress the sand to produce a dense pack.

Table 3.2: Properties of the sand packs

Pack	Porosity, % by water/ by mass measurements	Pore volume , cm^3	Absolute permeability, Darcy	Permeability with residual water, Darcy	Residual water saturation after oil saturation S_{wi}
Run #1	37/35	113.4	10.2	6.25	0.02
Run #2	36/36	116.0	19.8	11.2	0.18
Run #3	37/35.8	115.9	11.3	6.30	0.06
Run #4	35.8/33.4	108.1	11.3	7.90	0.06

Each pack was characterized for porosity and permeability, which were obtained prior to each flooding experiment. The obtained data are shown in Table 3.2. In order to obtain a porosity value (pore volume) for each pack, a vacuum pump (117, Labconco Corp.) was connected to the inlet side and a vacuum gage was connected to the outlet side of the core holder. The core holder was evacuated to 4 kPa absolute (28.74 in. mercury gauge or 1.18 in. mercury absolute) over half of an hour. Then the vacuum pump was disconnected and a tank filled with known volume of water, V_{kv}, was connected to the core holder and allowed to flow of water into the core holder. The remaining volume, V_{rem}, of water in the tank was recorded using a double metric scale glass cylinder (250 ml Brand 3025, Pyrex). From these measurements, the volume of water occupied by the pore space can be calculated using a modified Eq. 2.1, which provide the value of the porosity of the sand pack:

$$\phi = \frac{V_{kv} - V_{rem}}{V} \tag{3.1}$$

In addition, the porosity was calculated using the mass of packed sand, void volume inside the core holder and bulk density of silica sand (Systems, 2014) (2.65 gm/cm^3). Pore volumes (PV), the volume of fluid within the packed core holder, were in the range from 113.4 to 120.0 cm^3.

For each pack, the permeability was obtained using three different methods: with nitrogen, water and finally, with residual water saturation during oil flooding.

The absolute permeability was first found using nitrogen immediately after dry sand was packed in a core holder. The mass flow controller with built-in pressure sensor was connected to the inlet and a pressure sensor was installed at the outlet of the core holder. At different flow rates of nitrogen, the pressure difference was recorded. The absolute permeability was found using the Klinkenberg equation (Klinkenberg, 1941):

$$K_g = K_l \left(1 + \frac{b}{P_m}\right) \tag{3.2}$$

where, K_g is the gas permeability, mD; K_l is the liquid permeability, mD; b is the Klinkenberg factor, Pa; and P_m is the mean absolute pressure, Pa.

The absolute permeability with water as the working fluid was calculated for water saturated pack using Eq. 2.11. Prior to obtaining permeability measurements with residual water saturation, the oil saturation process was carried out using paraffin oil. The oil was injected into the water saturated pack with a constant injection rate of 0.5 cm^3/min for 1 PV of injection; thereafter, the injection rate was increased to 1.0 cm^3/min for an extra 0.5 PV of injection, until the residual water saturation, S_{wi}, was reached (see Table 3.2). At the end of the process, the flow rate was reduced back to the 0.5 cm^3/min and the permeability was calculated using Eq. 2.11. The effluent stream was collected in batches in test tubes. The volume of water and oil collected were compared to the injected one and used to obtain values for residual water saturation, shown in Table 3.2. Porosity and permeability measurements showed that sand packing process was consistent for all one dimensional experiments experiments.

3.5 Experimental Validation of the Core Flooding System

3.5.1 Effluent Management System

The comparison of different flooding strategies in terms of oil recovery depends on the underlying physical processes in terms of the displacement of the resident oil phase by the invaded flooding agent. At the pore-level flooding strategies can be evaluated using a Reservoir-on-a-Chip (ROC) (Gunda et al., 2011) type system. However, on a macro-scale, where integrated cumulative measurements take place, it is important to estimate the volumes of respective phases through a reliable effluent management system. Thus, it is important to calibrate and ensure that the downstream stream is measuring both the volume of water and oil for the effluent streams in developed system. In developed core flooding system, two different approaches for the downstream analysis were utilized. The fractions collected into the test tubes with fraction collector were analyzed using mass flow meter data at first and later through visual inspection of test tubes.

In order to record the volume of each phases, the effluent flow through the mass flow meter was analyzed. A density reference point, ρ_{ref}, was set at 935 kg/m^3 for measurements during the four runs, corresponding to different flooding experiments. This reference point was selected based on initial calibration runs with paraffin oil and DI water. As the liquid flows through the downstream mass flow meter during a single time step, t_{step} ($\approx$ 1 second), the density, ρ_{record} (kg/m^3) and the current volume flow rate Q_{cur} (cm^3/min) were recorded. Based on these quan-

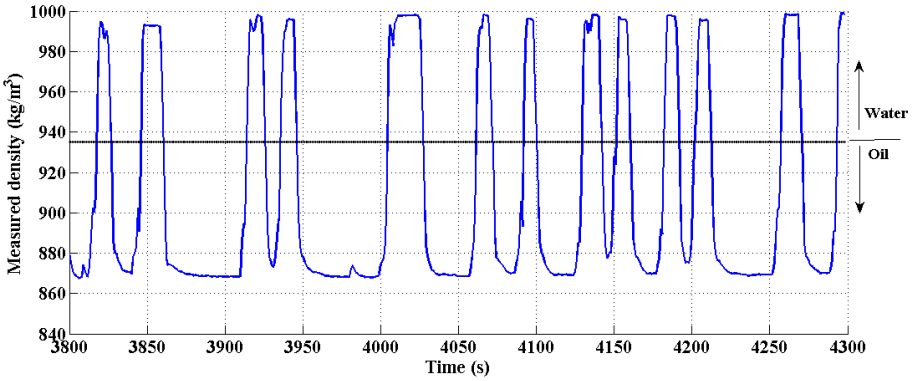

Figure 3.10: An example of density measurements at the effluent side during core flooding experiment.

tities, the fluid volume for a given phase,$V_{j,rec}$ (cm^3), was calculated as:

$$V_{j,rec} = \frac{Q_{cur} * t_{step}}{60}; \;\; j \;\; \text{= oil or water} \tag{3.3}$$

An example of density measurements at the effluent side is shown in Figure 3.10. If the density was larger than the reference level ρ_{ref}, the recorded volume (Eq. 3.3) was added to the water value $V_{water,rec}$ and the oil value $V_{oil,rec}$ was kept unchanged. Otherwise, it was vice versa. This approach was also used for emulsion flooding experiments, where the values above the reference level represented water and emulsion phases.

In total four runs - two water flooding experiments (Run #1 and Run #2), direct emulsion flooding (Run #3), and finally water flooding followed by emulsion emulsion flooding (Run #4) have been performed. For this purpose, the fractions of the effluent were collected into the test tubes and compared to the recorded volumes from the mass flow meter data and are shown in Figures 3.11 and 3.12. The error bars correspond to the error in mass flow meter and fraction measurements (the complete error analysis is available in Appendix A-2). The vertical axis here shows the total volume of each liquid recorded by the mass flow meter and the hor-

izontal axis represents the total volume collected in test tubes. Each test tube could be either filled with single liquid or can have multiple liquids, e.g. oil and water. Consequently, points on the graphs could be in a range from 0 to 15 ml. The diagonal line in these figures provides the measure of the data accuracy between two measurement techniques.

Figure 3.11 contains data points obtained during the process of water flooding for different runs, including one where the emulsion flooding was followed after the water flooding step (Run #4). Data points for produced water, shown in Figure 3.11 (a), follow the 45° line trend. Figure 3.11 (b) shows the similar trends for the recovered oil in the effluent stream. This highlights that measurements from the mass flow meter can be used for online determination of the effluent fraction.

Results obtained for the two emulsion flooding methods are presented in Figure 3.12. In Figure 3.12 (a) the results of produced mixture of emulsion and water are depicted and Figure 3.12 (b) shows the volume of recovered oil measured by the two techniques. Even though it can be observed a strong correlation between the two measurement techniques for certain measurement range, this is not true for the entire range of measured data, as was the case for Figure 3.11. In both cases, data correlation between the two measured techniques is not as strong compared to the water flooding results shown in Figure 3.11. This suggests further calibration for different regimes are required to increase the accuracy level(due to the limited amount of available emulsion, this has not been done in this research study). The worst deviation from the 45° line trend was found the be $\pm$ 22 %.

3.5.2 Core Flooding Experiments

Once the effluent management system is properly characterized and tested, the core flooding system was used to perform different flooding experiments. 19 to 22.5 hours are required to complete single experiment at a selected flow rate. Having reliable software with a graphical user interface allowed to run system overnight. The recovery curves for each set of flooding experiment is shown in Figure 3.13. Each recovery curve represents the cumulative oil production during single run/experiment. The presented data was obtained using determined volumes from test tube fractionation which were matched to the data collected from the effluent mass flow meter. Points used to plot recovery curves are collected from the test tubes analysis. The upstream and downstream mass flow meters supplemented mass balance calculations. It can be observed that the first two water flooding runs ended with recovery around 60% and 75% for Run #1 and Run #2, respectively. The water appeared at

the effluent side (breakthrough point) for Runs #1 and #2 occurred at 0.3 and 0.24 PV of injected displacement fluid, respectively. The obtained numbers were similar to the published data for unconsolidated sand packs with porosity around 30-40 % and permeability from 1.1 to 3.4 Darcy (Hadia et al., 2007b; Mandal et al., 2010b; Hadia et al., 2008a). It was observed that after 2 PV of injection of water, the ultimate recovery increased by only 6% and 8% for Run #1 and Run #2, respectively. Loose sand pack in Run #2 with higher absolute permeability compared to Run #1 resulted in higher oil recovery during water flooding. The data suggests that the pore volumes used in the experiments and the corresponding increase in the recovery are similar to the field applications (Dake, 1998, p.364). Alternate injection strategy must be incorporated to have economic recovery rate. Hence, instead of continuing with water flooding beyond a certain PV, emulsion was introduced to the system at 3.7 PV in Run # 4.

For Run #3, the emulsion was used as a primary flooding agent for the oil saturated porous media. As observed from Figure 3.13, the emulsion flooding alone produced larger oil recovery compared to water flooding for the same PV of injection. During the emulsion flooding almost 60% OOIP was recovered after injecting only 0.5 PV of emulsion. The total oil recovery was 79% OOIP at 1.25 PV of injection. From 1.01 PV of injection, additional oil recovery was not observed for Run #3. From the effluent analysis it was identified, that the breakthrough for this case happened at 0.72 PV of emulsion injection. Such a high efficiency of the emulsion flooding compared to the water flooding could be due to delayed breakthrough and having its viscosity similar to the viscosity of the paraffin oil. Emulsion saturated front moves steadily through porous media due to low viscous ratio between the

displaced and the displacing fluids (Doorwar and Mohanty, 2011).

For Run # 4, the complete water flooding experiment was carried out up to 3.7 PV of water injection. The recovery curve follows a similar trend to the Run #1 and Run #2, as is shown in Figure 3.13. At 3.7 PV of water injection, emulsion was introduced to the porous media as post water flooding process to enhance oil recovery. The total oil recovery was found to have increased. An additional 15 % of OOIP was recovered. The emulsion injection beyond 4.6 PV did not displace additional oil from the sand pack. Based on effluent collected into test tubes at the effluent side, similar to the Run #3, the emulsion saturated front moves steadily through a porous media. Complete understanding for the emulsion flooding process can be obtained by ceasing experiments and analyzing sand packs afterward. The residual oil saturation at the end of the Run #4 is around 18 %, which is similar to that in case of Run #3 with emulsion flooding only. It is to be noted that even though emulsion floodings (both Run #3 and Run #4) produced additional oil recovery ($\sim$ 20% OOIP), it required an amount of emulsion close to single pore volume to achieve such high recovery.

3.6 Conclusion

A core flooding experimental setup has been constructed to improve on the existing system which has been in use for several decades. The developed setup allows to test enhanced oil recovery techniques in more efficient time manner. The system was equipped with the up-to-date techniques and hardware available in fluid measurement systems. An automated effluent analysis incorporating properties (mass flow rate and density) measured by mass flow meters has been developed. This

allowed the replacement of the traditional fraction collector in the downstream section for online determination of effluent composition. The entire experimental setup is also monitored and controlled through a custom built software.

The core flooding experiments with unconsolidated sand packs as a medium has been performed for validation purpose. To understand the applicability of the system, emulsion (oil-in-water) used as a flooding agent, as an example of advanced technique for enhanced oil recovery. Here, two different strategies for emulsion flooding have been demonstrated - direct injection of emulsion (Run #3) and water flooding followed by emulsion flooding (Run #4). It has been shown that the engineered emulsion worked effectively as an independent flooding fluid and Run #3 produced 79% OOIP recovery at 1.2 PV of injection. Also, emulsion worked effectively as a substitute fluid after the water flooding in Run #4 and added an extra 15% OOIP to the total oil recovery at the cost of an additional 0.93 PV of emulsion injection. Comparison between these two runs suggests that, Run #3 was effective in terms of the time needed for the oil to be recovered from the porous media, while Run #4 was effective in terms of the emulsion used for the oil recovery process.

These core flooding experiments demonstrate that this newly developed core flooding system is capable of performing both the traditional water flooding and more advanced enhanced oil recovery process using *ex-situ* obtained emulsion as a flooding agent. This system can be used for academic research purpose using different types of core holders with various combinations of injection and production wells and at the same time can be adopted an industry bench mark to perform routine core studies and has a high potential of replacing the existing core flooding systems.

Chapter 4

Water-Alternate-Emulsion (WAE): A new technique for enhanced oil recovery[1]

4.1 Introduction

Existing literature suggests, that the oil and gas industry has faced a challenge working with produced water for EOR, where the goal has been to minimize the overall water injection inside the oil reservoirs. Processes were formulated where water/steam and another immiscible fluid were injected simultaneously to reduce the overall water footprint for oil recovery. Good examples of such processes are cyclic steam simulation (CSS) and water-alternate-gas (WAG) flooding (Alvarado and Manrique, 2010; Shah et al., 2010; Luo et al., 2013; Huang and Holm, 1988). In the case of CSS, the cyclic process requires around a month to implement and involves three stages: steam injection, soaking of the steam into the heavy oil formations and oil production by natural flow or by artificial lift (Shah et al., 2010; Scott, 2013). This cycle can be repeated till the oil production rate becomes uneco-

[1] A version of this chapter has been published. A. Baldygin, D. S. Nobes, and S. K. Mitra, "Water-Alternate-Emulsion (WAE): A new technique for enhanced oil recovery",*Journal of Petroleum Science and Engineering*, DOI:10.1016/j.petrol.2014.06.021, 2014

nomical (Shah et al., 2010). For WAG, different ratios for water to steam slugs for each cycle have been investigated, *e.g.* 2:1, 3:1, 4:1 and even 10:1 (Shah et al., 2010; Luo et al., 2013; Huang and Holm, 1988; Bagci and Tuzunoglu, 1998; Tüzünoglu and Bagci, 2000; Christensen et al., 2013). An increase in production was recorded up to 37% or even higher during cycling different slugs in a laboratory coreflooding system (Tortike, 1991). In order to further improve the WAG flooding technique an alternative technology was developed referred as chemical-augmented WAG (CAG), which replaced steam slugs with water-miscible chemical (alkali/surfactant/polymer) slugs (Luo et al., 2013).

All these mentioned techniques, i.e., CSS, WAG, CAG, etc., are referred as enhanced oil recovery for processes. CSS can achieve 60 % higher recovery of original bitumen in place (OBIP) compared to the steam assisted gravity drainage (SAGD) in the Clearwater formation (Scott, 2013). CO_2 - CAG allows to recover 71.07 % OOIP compared to CO_2 - WAG with 54.25 % OOIP at the same experimental conditions (Luo et al., 2013). WAG field experience shows an increase in oil recovery from 0.7 to 37 % of OOIP (Christensen et al., 2013). However, replicating these enhanced oil recovery processes with emulsion and water slugs, particularly when such emulsion is produced *ex-situ* from hydrocarbon sources quite different from the *in-situ* resident oil phase within the pores, remains to be explored. Only one study has been reported on sequential emulsion flooding (Guillen et al., 2012), where the amount of emulsion (1.65 PV) and water used (≈22 PV) was economically ineffective in terms of recovered oil and the overall time required to complete the process (Guillen et al., 2012). Hence, in this work, the focus is on using emulsion slugs alternatively with the water slugs in a cyclic manner similar to earlier

strategies for enhanced oil recovery with water and steam (CSS,WAG) or water and chemicals (CAG). Experimental results in the previous Chapter also suggested finding an alternative injection strategy to improve emulsion flooding efficiency. In this study, the emulsion flooding technique is named as water-alternate-emulsion (WAE) process.

Like any other new method for oil recovery, the technology first needs to be tested in a laboratory core flooding system (Santosh et al., 2007; Hadia et al., 2007b; Mandal et al., 2010b; Hadia et al., 2008a, 2012) before a field operation of the new process can be embarked. Hence, following similar trends, the WAE flooding technique was investigated in laboratory scale studies which are reported here. In this study, core flooding experiments with an unconsolidated sand pack as a model porous medium are conducted. For this purpose a biaxial core holder is used and three different water-emulsion flooding ratios, viz., 2:1, 4:1 and 5:1, are tested. The oil recovered using the WAE process is compared with the traditional flooding techniques such as water flooding, emulsion flooding, and water flooding followed by emulsion flooding, presented in previous Chapter 3. Based on the results obtained from this laboratory scale study, if the WAE method appears to be a promising option, further scale-up of this technique for field application can be readily executed (Hadia et al., 2008b; Islam and Farouq Ali, 1989, 1992; Abou-Kassem and Farouq Ali, 1995; Akin et al., 2000).

4.2 Materials and Methods

The laboratory core flooding system used in this study is the one reported in previous Chapter 3. The injection flow rate of water-alternate-emulsion slugs was set

at 0.5 cm^3/min for the entire flooding studies and temperature in the experimental facilities was maintained at room temperature (around 22°C).

The porous medium for the study is unconsolidated sand (dry water-wet silica sand from Ottawa IL sand deposit: US sieve size # 10 (100-140), 53-251μm), which was packed inside a biaxial core holder for each flooding experiment (www.corelab.com, 2014a). The core holder has an internal diameter of 38.1 mm (1.50 in) and the internal length of 321.6 mm (12.66 in) and was oriented horizontally during the core flooding e xperiments. Parameters of the sand packs used for different flooding experiments are summarized in Table 4.1. Using values for porosity, ϕ, cross section of the sand packs, A, and chosen flow rate, Q, the interstitial velocity, v, can be estimated for the studied porous media. This injection rate is equivalent to interstitial velocity of $2.187 \cdot 10^{-5}$m/s, $2.071 \cdot 10^{-5}$m/s, $2.074 \cdot 10^{-5}$m/s (6.20, 5.87, and 5.88 ft/day) for Run #5, Run #6 and Run #7, respectively. It can be defined by Tiab and Donaldson (2004):

$$v = \frac{Q}{\phi A} \tag{4.1}$$

With interstitial velocities of $2.117 \cdot 10^{-5}$m/s (6 ft/day), the saturation profiles would be independent of the capillary end effect (Tiab and Donaldson, 2004). In petroleum reservoirs with conventional multiphase flow the velocities are on the order of $3.528 \cdot 10^{-6}$m/s (1 ft/day) (Willhite, 1986, p. 21).

Values for residual water saturation, S_{wi}, absolute permeability, and porosity from Table 4.1 are consistent with available data in the literature for the core flooding experiments with unconsolidated sand packs (Kumar et al., 2010; Sarma et al., 1998; Hadia et al., 2008a; Luo et al., 2013). In addition to the presented parameters, the pore size distribution was measured using an automatic pore size ana-

lyzer (PoreMaster 33 , Quantachrome Instruments) using 1.0243 gm of sand sample with porosity of 38.9 %(loose pack). The total intruded volume was found to be 0.243183 cm^3. The pore radius lies in a range from 0.003 to 109.71 μm with an average value of 12.631 μm, as it is shown on Figure 4.1. Using data from Table 4.1 with assumption that sand pack can be represented as the bundle of capillary tubes, the pore throat radius, r, can be found using the following equation Tiab and Donaldson (2004):

$$r = \left(\frac{\phi}{8k}\right)^{-0.5} \tag{4.2}$$

where, ϕ is the porosity of sand pack in % and k is permeability of sand pack in Darcy. For Run #5, #6, and Run #7 it can be found that pore radius is equal to 13.09, 12.78 and 12.49 μm with an above assumption, respectively. The obtained values lie within the same range as the once found using automatic pore size analyzer.

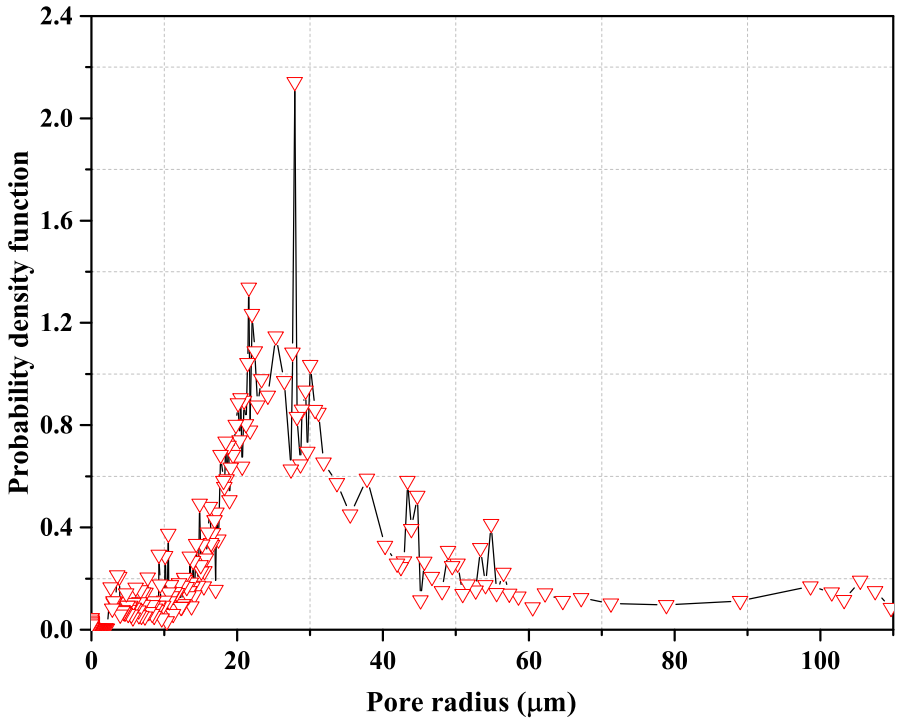

Figure 4.1: Pore size distribution of studied silica sand.

The packing process was followed the procedure discussed in previous Chapter 3. The residual water saturation was established using the following procedure. First, the sand was packed inside the core holder. The core holder was then evacuated using a vacuum pump (117, Labconco Corp.) to 4 kPa absolute (28.74 in. mercury gauge or 1.18 in. mercury absolute) over half of an hour. Graded tank was connected to the core holder and water was supplied by pressure difference to completely saturate the core. Once, the pressure of the effluent side of the core holder equals to atmospheric, the water supply was stopped and the recorded volume of water absorbed inside the core is used as the pore volume (PV), V_{pv}, for each pack. Once the absolute permeability was calculated, the paraffin oil was injected into the water saturated pack and effluent was collected into graded test tube. The injection rate was kept constant at 0.5 cm^3/min for 1 PV of injection; thereafter, it was increased to 1.0 cm^3/min for every 0.5 PV of injection till no water was observed at the effluent side. The amount of water recovered from the core holder, V_{water_rec}, was recorded. The residual water saturation, S_{wi}, was calculated with taking into account dead volumes of the system, V_d, such as supply lines, end plugs mass flow meter, etc. using:

$$S_{wi} = (V_{pv} - V_{water_rec} + V_d)/V_{pv} \tag{4.3}$$

The viscosity of the injected and produced fluids was measured using a rotational viscometer (Rheolab QC, Anton Paar USA Inc.) with a pre-installed double gap measuring system (DG42, Anton Paar USA Inc.). The density of the injected and produced fluids was measured by a mass flow meter (M13, Bronkhorst Cori-Tech BV) at the inlet and exit of the core holder. Surface tension of the injected and produced fluids was measured using the drop shape analyze (DSA 100, Krüs

GmbH) by the pendant drop technique (Waghmare and Mitra, 2010). The shear rate (100 s^{-1}) was selected as standard shear rate used in the literature (Cobos et al., 2009; Sorbie and Huang, 1991; Maia et al., 2009; Castro Dantas et al., 2006), so that it can easily compare WAE technique with previously used flooding reagents.

The internal shear rate, caused by the given injection rates used in the experiment, can be found from the known injection flow rate, sand pack dimensions, porosity and the estimated pore size. Hence, the superficial (or empty tube) velocity, U_o, can be calculated as (Darby, 2001):

$$U_o = \frac{Q}{A} = \frac{Q}{\frac{\pi d^2}{4}} = 7.309 \cdot 10^{-6}, \text{m/s} \tag{4.4}$$

Also, the velocity within the bed (i.e., interstitial velocity, U_{in},) can be calculated using porosity and the superficial velocity (Darby, 2001):

$$U_{\text{in}} = \frac{U_o}{\phi_{\text{run,n}}} \tag{4.5}$$

For Run #5, ..., Run #7 it can be found that the superficial velocity using porosity values would be equal to $2.188 \cdot 10^{-5}$ m/s, $2.071 \cdot 10^{-5}$ m/s, and $2.007 \cdot 10^{-5}$ m/s, respectively. Finally, the shear rate, γ, based on the given injection rate can be estimated using the formula for the shear rate at the inner wall of a Newtonian fluid flow inside a pipe of diameter d (or radius r) (Darby, 2001):

$$\gamma = \frac{8U_{\text{run,n}}}{d} = \frac{4U_{\text{run,n}}}{2r} \tag{4.6}$$

For Run #5, ..., Run #7 it can be found that the shear rate with selected injection rate would be equal to 6.687 s^{-1}, 6.482 s^{-1}, and 6.653 s^{-1}, respectively. Taking this into account, the viscosity presented in this Chapter of the paraffin oil, produced oil and emulsion has been measured at 6 s^{-1} in addition to 100 s^{-1}.

Table 4.1: Relevant parameters for unconsolidated sand pack samples used in flooding experiments.

Pack	WAE ratio	Porosity, %	Pore volume, cm^3	Mass of sand pack, g	Absolute permeability, Darcy	Permeability with residual water, Darcy	$S^{\ddagger}_{wi}$
Run #5	2:1	33.4	117.01	617.5	7.0 .. 7.5	5.5 .. 5.8	0.096
Run #6	4:1	35.3	123.83	599.4	7.2 .. 7.4	6.4 .. 6.8	0.085
Run #7	5:1	35.2	123.37	600.7	6.9 .. 7.0	6.8	0.085

‡ - Residual water saturation after oil saturation.

Initial water saturation and water flooding were completed using distilled water (DI) produced from a water purification system (PURELAB© Ultra, Elga Labwater, LLC). DI water used for this study has a density of 1000 kg/m^3(measured using mass flow meter (M13, Bronkhorst Cori-Tech BV)) and measured viscosity of 1.0 mPa·s at 500 s^{-1} shear rate and surface tension of 72.40 mN/m. Oil saturation was executed using paraffin oil (CAS Number 8012-95-1, obtained from Sigma-Aldrich Co. LCC) with a viscosity of 122.7 mPa·s and 120.5 mPa·s at 6 s^{-1} and 100 s^{-1} shear rate , respectively. The density of the paraffin oil was 868 kg/m^3 and surface tension of 29.85 mN/m. Stable oil-in-water emulsion (70.75 wt% oil and 29.25 wt% water with average oil drop size of 2.46 μm) was procured from a commercial provider (Quadrise Canada Corporation, Canada) (Patrick Brunelle (Quadrise Canada Corp.), 2012). It should be noted that the emulsion used for flooding was made from heavy oil which is noticeably different from the residual oil (paraffin oil). The emulsion had a viscosity of 1084.9 mPa·s at 6 s^{-1} shear rate and 495 mPa·s at 100 s^{-1} shear rate and density of 1014 kg/m^3. It was difficult to measure the surface tension of this emulsion using pendant drop method as symmetric drop generation was not achievable for a fluid of such high viscosity.

Three different ratios of water to emulsion slugs, 2:1, 4:1 and 5:1 were tested. For these tested WAE slug ratios, the water amount was kept fixed at 0.5 pore

volume (PV). Hence, the emulsion PV was varied accordingly to maintain the ratios between the water to emulsion slugs. As an example, 4:1 WAE slug would mean water with 0.5 PV and emulsion with $0.125(= 0.5/4)$ PV. In the case of 2:1 slug (Run #5), the WAE method has been applied only for two cycles, which amounts to cumulative injection of 1 PV of water and 0.5 PV of emulsion. In the case of 4:1 (Run #6) and 5:1 (Run #7) slug ratios, the WAE method was applied for three cycles, which amounts to 1.5 PV of water and 0.375 PV of emulsion for 4:1 ratio and 1.5 PV of water and 0.3 PV of emulsion for 5:1 ratio, respectively. It should be noted that at the end of each cyclic WAE process, only water injection has been performed, the amount of PV injected for each run is different. In addition, the effluent analysis has been performed to compare the viscosity and surface tension between the injected and the produced fluids.

4.3 Results and Discussion

The aim of this study was to demonstrate the efficiency of an enhanced oil recovery technique, viz., WAE flooding, using laboratory core flooding experiments. In this section, detailed results for WAE are provided and this technique is compared with traditional water flooding or with emulsion flooding alone. These provide a comparative indicator of the efficiency of the proposed WAE technique. First, a qualitative analysis was performed through actual visualization of the sand pack after the WAE flooding and later, quantitative data in terms of pressure profiles during water-alternate-emulsion injection and resultant oil recovered from the sand pack during WAE flooding was provided.

4.3.1 Qualitative analysis of WAE Flooding

Figure 4.2(a) shows the cross-section image of the actual sand pack corresponding to Run #5 (i.e., WAE ratio 2:1), which was removed from the core holder at the end of Run #5. This includes two cycles of WAE followed by $\approx$4.1 PV of water flooding. Visual inspection of the core pack suggests that there is a large build-up of the heavy oil component of the emulsion at the inlet section of the core. The hypothesis is that after the first cycle of WAE, further water injection for the next cycle causes water to interact with the emulsion available within the pore space of the sand pack. This destabilizes the emulsion resulting in phase segregation and thereby more of the heavy oil fraction of the emulsion is accumulated at the inlet section and the water phase of the emulsion is transported to the downstream section of the core.

(a)

(b)

Figure 4.2: Cross-section images of the sand pack (a) after complete WAE flooding with 2:1 ratio followed by water flooding up to 5.6 PV; (b) after complete water flooding followed by approximately 0.3 PV of emulsion injection. Here, the direction of injection is from left to right.

In contrast, when first traditional water flooding (≈3.5 PV of injection) followed by only emulsion injection (≈0.3 PV of injection) was performed, it was noticed that there is a piston like displacement of the resident oil and water phases by the injected emulsion. This is evident by a clear vertical front movement of the emulsion, as observed in Figure 4.2(b). Such piston-like displacement has been reported earlier for emulsified solvent flooding (Sarma et al., 1998; Shah et al., 2010; Mahmood and Brigham, 1987).

The amount of emulsion used in WAE flooding was both 0.52 PV and 0.3 PV for water flooding followed by emulsion flooding. The emulsion front progressed through the sand pack up to 9 cm in both cases. It indicates that for the alternative flooding, the emulsion stays inside the pack and slowly builds up the emulsion front at the inlet region cycle after cycle.

4.3.2 Quantitative Analysis of WAE Flooding

Pressure drop was continuously monitored and measured by differential (dP1 in Figure 3.1) and two inline pressure sensors(TP-2 and TP-1 in Figure 3.1) (FP2000 series, Honeywell International Inc.) across the core holder for each WAE ratio. Figure 4.3, 4.4, and 4.5 shows the pressure profiles for different WAE ratios along with the corresponding oil recovery curve. The raw pressure data obtained from the measurement has been processed using B-spline interpolation using graphical and data analysis software (Origin 9.1, OriginLab, Co.) to remove noise and smooth data, and the obtained values are plotted here.

In Figure 4.3, there is the graph where the left vertical axis is a percentage of original oil in place recovered from a porous media, the right vertical axis is a

pressure drop measured across the core holder and the horizontal axis is a volume of liquid injected normalized by a pore volume. The horizontal dashed lines indicate the location of the pressure jumps. There are two inflection points in the pressure drop curve which correspond to emulsion injection during the cyclic WAE process. During the first cycle, the introduction of the emulsion phase resulted in a gradual increase of pressure inside the core till the end of the emulsion injection with a resultant in total differential pressure rise of 12 psi. This pressure rise data is also confirmed by the visual inspection of the sand pack (Figure 4.2(a)) where most of the emulsion is plugged inside the pore-space which may result in the increase in overall pressure drop. This process has also been observed by others and is often referred as a blockage process (Decker and Flock, 1988). Also, the effluent analysis for this cycle suggested that the oil recovered from the core pack corresponds to paraffin oil only without any traces of the heavy oil phase of the emulsion. This again emphasizes that most of the emulsion is trapped at the inlet of the core pack as observed through visual inspection.

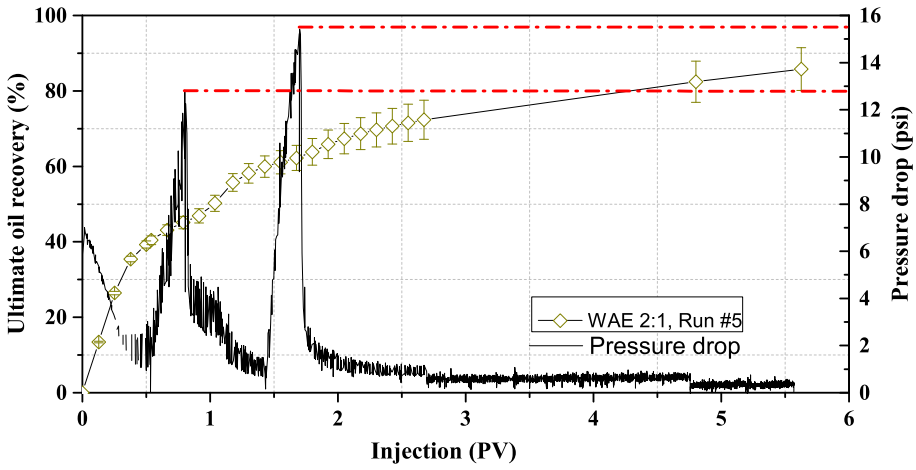

Figure 4.3: Variation of pressure drop across the core holder and the oil recovery with respect to PV of injected fluids, 2:1 WAE. The horizontal dashed lines indicate the location of the pressure jumps.

After the end of emulsion injection shown in Figure 4.3, water injection starts which is evident from the gradual drop in pressure across the core, allowing more oil to be recovered. This additional oil recovery is observed through the sudden change in the slope of the oil recovery curve during the start of the water injection. This pattern continues till the next WAE cycle, however the jump in the oil recovery is not as much as compared to the first cycle. The reason for comparatively higher recovery for the first cycle can be attributed to the much broaden pressure drop over 0.5 PV of water injection and higher oil availability compare to the following cycles. It confirms that the given emulsion blocks high permeable zones and redirects following water flooding to the oil saturated regions. Further water flooding breaks through the new regions and results in a pressure drop across the core holder after breakthrough. The oil recovery data shows that at the end of the second WAE cycle, the oil recovery from the core pack is around 60%. After the completion of the cyclic WAE process, water injection was always conducted to recover further resident oil. In this case, such water flooding eventually results in almost 86% recovery of the resident oil with only 0.5 PV of overall emulsion injection. The oil recovery for 2:1 WAE ratio can be compared with data presented in previous Chapter 3 involving direct emulsion flooding into a similar core holder (with slightly shorter internal length (284 mm (11.18 in)). It was found that this present technique produced higher oil recovery and more importantly using significantly less emulsion compared to direct emulsion injection of 1.01 PV used in previous experiment.

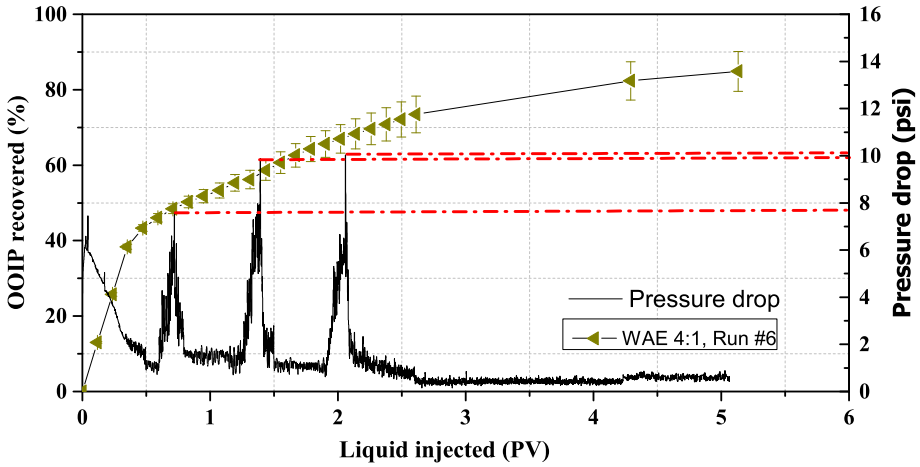

Figure 4.4: Variation of pressure drop across the core holder and the oil recovery with respect to PV of injected fluids, 4:1 WAE. The horizontal dashed lines indicate the location of the pressure jumps.

A similar trend in pressure drop was found for 4:1 WAE flooding, as shown in Figure 4.4. Since emulsion was injected three times during 4:1 WAE flooding, there are three inflection points which correspond to emulsion injection during the cyclic WAE process. During the first cycle, the introduction of the emulsion phase resulted in a gradual increase of pressure inside the core till the end of the emulsion injection with a resultant in total differential pressure rise of 8.3 psi. During both the second and the third cycle, the differential pressure across the core holder has increased to almost 10 psi which corresponds to the second and the third peaks in the pressure profile data. Also, in this case, no emulsion was observed at the effluent stream at the end of the first cycle which suggests the presence of a similar blockage process as observed for 2:1 WAE ratio has also occurred for this case. At the end of three cycle of WAE flooding, the recovered oil is ≈65% of OOIP and the final ultimate oil recovery equals to 85% of OOIP for overall 0.375 PV of emulsion injection.

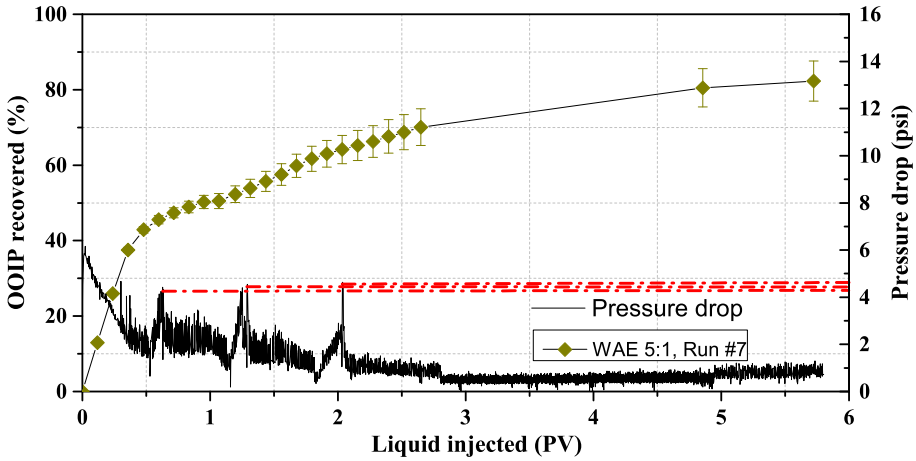

Figure 4.5: Variation of pressure drop across the core holder and the oil recovery with respect to PV of injected fluids, 5:1 WAE. The horizontal dashed lines indicate the location of the pressure jumps.

For the case of 5:1 WAE ratio, as observed for Figure 4.5, it was found that the pressure rise corresponding to each cyclic emulsion injection is almost three times lower than 2:1 WAE ratio. This can be attributed to the lower amount of emulsion injected in each cycle (0.1 PV). However, the overall oil recovery is similar to the other two ratios but with significantly less amount of injected emulsion ($\approx$0.3 PV). At the end of three cycles of WAE flooding, the recovered oil is $\approx$ 62% of OOIP and the final ultimate oil recovery equals to 82% of OOIP for overall 0.3 PV of emulsion injection.

4.3.3 Effluent Analysis[2]

Each effluent fraction, obtained from the different WAE flooding studies was analyzed to observe any change in density, viscosity and surface tension with respect to the original injected fluids. Here, the data for the 2:1 WAE flooding process is

[2]The photograph presented in this section has been published as conference paper. A. Baldygin, D. S. Nobes, and S. K. Mitra, "Oil recovery from porous media using emulsion",*The ASME 2014 International Mechanical Engineering Congress & Exposition*, IMECE2014-37248, 2014

provided and summarized in Table 4.2. A photograph of liquids injected and collected during during complete 2:1 WAE flooding is shown in Figure 4.6. Recovered emulsion is not present in a bottle, since it undergoes a separation process inside the porous media, as it was hypothesised in Section 4.3.1. It was found that the produced water, after the completion of two cyclic WAE flooding, is light brown in colour, which is quite similar to the emulsion colour. Recovered oil has dark yellow color, which is in between emulsion and produced water in a color scheme.

Figure 4.6: A photograph of liquids injected and collected during complete WAE flooding. From left to right: water, paraffin oil, emulsion, recovered oil, produced water.

The density of produced water is measured to be 970 kg/m^3 and viscosity is 1.2 mPa·s at 500 s^{-1} shear rate. Also, the surface tension of the produced water is 40.50 mN/m. It is observed that the density and the surface tension of the produced water are lower compare to the injected DI water, while its viscosity is higher. The measured density, viscosity, and surface tension of the recovered oil fraction at the effluent are 865 kg/m^3, 112.3 mPa·s at 6 s^{-1} shear rate, 112.0 mPa·s at 100 s^{-1} shear

Table 4.2: The physical properties of the liquids shown in Figure 4.6.

Liquid	Density, kg/m^3	Viscosity at 100 s^{-1}, mPa·s	Viscosity, at 6 s^{-1}, mPa·s	Surface tension, mN/m
Water	1000	1.0‡	-	68.40
Produced water	970	1.2‡	-	40.50
Paraffin oil	868	120.5	122.7	29.85
Recovered oil	865	112	112.3	29.85
Emulsion	1014	495	1085	n/d

‡ - measured at 500 s^{-1}.

rate, and 29.85 mN/m, respectively. It is found that the density and surface tension of the recovered oil is similar to the injected paraffin oil, while the viscosity is lower than the paraffin oil. These observations confirm that the emulsion blockage inside the sand pack and the surfactant present in the emulsion interacts with the injected DI water, thereby lowering its surface tension. The recovered oil has properties close to the the injected paraffin oil, which suggests that the heavy oil component of the emulsion remains trapped inside the core pack, with almost negligible amount being displaced out of the core holder.

The hypothesis stated in Section 4.3.1 is substantiated with effluent analysis, the water fraction recovered shows different surface tension and viscosity compared to the injected DI water. This may result in a change of the internal mobility ratio between the resident oil phase and the invading water phase, which may aid in recovering more oil from the core pack.

4.3.4 Comparison of WAE with Traditional Flooding

Figure 4.7 shows the cumulative recovery curves for the three different WAE ratios used in this present study compared with Chapter 3 results for water flooding, direct

emulsion flooding and water flooding followed by emulsion flooding. It is found that at least 20% more recovery can be achieved compared to traditional methods, be it water flooding or only emulsion flooding. It is also found that for a given oil recovery with any of the methods illustrated in Figure 4.7, the proposed technique of water-alternate-emulsion always requires significantly less amount of emulsion injection. For the studied parameters, it is observed that the most economical way, in terms emulsion usage, to recover oil is with 5:1 WAE ratio. In such injection strategy, only 0.3 PV of emulsion injection is required to obtain 82% of OOIP. Hence, this laboratory scale study shows promising technology breakthrough in terms of the development of an enhanced oil recovery process, which further needs to be field tested.

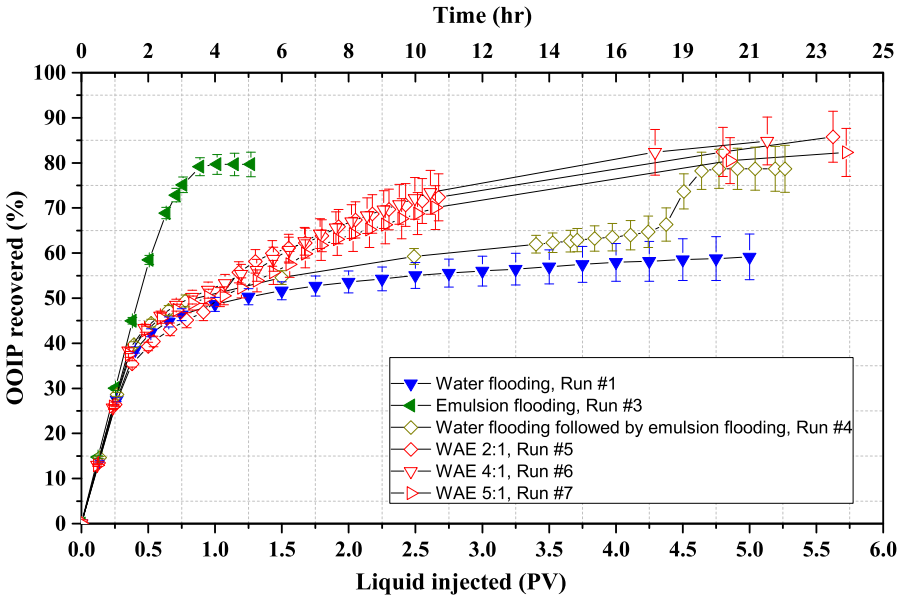

Figure 4.7: Cumulative recovery curves for WAE flooding and comparison with waterflooding, emulsion flooding, and waterflooding followed by emulsion flooding (presented in Chapter 3).

4.4 Conclusions

The present study reports an efficient technique for enhanced oil recovery with utilization of emulsion (oil-in-water) produced *ex-situ*. The developed technique, water-alternate-emulsion (WAE), was tested using laboratory core flooding system. Three different slug ratios, 2:1, 4:1 and 5:1, were experimentally investigated. The qualitative analysis of the sand packs after the WAE floodings shows that emulsion has separated inside the porous media and the heavy oil fraction of the emulsion has been trapped near the entrance region of the core. In addition from the effluent analysis, it can be assumed that the surfactant present in the emulsion combines with the injected DI water which further assists in removing the resident oil phase from the pore spaces.

The quantitative data suggests that one can achieve 22 % - 26 % more recovery with WAE compared to the traditional flooding process. In summary, the WAE flooding technique appears to be a promising enhanced oil recovery process which utilizes minimum amount of emulsion and recovers a significant portion of the resident oil. Further steps are needed to test the efficiency of this process in field reservoirs, which may have been abandoned after water flooding.

Chapter 5

Experimental flow visualization and pressure mapping of emulsion flooding with horizontal and vertical wells[1]

5.1 Introduction

The efficiency of emulsion flooding as a recovery agent (*ex-situ* produced oil-in-water emulsion) has been proved in previous Chapters 3 and 4. It was shown that emulsion flooding can potentially recover up to $\approx$ 85 % of OOIP at 0.375 PV of total emulsion injection and $\approx$ 4.5 PV of total water injection using efficient method of injection - water-alternative-emulsion (WAE) (Guillen et al., 2012; Son et al., 2014; Ponce F. et al., 2014). Other methods for injection, such as direct emulsion flooding, presented in Chapter 3 and water flooding followed by emulsion (Qiu and Mamora, 2010; Willhite et al., 1980) or surfactant/polymer flooding (Samanta et al., 2012; Kumar et al., 2012; Bryan and Kantzas, 2009; Krumrine and J.S., 1983), also showed promising results. However, the time required to recovery the same

[1] A version of this chapter has been prepared for submission to the journal. A. Baldygin, D. S. Nobes, and S. K. Mitra, "Experimental flow visualization of emulsion flooding with horizontal and vertical wells",*Journal of Petroleum Science and Engineering*, 2014

amount of oil is significantly higher. Close to 97 % of resident oil at $\approx$ 22 PV of liquids injected can be recovered using emulsion made of a synthetic oil (Shell Tivela 460) (Guillen et al., 2012).

One of the important properties of the emulsion is the drop size distribution (DSD). The conventional methods which were previously used to get the drop size distribution reported presence of single particle group (Wasan et al., 1978; Moradi et al., 2014; Romero et al., 2011; Moradi et al., 2011; Romero et al., 2006). Compared to the previously used methods used for particle analysis, currently available particle analysers count particles individually (Anderson et al., 2013). They are able to distinct different sizes and to provide total number of particles (Anderson et al., 2013). It can be hypothesised that due to the availability of particle-by-particle analyzer the presence of two distinct groups of oil particles in emulsion can be now measured.

There are two ways for emulsion interaction within porous media. Either it can increase mobility of resident oil (Mandal et al., 2010a) or block high permeable regions (McAuliffe, 1973). In previous experiments, a biaxial (Chapter 3 and 4) and Hassler core holder (Qiu and Mamora, 2010; Ko et al., 2014) have been used to simulate reservoir conditions during emulsion flooding. Even after post-experimental analysis on collected sand packs in Chapter 4, the *in-situ* interactions during emulsion flooding process are still unclear. Understanding of the emulsion flooding process at the tertiary stage without ceasing experimental progress or changing experimental parameters (repacking), its interaction with oil saturated porous media, require nondestructive testing (NDT). It is limited in the core holders previously used in full-scale studies.

The way of studying interactions within porous media without causing damage to the porous media can be by using multi-dimensional experimental setups. At the micro-scale, the converging-diverging quartz capillary tube can be used to understand the physics of emulsion flow at the scale of the pore size (Cobos et al., 2009; Romero et al., 2011). At the macro-scale, reservoir on a chip (ROC) with glass beads (Guillen et al., 2012) or artificially constructed porous media (Mei et al., 2012) can be used to mimic porous media stricture, which is preset in the reservoir. Experimental data collected from these experiments allows the validation and development of fundamental theory about emulsion flooding. Thus, the efficiency of emulsion flooding at given reservoir conditions can be predicted. However, the pore volume utilized in these studies are about 0.822 cm^3 (Mei et al., 2012) or 2.980 cm^3 (Guillen et al., 2012) which is even less than in biaxial and Hassler core holder. A step further in terms of the experimental scale can be by utilizing a two dimensional (2D) core holder with the pore network 10 times larger than in conventional biaxial or Hassler core holders.

A two dimensional core holder shows how the front of the *in-situ* flow spreads through the porous media (Santosh et al., 2007; Doorwar and Mohanty, 2011; Robert et al., 2006; Chaudhari et al., 2011b; Naderi and Babadagli, 2011). The 2D core holder represents a sectional cut of a real reservoir with dimensions obtained from scaling parameters (Hadia et al., 2008b; Islam and Farouq Ali, 1989). The side wall of the 2D core holder can be transparent or solid piece with pressure/temperature ports (Butler and Chung, 1988; Li and Mamora, 2010). It is thin enough to assume that the flow is distributed in two directions only and there is no influence (flow) in the third direction. Another aspects, such as well configura-

tion, can be studied in addition to the flood front studies. Vertical injection - top or bottom horizontal production (VI-THP and VI-BHP), horizontal injection - vertical production (HI-VP), horizontal injection - horizontal production (HI-HP), vertical injection - vertical production (VI-VP) wells configurations can experimentally investigated (Santosh et al., 2007, 2008; Hadia et al., 2008a,b).

Flow visualization and pressure mapping of the emulsion flooding process can help to understand the internal dynamics happening inside the porous media. It also provides answers as to how well a configuration can affect on efficiency of emulsion flooding or how dynamics of emulsion flooding front through previously abandoned regions depends on well configuration and what is the increase in ultimate oil production. The previously utilized experimental setup has been modified accordingly to provide answers. In this Chapter, the results of water flooding followed by emulsion flooding experiments for three different configurations are presented. Details for the experimental setup components and materials and methods used to carry out experiments are provided. Results consist of visual image analysis, pressure data analysis, effluent analysis and internal flood front velocity analysis. Collected results provide one step further towards developing theory for the scale-up of emulsion flooding technique to the field application (Islam and Farouq Ali, 1989, 1992; Abou-Kassem and Farouq Ali, 1995; Akin et al., 2000).

5.2 Experimental Setup

A hydraulic schematic of the system developed for this study, previously described in Chapter 3, is a further modification of the concept of the core flooding system. The core block was modified compared to the previous configuration. The biax-

ial core holder has been replaced with a two dimensional (2D) core holder using the "plug-and-play" advantage of the developed system described earlier. A photograph of the final version of the experimental setup is shown in Figure 5.1. Final configuration of experimental setup prepared for the flow visualization and pressure mapping of emulsion flooding with horizontal and vertical wells is shown. It has an external light source to guarantee uniform light intensity on a core holder surface. Pressure demodulators are also added to process signals from 15 pressure sensors and to demodulate and amplify the input signals to a $\pm$ 10 Vdc full-scale output.

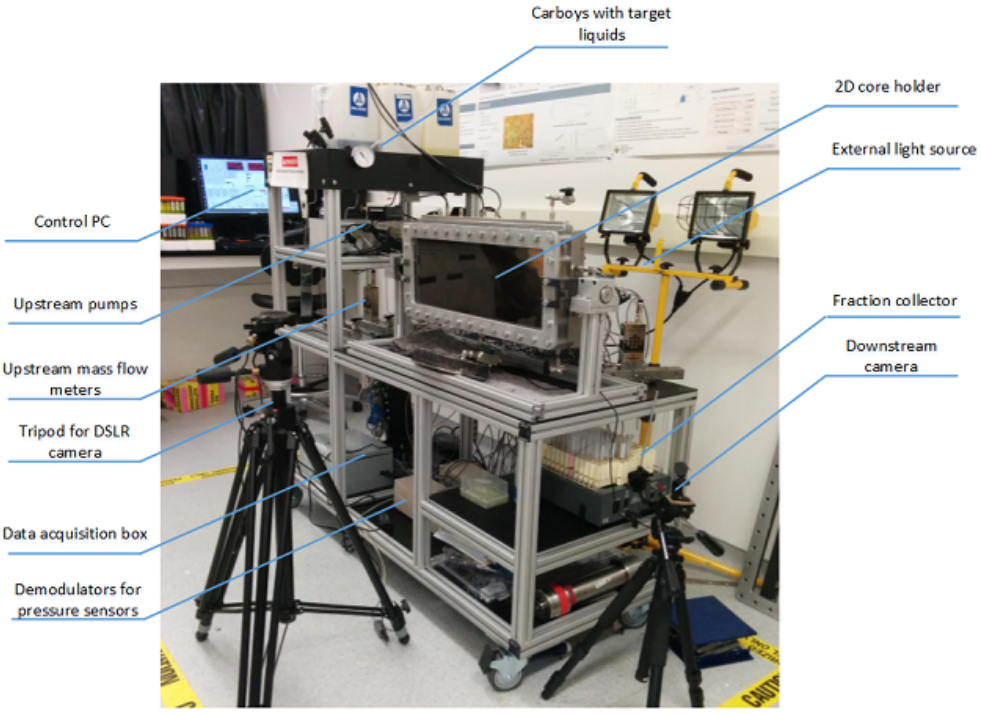

Figure 5.1: A photograph of experimental setup used for the core flooding experiments with 2D core holder.

The software with graphical user interface (GUI) used to control the system was developed based on the original version, previously discussed. Additional channels have been added to record data from extra pressure sensors installed on a two 2D core holder. Since the single experiment requires more than three days con-

tinuous running, it is crucial to provide sustained monitoring. The software was modified compared to previously released version used in previous Chapter 3 and 4 to have remote visual monitoring via a web-camera (Lifecam Studio Webcam, Microsoft, Corp.) and system monitoring via email reporting of important system parameters. The command line simple mail transfer protocol SMTP email client (sendEmail (Zehm, 2009), Brandon Zehm) was integrated into software and used for notifications. Email notifications and camera allows to monitor and to control the system 24 hours a day.

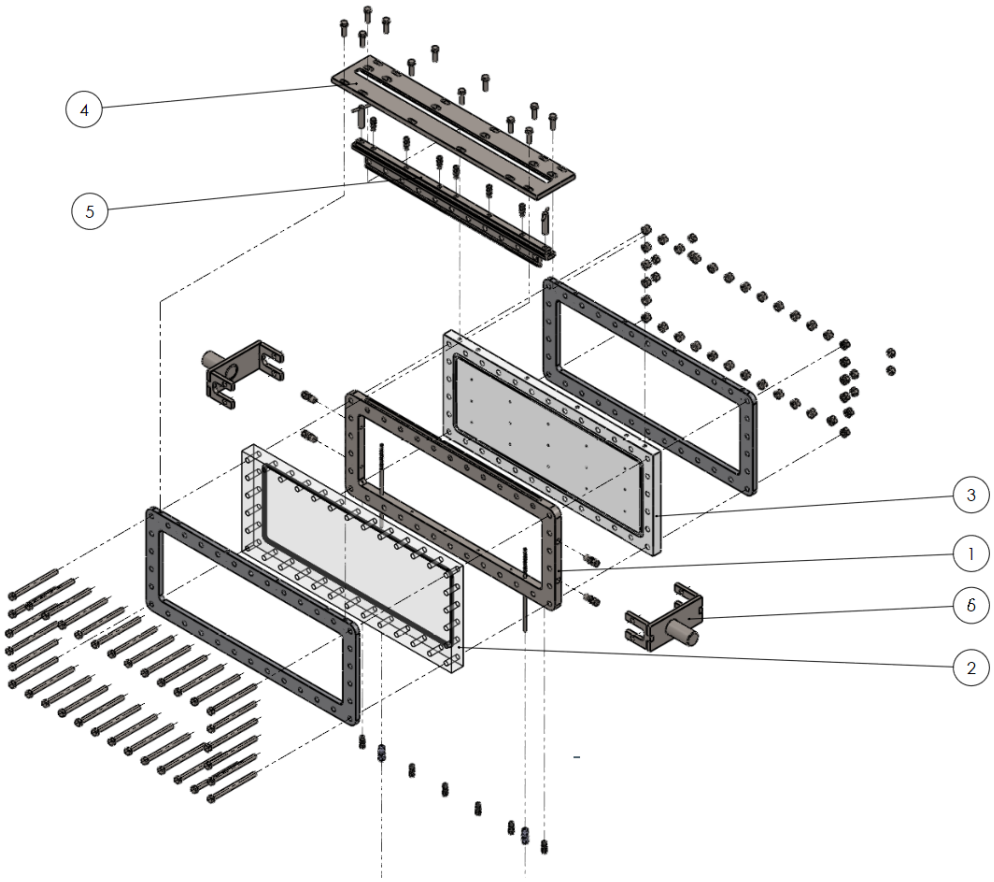

Figure 5.2: Exploded view of the 2D core holder (1) main frame with profiled slot, (2) cast acrylic wall, (3) stainless steel wall with pressure ports, (4) top cap, (5) profiled cap, and (6) holder.

The exploded view of the 2D core holder, shown in Figure 5.2, has an internal

void space of 600 x 200 x 20 mm. The main components, such as the main frame with profiled slot, cast acrylic wall, stainless steel wall with pressure ports, top cap, profiled cap, and holder are numbered. Compared to others Chaudhari et al. (2011a); Veerabhadrappa et al. (2013b), the current design has a modified configuration for the packing of sand. It has a main frame with profiled slot at the top for pouring sand inside the void space. Once the core holder is fully packed, the profiled cap closes the core holder and the top cap places on top of it. By tightening bolts, an additional compression allows to achieve a denser pack. The holder is mounted into a horizontal base (Part No. 8020-5930, 80/20 Inc.). It allows to fix at any angle and to rotate 360 degrees around horizontal axis. Well configurations can be reconfigured using multiple ports on side walls, two at the top, at the left and at the right side.

In order to recover oil from a reservoir, injection and production wells must be drilled into a reservoir. Wells used in the current study are designed in agreement with industrial requirements written for reservoirs with expected conditions close to the unconsolidated sand packs (King, 2009). Stainless steel tubes of 6.35 mm (1/4 in) outer diameter (OD) with perforations of 1.59 mm (1/16 in) were used during the core flooding experiments. The hole pattern, shown on Figure 5.3, was designed using existing recommendations (Cosad, 1992; Parrott and Walton, 2001). During the flooding process, wells were held in place with bored-through male connector (6.35 mm (1/4 in) tube OD x 1/4 in male NPT, SS-400-1-4BT, Swagelok, Co.) and were wrapped with stainless steel wire cloth (wire diameter 53.34 μm (0.0021 in.), opening size 73.66 μm (0.0029 in.), mesh size 200 x 200) (Article No. 54058, G. Bopp USA, Inc.) to provide sand control (Voll et al., 1998).

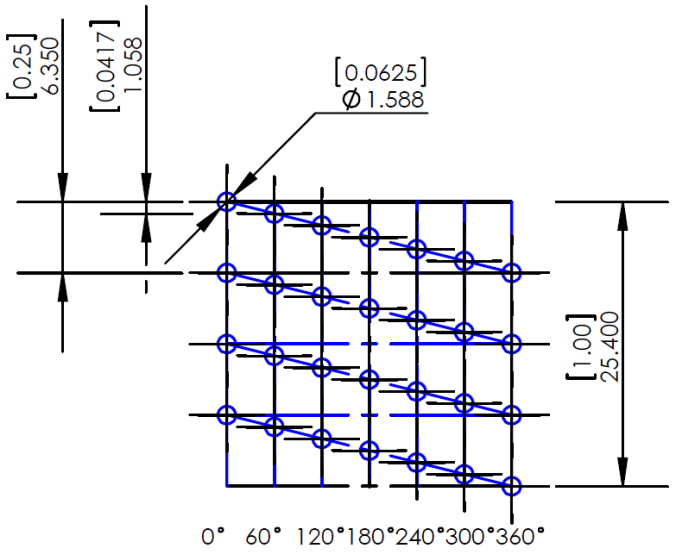

Figure 5.3: Pattern for hole perforation in wells (28 holes/in^2).

A cast acrylic sheet was installed on one side of the core holder to allow visualization of emulsion flooding with horizontal and vertical wells. A digital single-lens reflex (DSLR) camera (D7100, Nikon Canada, Inc.) with 18-105mm lens (Nikon Canada, Inc.) is mount on a tripod (Part# 028B, Manfrotto Co.) with a professional head (Part# 229, Manfrotto Co.) to capture the process of emulsion flooding and record any changes which may occur inside porous media. The images collected during flooding process have 6000 x 4000 resolution with 24 bit depth and sRGB color representation. The back plate of the 2D core holder has 15 pressure ports for monitoring the 2D pressure in the sand pack. Differential pressure sensors with replaceable membrane (DP15, Validyne Engineering Corp.) were chosen with an open end to the atmosphere. Pressure maps were generated using collected data from pressure sensors. These maps accompany data from the image analysis and provide better understanding of emulsion flooding process. Pressure sensors are named as $CP_{i,j}$, where i is the row and j is the column. Reference images with

coordinates for pressure sensors are shown in Figure 5.4. These configurations, vertical injection - vertical production (VI-VP), vertical injection - horizontal production (VI-HP), horizontal injection - horizontal production (HI-HP), were chosen as a continuation of existing experimental results with well configurations using 2D core holder for water flooding Santosh et al. (2007). It allows a comparison of results for the water flooding and benchmarking of the developed system.

(c)

Figure 5.4: Reference images with coordinates for pressure sensors in (a) VI-VP; (b) VI-HP; (c) HI-HP configuration.

The processing code for image analysis was developed using commercial multi-paradigm numerical computing environment (MATLAB R2014a, MathWorks). This code provides data for the velocity of the flood front at three vertical locations for each well configuration. The locations can be obtained by individual bases for each run, based on image resolution. The code follows the same processing steps for each run: cuts three slices for each individual image, reads out the red-channel of the image, converts the image to the binary image based on threshold, detects emulsion edge using the Prewitt method (Pre), calculates the location for the end in horizontal direction, and scales it to the actual coordinate in millimeters. Finally, it loads the obtained data and fits and plots a cubic polynomial function with robust fitting options and centers and scales (normalize) for displacement versus time. The order of a cubic polynomial function was adjusted manually from case to case to reduce numerical error. In order to obtain velocity, it finds the first derivative of the polynomial function and scales from mm/min to m/s and plots.

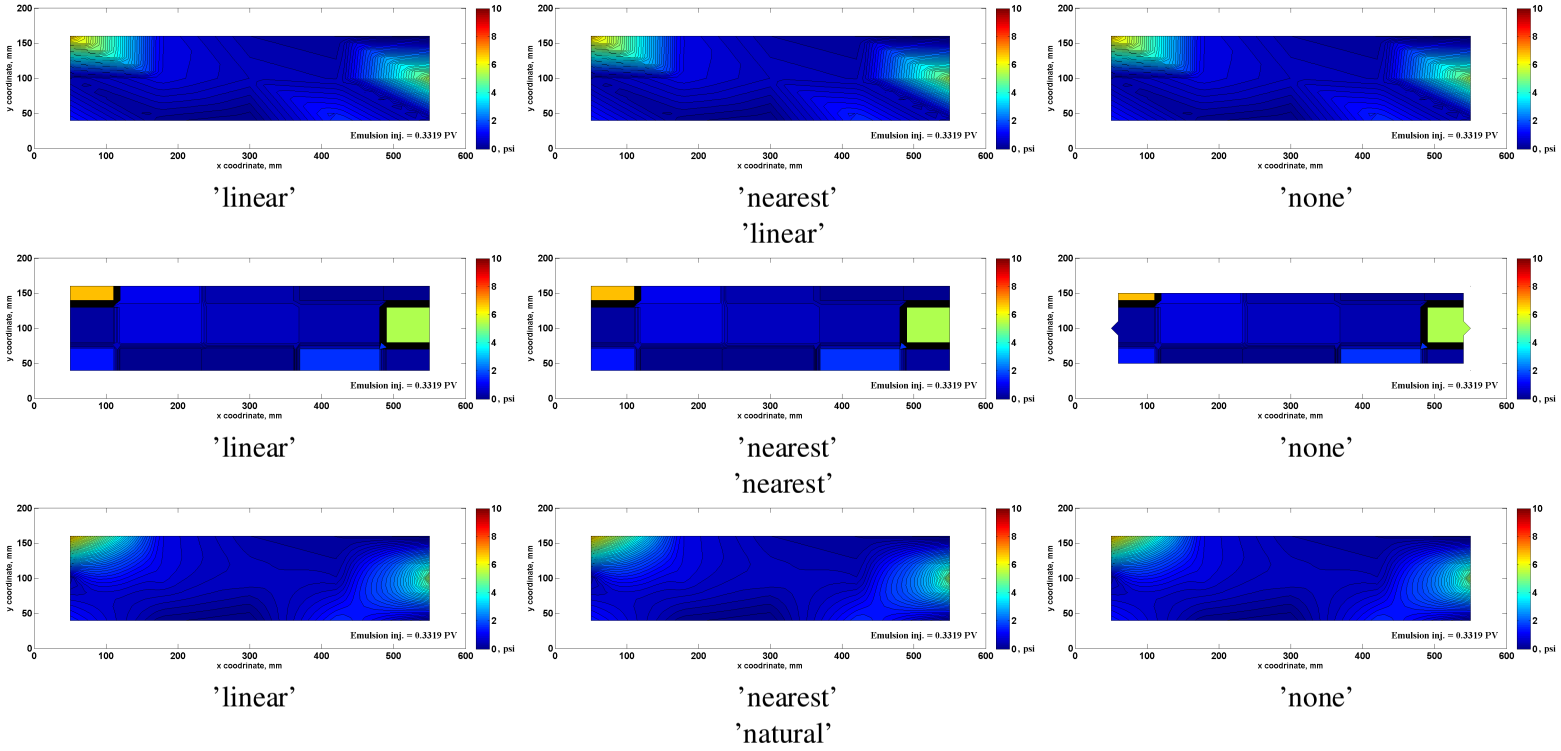

Figure 5.5: Comparison of pressure maps collected with different settings in $scatteredInterpolant$ function.

Another code was developed to analyze data from pressure sensors collected during emulsion flooding. Collected data from pressure sensors along with coordinates was prepared for plotting as filled contour plot using scatteredInterpolant function. This function allows to perform interpolation on a 2-D scattered data set.

All nine configurations for $ScatteredInterpolant$ function were investigated and are compared in Figure 5.5 to identify optimal configuration with a representation close to reality. There are three interpolation methods: linear, nearest and natural. Nearest method showed coarse results compared to two others and showed lack of representative information about *in-situ* processes. Natural neighbor interpolation re-distributes pressure equally in radial direction compared to linear interpolation with axial distribution. It is also expected that pressure follows fluid fronts. Considering images collected over different runs and presented later in this Chapter, the 'nearest' option was selected for interpolation method and 'linear' option for extrapolation method.

5.3 Materials and Methods

In this section, the details of materials and methods used to prepare and carry out experiments are provided along with a standard characterization for core flooding experiments. This data includes physical properties of utilized liquids, porosity, permeability and residual oil saturation.

The suppliers for liquids, water, oil and emulsion, were chosen the same as in previous Chapters. In order to have visible difference between liquids compared to previously reported data, the distilled water (DI) was dyed with liquid concentrate of yellow/green dye (Part # 106001, Bright Dyes, Division of Kingscote Chemicals

Inc.). Concentration was chosen as 1 ml per 1 L of DI water. The paraffin oil was dyed with liquid concentrate of red dye (Part # 506250-RF4, Bright Dyes, Division of Kingscote Chemicals Inc.). Concentration was chose as 10 ml per 5.5 L of oil. Emulsion was not dyed because of its natural high contrast compared to oil and water.

Viscosity, density and surface tension of dyed liquid were measured and compared with pure liquids to ensure that the introduced dye does not critically effect physical properties of the liquids. A rotational viscometer (Rheolab QC, Anton Paar USA Inc.) coupled with double gap measuring system (DG42, Anton Paar USA Inc.) was used to measure viscosity. A mass flow meter (M13, Bronkhorst Cori-Tech BV) was used to measure density. A drop shape analyzer (DSA 100, Krus GmbH) was used to measure the surface tension of dyed liquids using the pendant drop technique (Waghmare and Mitra, 2010). The physical properties of liquids are summarized in Table 5.1. Physical properties of dyed and pure paraffin oil have 0.67 % and 0.83 % deviation for surface tension and viscosity, respectively. Dyed water has 5.6 % deviation for surface tension. Considering difficulties associated with measuring surface tension of water, it is an acceptable deviation. Hence, both liquids can be used for the experiments without significant effect on results due to presence of dye.

The emulsion used for experiments was produced *ex-situ*. It is stable and oil-in-water type with composition of 70.75 wt % oil and 29.25 wt % water (Corp.), 2012). Quadrise Canada Inc. provided the drop size distribution which is shown in Figure 5.6. It shows normalized a Gaussian curve, which is available in the literature as was discussed earlier. A microscopic image of diluted emulsion in phos-

phate buffered saline pH 7.4 (PBS) solution and stabilized with surfactant (Tween 20, CAS Number 9005-64-5, obtained from Sigma-Aldrich Co. LCC) is shown in Figure 5.7. The optimal concentration was found to be 2 μL of emulsion in 49 μL of PBS with 1 μL of surfactant. Two dimensional groups can be identified from this image. First group shows the size of the drops close to 2 μm, while second group stays in a range of 10 μm. It is an evidence that the current emulsion has bimodal structure, namely two groups of particles. In order to prove the hypothesis for presence of bi-dispersal structure, emulsion has been tested using two particle analyzers (qNano and qMicro, Izon Science Ltd.). These particle analyzers use different membranes to count particles individually and provide total count per volume of liquid. Emulsion was diluted in 25 % PBS. Obtained results are presented in Figure 5.8. It provides evidence that emulsion consists of two distinct group of particles around 1.5 μm and 9 μm. The obtained curve is different compared to the supplied. Previously reported data in the literature does not provide such evidence either (Wasan et al., 1978; Romero et al., 2011; Moradi et al., 2011; Romero et al., 2006). DSD is an important parameter in fundamental theory of emulsion flooding. Having data different from existing in the literature leads to the reviewing existing

models which covers emulsion flooding process with the presence of single group of oil particles. However, it does not consider as part of the field of study in the current research project.

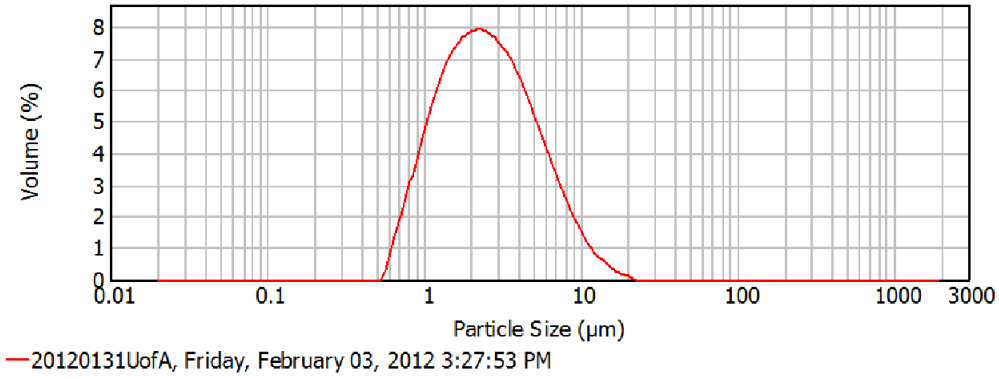

Figure 5.6: Drop size distribution measured by Quadrise Canada Inc.

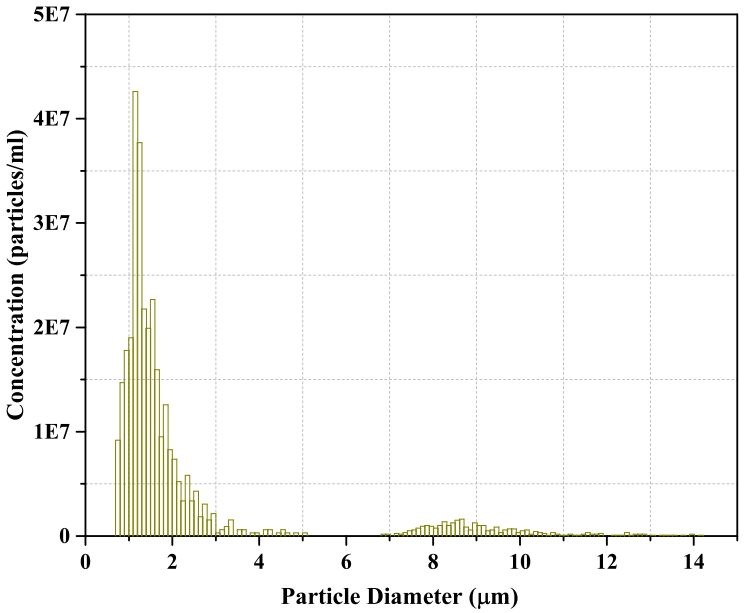

Figure 5.8: Drop size distribution measured using two particle analyzers (qNano and qMicro, Izon Science Ltd.).

The 2D core holder has been packed with unconsolidated sand from two batches. For Run #8 and Run #9, dry water-wet silica sand (Ottawa IL sand deposit, US sieve size #10 (100-140), particle size 53-251 μm) was used and for Run #10, dry water-wet testing silica sand (AGSCO Part #SSS000080-B5MBNK, US sieve size #10 (100-140), particle size 53-251 μm) was used. In order to prove that these sands can form similar porous media structure, an automatic pore size analyses (PoreMaster 33, Quantachrome Instruments) was used to measure the pore size distribution. Identical distributions were found for two batches, as it is shown in Figure 5.9. The pore size has distribution from 0.003 μm to 109.71 μm and 0.003 μm to 107.51 μm with an average 12.631 μm and 17.27 μm for silica sand and testing silica sand, respectively. Thus, sand packs would have similar pore size distributions and wetting properties.

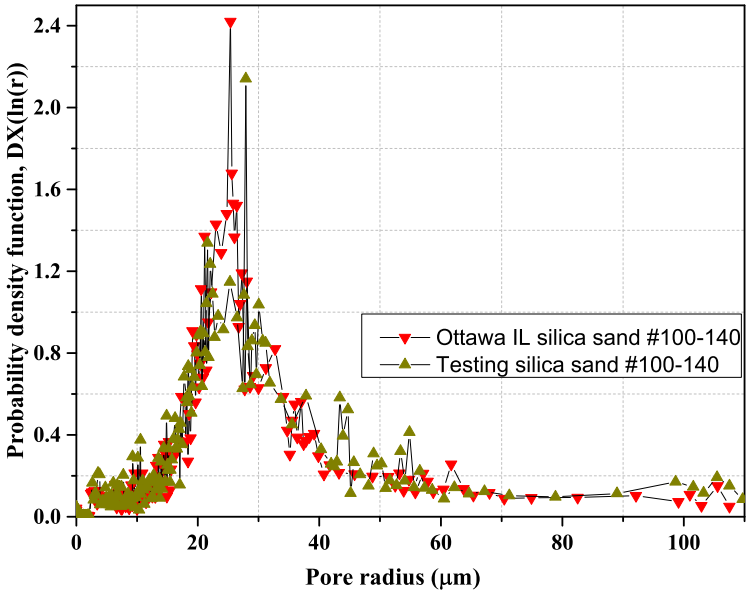

Figure 5.9: Pore size distribution of studied silica sands.

The sand packing process was different compared to previously described for biaxial core holders. The core holder was oriented vertically and fixed into the base. Dry sand with known mass was poured into the 2D core holder through the slot located at the top of the main frame. A concrete vibrator were applied on a stainless steel side of core holder for 15 minutes to create dense pack. Additional sand was added during this process, if required. At the end of this process, the slot was covered with profiled cap and compressed with top cap using bolts.

In order to saturate the core holder with water and estimate the pore volume, one side was connected to the vacuum pump (117, Labconco Corp.) and another one to a vacuum gauge. The vacuum pump was turned on for 60 minutes to guarantee vacuum level at 4 kPa absolute (28 in. mercury gauge). Once the desired vacuum level was reached, the vacuum pump was disconnected and a reservoir with a known volume of water was connected. The mass of the reservoir was measured before and

Table 5.2: Relevant parameters for unconsolidated sand pack samples used in flooding experiments.

Pack	Well configuration	Porosity, %	Pore volume, cm^3	Mass of sand pack, g	Absolute permeability, Darcy	Permeability with residual water, Darcy	$S^{\ddagger}_{wi}$
Run #8	VI-VP	35.4	847.1	4107.5	0.973 ± 0.063	0.497 ± 0.088	0.114
Run #9	VI-HP	34.6	827.7	4159.0	0.630 ± 0.083	0.248 ± 0.006	0.022
Run #10	HI-HP	34.3	820.1	4179.2	0.468 ± 0.074	0.379 ± 0.053	0.057

‡ - Residual water saturation after oil saturation.

after connection using portable balance (SPE6001, OHAUS Canada, Co.). Taking into account the density of water and the difference in volume before and after and internal dead volumes for fittings and the core holder, the pore volume was recorded.

The procedures for absolute permeability, permeability with residual water saturation and residual water saturation after oil saturation are identical to the previously discussed for biaxial core holders. The only difference in flow rates, the flow rate for oil saturation was kept at 1.75 cm^3/min and was changed to 2.00 cm^3/min at the end of oil saturation process. Relevant parameters for unconsolidated sand pack samples are summarised in Table 5.2.

5.4 Results and Discussion

The main objective of this study was to understand the behavior of emulsion flooding process in a 2D and identify the effect from well configuration on ultimate oil recovery and *in-situ* velocity profiles. The modified system has been used to carry out experiments. In this section, detailed results for visualization experiments with three well configurations, vertical injection - vertical production (VI-VP), vertical injection - horizontal production (VI-HP) and horizontal injection - horizontal production (HI-HP) have been provided along with *in-situ* the pressure mapping analysis. Since the data for the water flooding has been reported before (Santosh et al., 2007), this work focuses mainly on post water flooding process - emulsion flooding. The water flooding at 1.75 cm^3/min was performed up to 2.05 PV, 2.54 PV and 2.12 PV of water injection for VI-VP, VI-HP and HI-HP, respectively, and continued with emulsion flooding at 1.00 cm^3/min.

Image analysis was performed to compare collected photographs at different stages of experiment and understand the *in-situ* interactions. A pressure mapping analysis was used to provide support to the image analysis. Also, the effluent collected into test tubes was analyzed and effect from the configuration. The quantitative analysis is given from analysis of velocity profiles which has been compiled using processing code.

5.4.1 Visual Analysis

An example snapshot from the emulsion flooding process after water flooding is shown in Figure 5.10. The direction for the liquid flow is from the left to the right, and injection and production well was installed on the left and right side, respec-

tively. The emulsion flood front can be identified due to high contrast between emulsion, oil and water. Trapped oil is an oil saturated region which is surrounded with low permeable zones. The region preferably saturated with water is named as water saturation region. A morphologically unstable interface between emulsion and oil/water present in a porous media forms a pattern, emulsion channeling (Blackwell et al., 1959). Locations for velocity measurements and wells and over all dimensions are also shown in Figure 5.10. The dark colour represents emulsion, yellow color represents water and red color represents oil saturated regions. During sand packing process different sand patterns can be formed, as it is shown in Figure 5.10.

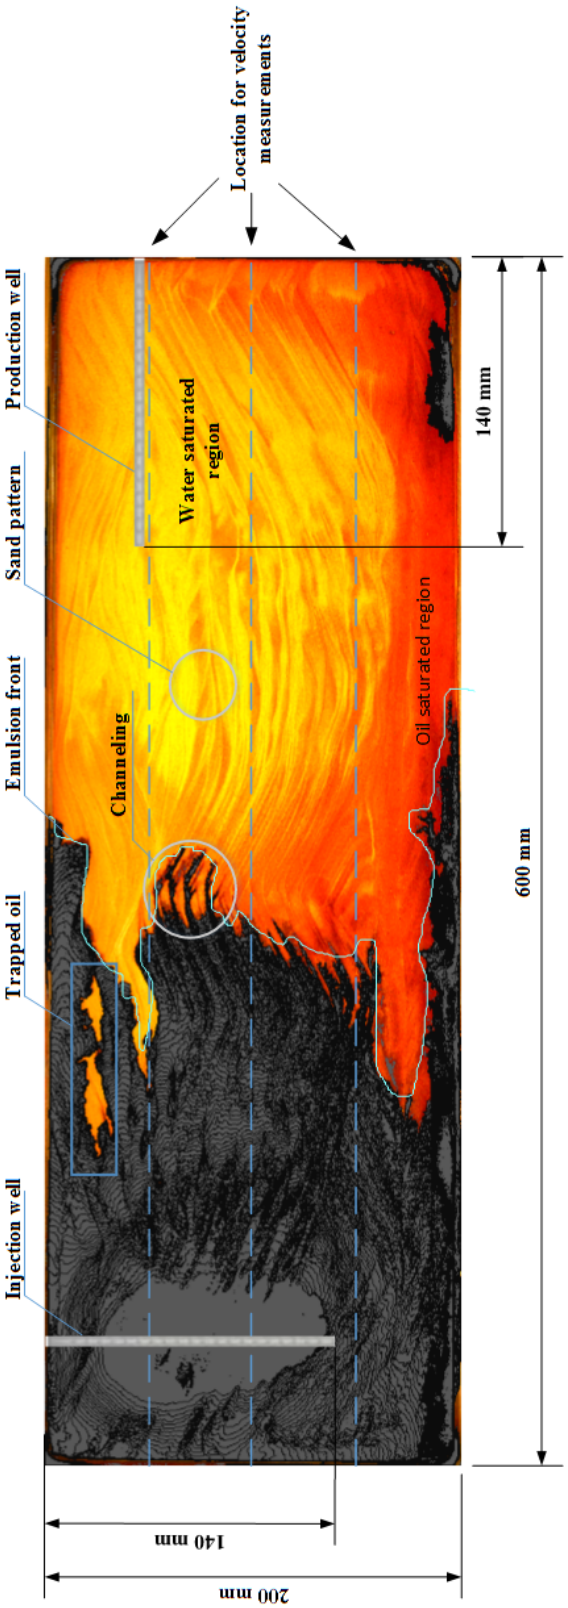

Figure 5.10: An example snapshot from the emulsion flooding process after water flooding.

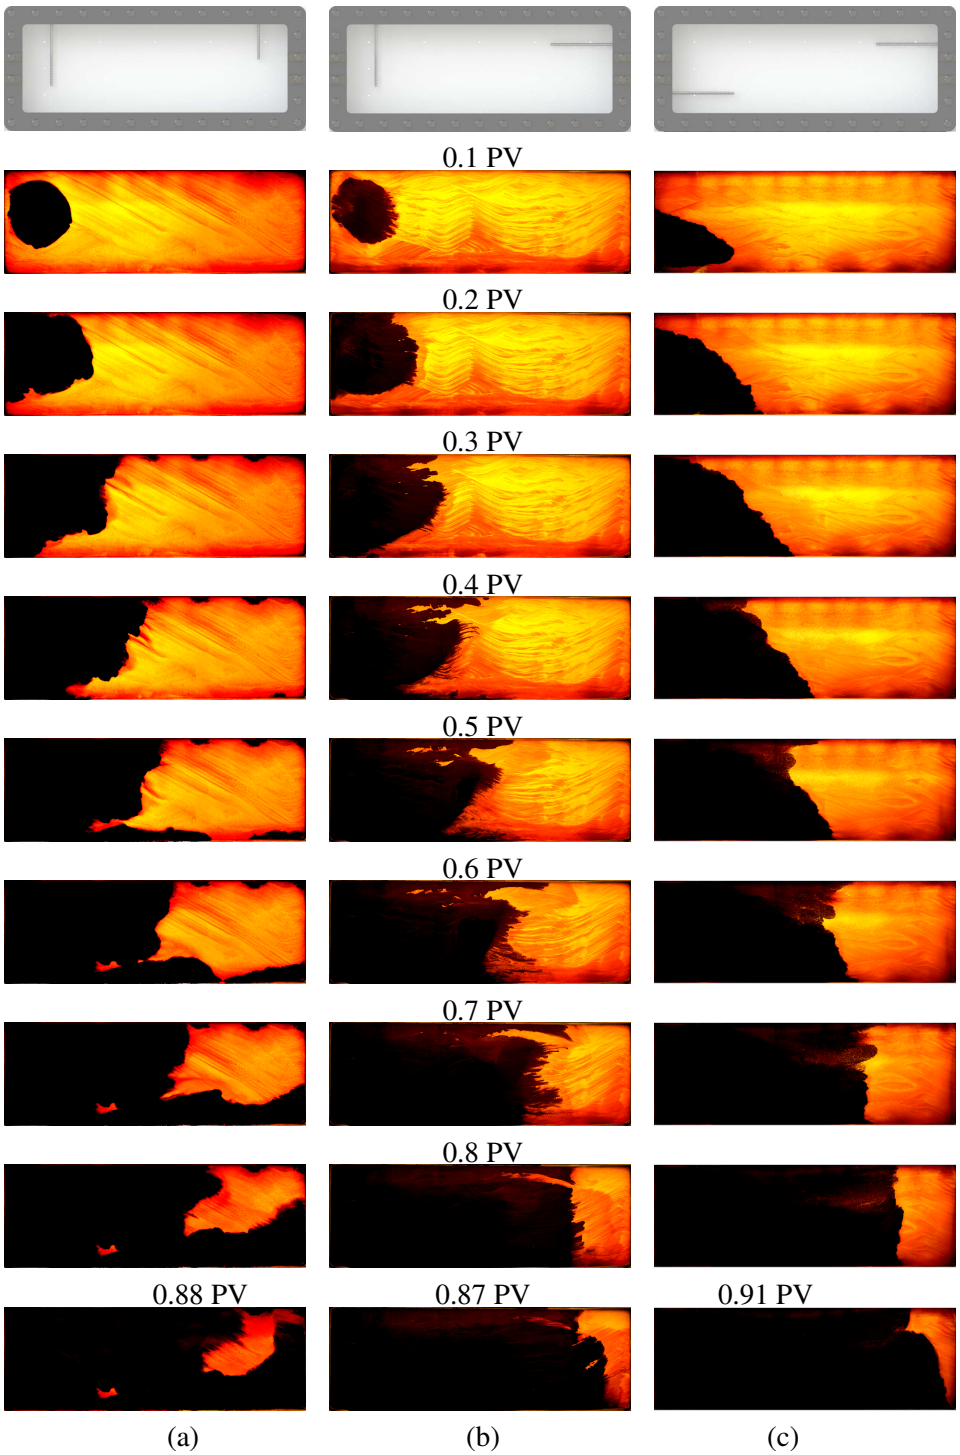

Figure 5.11: Cross-section images of the sand pack for different configurations: (a) VI-VP; (b) VI-HP; (c) HI-HP.

The photographs in Figure 5.11 (a)-(c) show snapshots of the 2D core holder at different pore volumes of emulsion injection for the studied configurations. Well configuration for each column is shown in the first image. Injection wells were half-perforated for vertical injection configurations and fully perforated for others with previously discussed perforation pattern.

In general, the pattern for the emulsion has similarities for VI-VP, VI-HP and HI-HP at the beginning of injection process, as it is shown in Figure 5.11 for 0.1, 0.2, and 0.3 PV of emulsion injection. The emulsion fills a region close to the left boundary first and then progresses towards the production well. For VI-VP, emulsion uses boundaries at first, due to slippage along the wall formed after water flooding process. It caused oil to be trapped inside the reservoir for VI-VP and VI-HP, as it is shown on last images in Figure 5.11. Emulsion pushes oil through the sand pack and forms a new oil saturated front. It can be observed compare images for 0.2 and 0.3 PV of emulsion injection.

An emulsion can block high permeable zones first during flooding process and re-direct post-flooding into high oil saturated regions. There is evidence of emulsion channeling in VI-VP and VI-HP configurations, as it is shown in Figure 5.11 (a) and (b). During water flooding water saturated channels inside the sand pattern are formed. The *in-situ* process at the scale of pore can be described as, oil drops present in the emulsion start to coalesce when the emulsion interacts with porous structure full of water and surfactant concentration drops down to a critical level. The result of this process is a significant local viscosity reduction for the emulsion. Taking into account that injection flow rate remains the same, local pressure reduction can occur in accordance with Poiseuille equation. This process can cause local

instabilities (Blackwell et al., 1959; Weitz et al., 1987) for the flow and the interface between two liquids cannot be predicted easily and channeling can form. Collected images support this hypothesis.

While HI-HP showed least oil production during water flooding, shown in Figure 5.11 (c), less high permeable zones were formed. As a results, the emulsion front has piston-like behaviour (Sarma et al., 1998; Shah et al., 2010; Mahmood and Brigham, 1987) and no channeling can be observed. Similar results were obtained during analysis of extracted sand packs from biaxail core holder in Chapter 3.

Flow visualization shows that VI-VP has a higher recovery during the water flooding process. However, emulsion flooding was not effective and caused oil to be trapped behind the emulsion front. At the same time, HI-HP was the most stable method for the emulsion injection after water flooding process.

5.4.2 Pressure Maps

Data collected from 15 pressure sensors was analyzed and plotted as filled contour plot. The filled contour plots represent the pressure map inside the 2D core holder, as it is shown in Figures 5.12 - 5.20, at given amounts of emulsion injected into porous media. From analysis of the data it was found that the maximum pressure gained during emulsion flooding inside the core holder is different from configuration to configuration. The maximum pressure drop across the core holder was found to be 9.5 psi, 59.4 psi and 114.4 psi for Run #8, Run #9 and Run #10, respectively. The color bars on the contour plots are set for three ranges 0 to 10 psi, 0 to 60 psi and 0 to 115 psi, respectively to the maximum pressure for each configuration. The difference in pressure drop scale from experiment to experiment is due to initial

conditions of porous media prior emulsion flooding. In Run #8 with VI-VP configuration, most of the oil was washed out during water flooding, even close to the boundaries. It allowed emulsion to penetrate through porous media without resistance, slipped along boundary and resulted in 10 psi pressure rise. While for Run #9 with VI-HP configuration, sand pack was still highly oil saturated, as it is shown in Figure 5.11 (b), after water flooding, emulsion at first blocked high permeable zones and proceeded with a piston-line flood front pattern. It resulted in a continuous pressure rise up to 59.4 psi at the end of emulsion flooding process. Similar was to Run #9 was found for Run #10 with even higher rise up to 114.4 psi.

The pressure during VI-VP rises after the initiation of the injection process and reaches a maximum around 0.4 PV of emulsion injection, as it is shown in Figure 5.15. After this point, pressure returns to the initial point. Comparing the pressure map with cross-section images for VI-VP, it can be seen that the emulsion slips across the boundary after 0.4 PV of emulsion injection and the drop in pressure values happened at the same time. Hence, there is *in-situ* bypassing process during VI-VP configuration.

For other configurations, VI-HP and HI-HP, pressure raises from the start of the emulsion flooding process and continues to a maximum by the end of injection, as it is shown in Figure 5.20. The direction of pressure contours has similarities with the emulsion front shown in the cross-section images. For HI-HP configuration in Figures 5.17 and 5.18, the front of emulsion goes with the same angle to the horizontal plane. Similar contours are found in the pressure maps. However, there are still differences in the data. A low pressure gap in the pressure data is observed for all configuration compared to the image data with continuous emulsion slug along

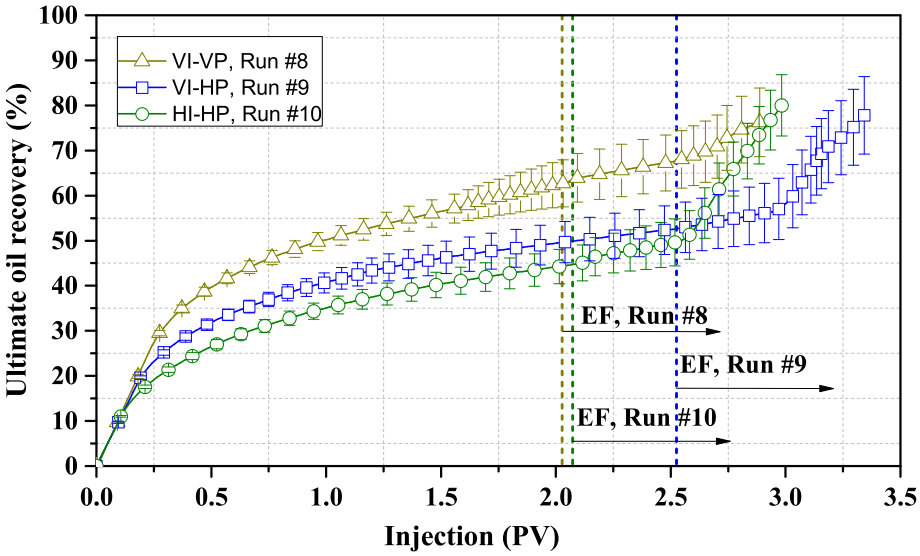
the flow direction. This can be due to the lack of data close to the boundaries where emulsion is possibly trying to slip through and builds up internal pressure. Due to the the lack of data points between pressure sensors and close to the boundaries, clear answer cannot be outlined.

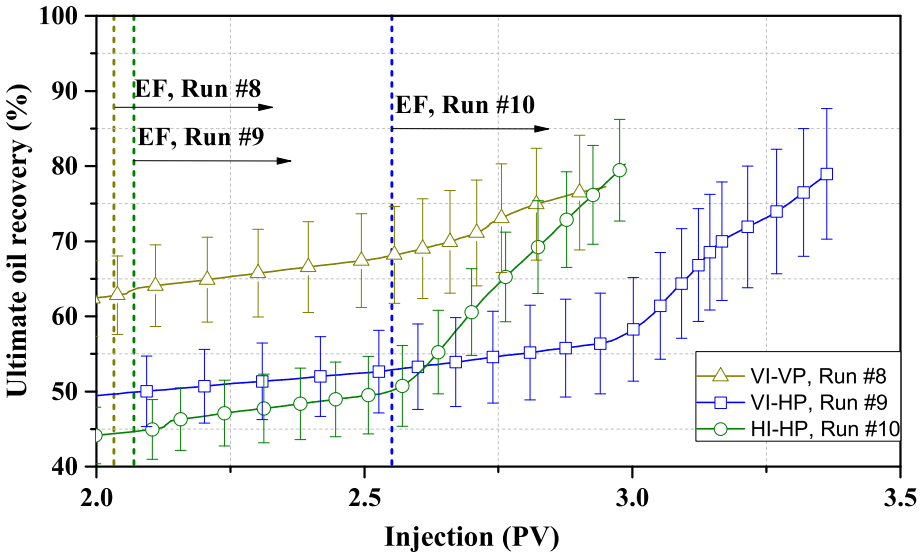
5.4.3 Effluent Analysis

Compared to the previous effluent analysis undertaken in previous experiments with 1D core holder, for the 2D core holder, the process of gravity segregation was stimulated using a centrifuge (Part #EW-17414-21, Cole-Parmer Canada, Inc.). The test tubes collected with fraction collector were centrifuged at 4000 rpm for one minute. The configuration with one minute and 4000 rpm was found experimentally as the most time-efficient.

Figure 5.21 (a) shows the ultimate oil recovery curves for the three different well configurations used in a 2D core holder. The data for recovery curves was collected from the test tubes after centrifuge. In order to compare data from different experiments, the injected volume was normalized using respected pore volume (PV). In terms of oil recovery during water flooding, it was found that VI-VP is the most efficient configuration. At least 19 % more can be recovered compare to others at 2 PV of water injection. This result mainly can be due to a delayed break through point and significantly larger distance between wells surfaces in horizontal direction.



(a)



(b)

Figure 5.21: Ultimate oil recovery curves for water flooding followed by emulsion flooding at different well configurations: (a) complete flooding process and (b) emulsion flooding process after water flooding.

Figure 5.21 (b) shows a zoomed view of the recovery trends. VI-VP configuration is not as efficient for the emulsion flooding as for the water flooding, only 14 % can be recovered at 0.9 PV emulsion injection. For the studied parameters, it is observed that the most efficient configuration for the emulsion flooding is HI-HP, almost 34.75 % of OOIP can be additionally recovered from reservoir. The ultimate oil recovery for VI-VP, VI-HP and HI-HP are 77.2 %, 78.9 % and 80.2 %, respectively. Emulsion injection was ceased for each run, once it appeared at the effluent side. There is a delay in oil recovery after the emulsion is introduced to the porous media. Oil and water require time to form new fronts inside the porous media and initially only water is present in the effluent.

Similar observations were made from image analysis and pressure mapping analysis. The lowest pressure drop across the core holder measured during emulsion flooding was found in VI-VP configuration, where emulsion flooding was found to be ineffective process in terms of oil recovery. While the pressure drop across the core holder gradually increases in VI-HP and HI-HP configurations up to 59.4 psi and 114.4 psi, respectively, and caused higher production rates. Hence, the *in-situ* pressure rise has connection to the efficiency of emulsion flooding process.

5.4.4 Quantitative Analysis

In order to estimate the behavior of emulsion flooding and provide a reasonable explanation for the velocity profiles, reference photographs are taken after oil saturation was completion and after water flooding completion at different configurations. These are shown in Figure 5.22. In addition, the last column shows evolution of the fractal interface of emulsion injection collected using commercial image analysis

software (Image-Pro Premier 9.1, Media Cybernetics, Inc.). The interface shows the boundaries of emulsion filled regions collected from each image. The background for the interface is post water flooding condition. The denser region means slower progress for the interface over singe time step.

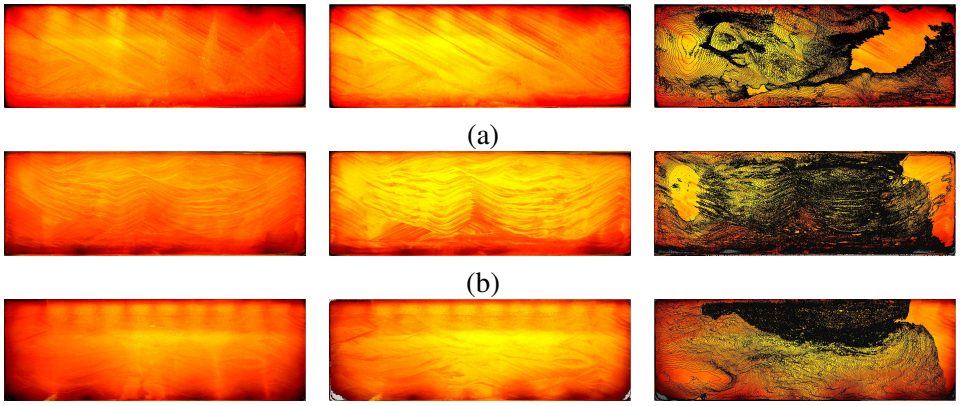


Figure 5.22: Left column shows sand pack prior to water flooding, central column shows sand pack prior emulsion flooding, right column shows evolution of interface of emulsion injection in (a) VI-VP configuration; (b) VI-HP configuration; (c) HI-HP configuration. Here, the direction of injection is from left to right.

After water flooding, most of the oil was washed out from central part of the core holder as represented by the yellow dyed water presented in Figure 5.22 (b). The least amount was for HI-HP, the most was for VI-VP, as it can be noticed on Figure 5.22 (a) and Figure 5.22 (c) and was previously confirmed with effluent analysis.

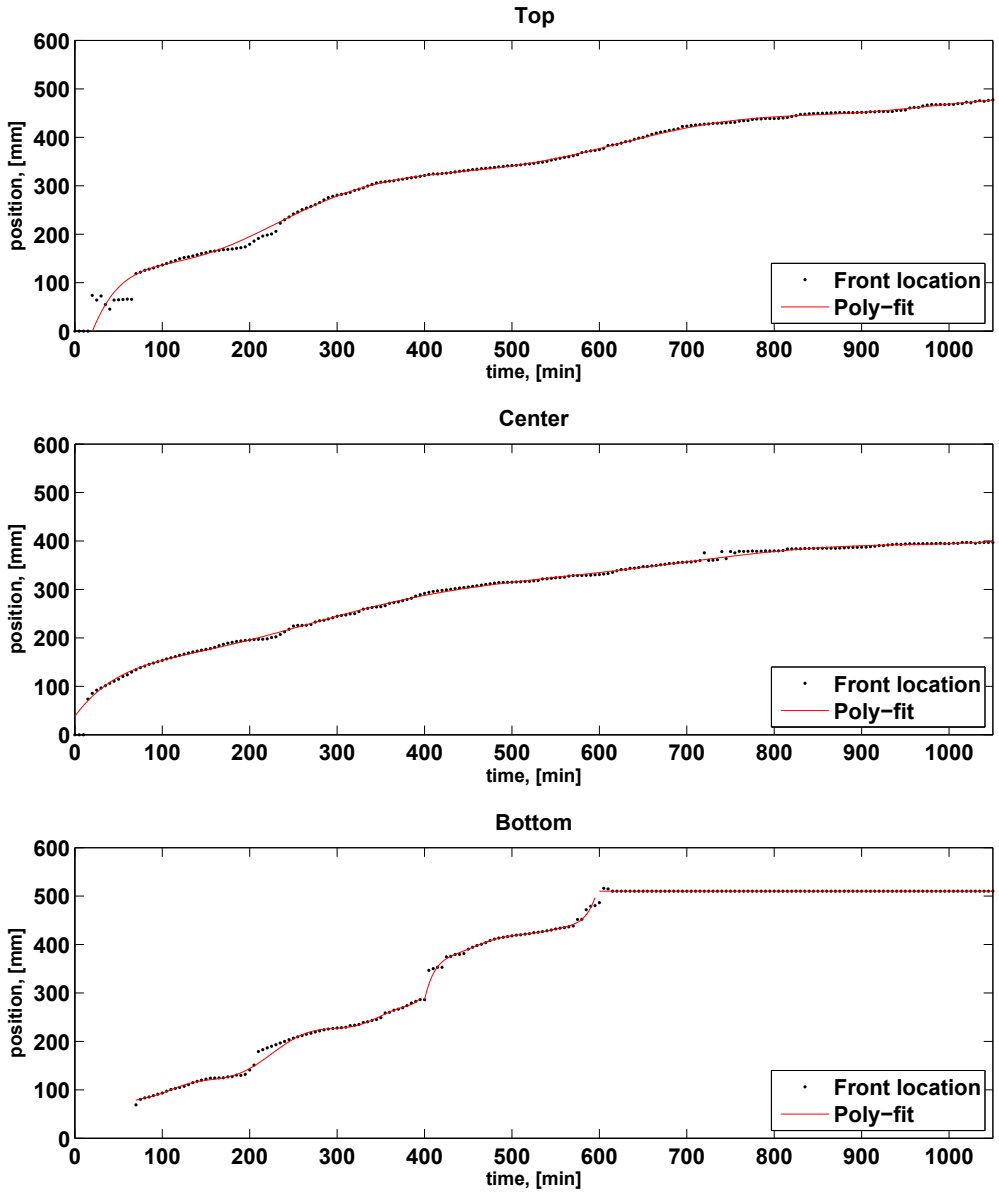

Figure 5.23: Emulsion front position versus time at three locations of a sand pack (a) top; (b) center; (c) bottom, as it is shown in reference Figure 5.10, for VI-VP configuration.

The position of the front plotted over the time for VI-VP configuration is shown in Figure 5.23. The position for the flood front follows a smooth curve for top and center locations. It also remains constant for bottom location at the 600 min due to a reflected flow from the right boundary. The order of cubic polynomial function fit is nine for top and eight for center location. For the bottom, the curve was divided into three regions, from 0 to 480 min, from 480 to 600 min and from 600 to ongoing. The orders for cubic polynomial function fits are nine, eight and seven, respectively.

The position of the front plotted over time for VI-HP configuration is shown in Figure 5.24. The position for the flood front follows smooth curve for top and center locations. There are some offset point at the top. The order for cubic polynomial function fit is nine for top and seven for center location. For the bottom, the curve was divided into two regions, from 0 to 480 min, from 480 to ongoing. The orders for cubic polynomial function fits are six and seven, respectively.

The position of the front plotted over time for HI-HP configuration is shown in Figure 5.25. The position for the flood front follows smooth curve for all three locations. The order for cubic polynomial function fit is 9, 7 and 6 for top, center and bottom location, respectively.

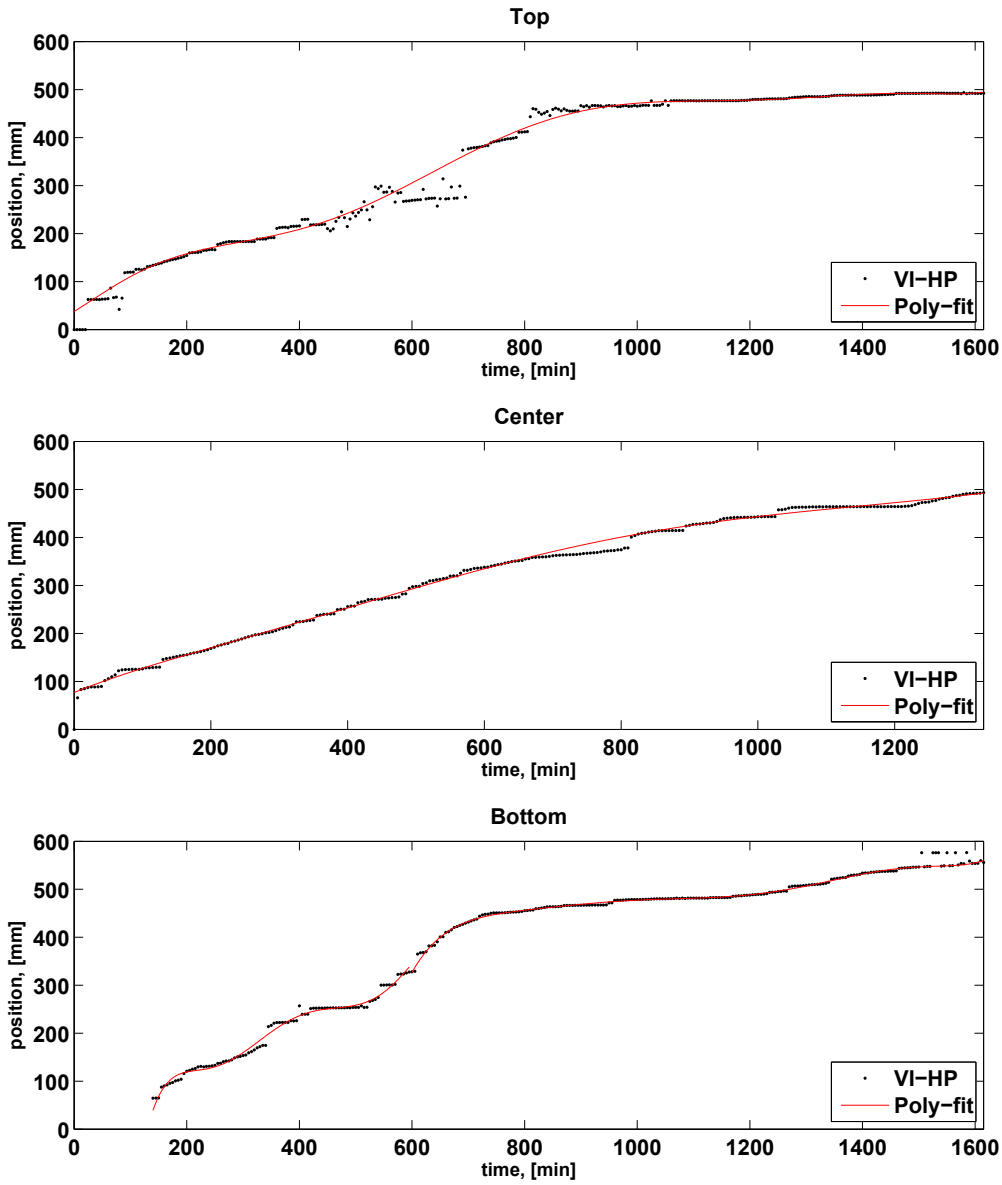

Figure 5.24: Emulsion front position versus time at three locations of a sand pack (a) top; (b) center; (c) bottom, as it is shown in reference Figure 5.10, for VI-HP configuration.

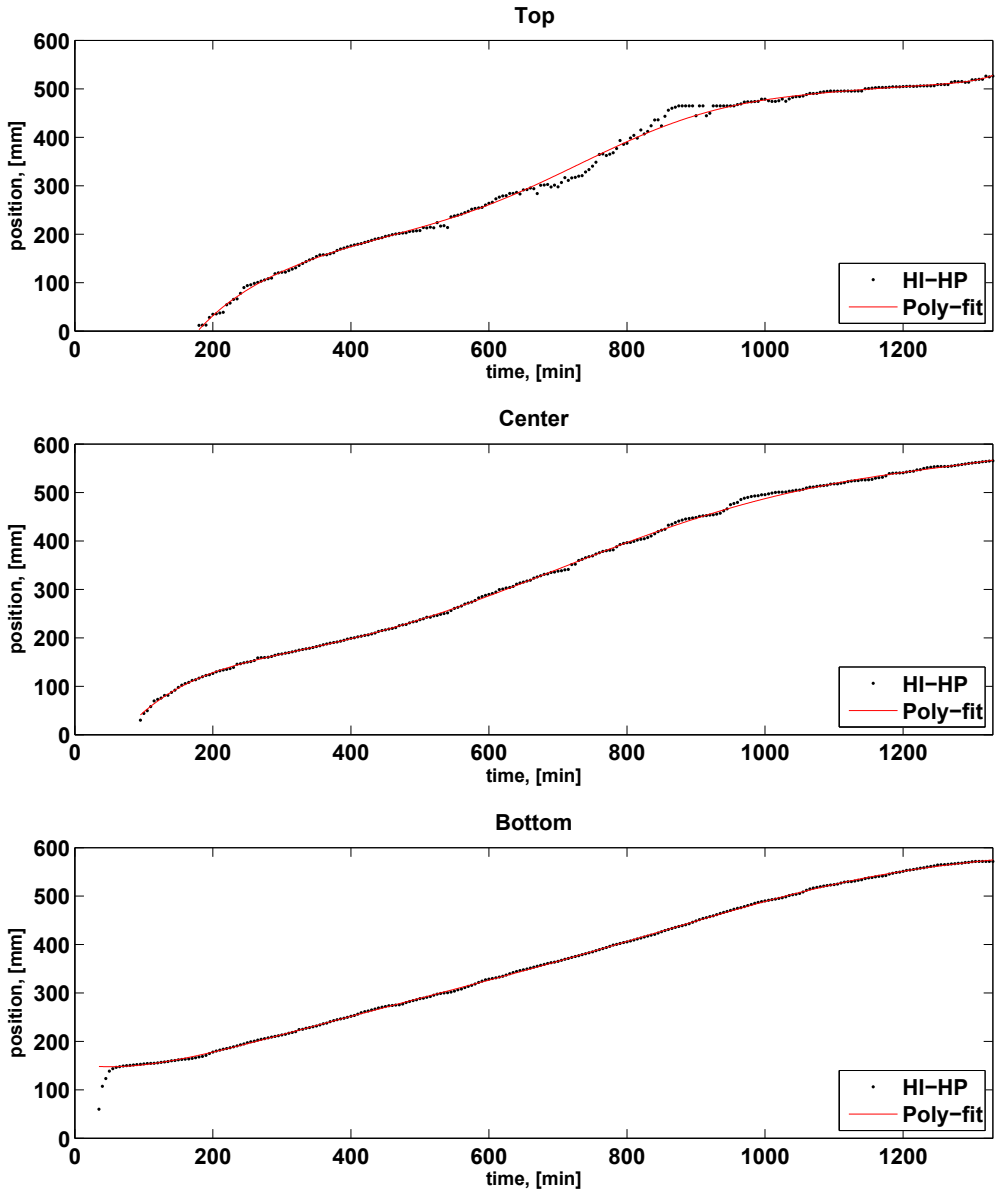

Figure 5.25: Emulsion front position versus time at three locations of a sand pack (a) top; (b) center; (c) bottom, as it is shown in reference Figure 5.10, for HI-HP configuration.

The derivatives of the collected cubic polynomial function fits were calculated to generate velocity profiles of the emulsion flood front. Figure 5.26 shows the velocity profiles versus volume of emulsion injected, collected at three locations, top, center and bottom, for each well configuration using custom developed code. The reference level for the velocity can be identified using parameters of sand packs from Table 5.2 and expected pore size distribution reported above. The superficial velocity, $U_{\text{ref,n}}$, taking into account emulsion injection flow rate, Q (1.0 cm^3/min), porosity, $\phi_{\text{run,n}}$, and geometry of sand pack (h - height and w - width) can be written as (Darby, 2001):

$$U_{\text{ref,n}} = \frac{Q}{h \cdot w \cdot \phi_{\text{run,n}}} \tag{5.1}$$

For Run #8, Run #9 and Run #10 it can be found that superficial velocity can be estimated as $1.177 \cdot 10^{-5}$m/s, $1.204 \cdot 10^{-5}$m/s, $1.215 \cdot 10^{-5}$m/s, respectively for the emulsion flooding process. For the water flooding process with flow rate equal to 1.75 cm/m^3 during Run #8, Run #9 and Run #10 the superficial velocity can be estimated as $2.06 \cdot 10^{-5}$m/s, $2.107 \cdot 10^{-5}$m/s, $2.126 \cdot 10^{-5}$m/s, respectively. These numbers are close to the values reported earlier in previous Chapter. The superficial velocities are plotted along with emulsion front velocity for all configurations as a reference velocities.

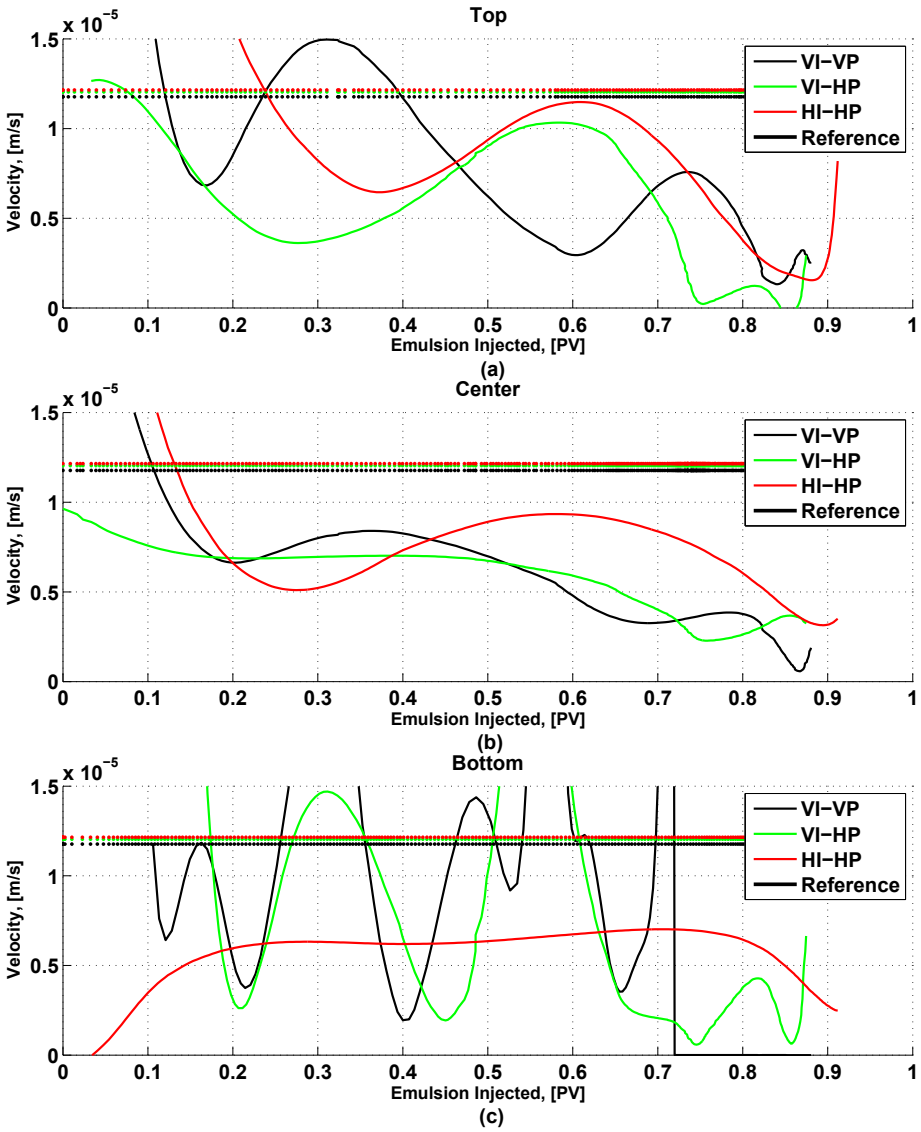

Figure 5.26: Emulsion flood front velocity at three locations of a sand pack (a) top; (b) center; (c) bottom, as it is shown in reference Figure 5.10

Velocity profiles, in Figure 5.26 (a), follow the same trend for all configurations. They fluctuated during the fronts movement across the core and slowly went down at the end of process as the front was getting closer to the production well. This can be due to presence of resident oil and its interactions with emulsion. It can be observed, that the profile was more stable for VI-HP configuration, as the least amount of oil can be observed in Figure 5.22.

Due to the presence of previously abandoned regions after water flooding at the center of the sand packs, as shown in Figure 5.22 central column, front velocity values are fluctuating close to the reference velocity level. The amplitude of fluctuations is smaller compared to the top profile, Figure 5.26 (b).

The most stable velocity profile was obtained for VI-HP configuration. Velocities for VI-VP and HI-HP follow similar trend with higher dispersion for HI-HP configuration. Compared to the top level, the velocities profiles behave more stable due to the presence of only a single liquid, water, in the porous media. By the end of emulsion flooding, front velocity stabilizes and all configurations end in the same region.

The most unstable trends for the velocity profiles were found at the bottom reference level for VI-VP and VI-HP configurations, where most of the resident oil was accumulated after water flooding, as shown in Figure 5.26 (c). However, HI-HP shows a smooth and stable curve with values close to the reference level. Horizontal injection for the emulsion allows the use of boundary conditions to guarantee improved stability for the front. From interface observation, Figure 5.22 the right column,it can be seen that emulsion progresses as piston like along the bottom surface without any instabilities. That observation can lead to the stable velocity

profile.

As it was found from the image analysis, pressure mapping and effluent analysis the most efficient and stable configuration for the water flooding followed by emulsion flooding is HI-HP. The stability of velocity profiles may also lead to the efficiency of enhanced oil recovery process, as it is also the most stable configuration.

5.5 Conclusion

The flow visualization and pressure mapping study has been carried out to investigate the effect from the well configuration on emulsion flooding after water flooding. Three different configurations for well orientation have been tested and analysed in terms of oil recovery and stability of the emulsion front. Visual analysis reports the pattern for the emulsion and shows *in-situ* processes happening inside porous media, such as oil trapping and channeling. Due to the presence of the red dye in oil, the region in front of emulsion turns into a red color during flow visualization. In a field test emulsion can be used to create regions with low permeability and the new well can be placed in front of the emulsion. It allows continue of oil recovery with traditional water flooding method.

Effluent analysis shows that vertical injection (VI) - vertical production (VP) is an efficient method for water flooding. However, emulsion flooding provides higher efficiency rate for the reservoirs with higher concentration for resident oil. It can be concluded that horizontal injection (HI) - horizontal production (HP) enhances oil recovery higher than any other configurations. The quantitative analysis suggests that stable velocity profile for an emulsion front can be achieved in HI-HP

configuration. While vertical injection (VI) - horizontal production (HP) and VI-VP has similar profiles to each other. It can be due to the same configuration for injection point. Obtained results can be used in future during field trials or in theory developments for the emulsion flooding.

Chapter 6

Conclusion and Future Work

6.1 Conclusion

This study was aimed to investigate the efficiency of using emulsion flooding as a recovery agent. After reviewing the literature for physical processes inside oil reservoirs, important parameters for reservoir characterization were identified. It was also found that emulsion produced *ex-situ* and *in-situ* can be used as flooding agent. However, due to similarities in emulsion properties to the resident oil and water, extensive post-experimental analysis is required. As a result, the first priority was identified to be developing a core flooding system, which can be used in future core flooding experiments. Extensive literature review outlined the existence of traditional core flooding system and their limitations. An improved experimental apparatus was designed and constructed using up-to-date available technologies in the market. In addition, the main component of the system, core holder, was also modified. Established design for the end plugs of core holder was improved using available computational resources. It was also shown that developed apparatus can be further upgraded if it is required to study other flooding regimes. The software with graphical user interface and remote alarming system was developed to

guarantee continuous control in experiments.

Having highly controlled experimental apparatus allowed to perform benchmark experiments with oil and water and to understand the limitations of developed systems. As a result of routine core flooding experiments, an automated method for effluent analysis was developed using real time readings from the downstream mass flow meter. This method allows to automate process of core flooding experiments and collect effluent data in efficient time manner. Using this method, first experiments for enhanced oil recovery were conducted with emulsion. It was found that *ex-situ* produced emulsion has high recovery rate and it is a feasible method to recover oil from porous structure. Up to 80 % of resident oil can be recovered using direct injection or after water flooding. However, taking into account costs for emulsion production, as it was pointed out earlier, new technique for the emulsion flooding must be developed.

An alternative flooding technique for the emulsion flooding was proposed, developed and tested. This technique bases on a cyclic flooding of emulsion and water slugs through porous media with specified ratio, similar to water and steam (CSS, WAG) or water and chemicals (CAG) flooding techniques. The process was termed as water-alternate-emulsion (WAE). Collected data showed that at least an additional 20 % of a resident oil can be recovered from a reservoir compare to traditional flooding processes. It also allows the reduction of the required amount of emulsion three times compared to the direct injection. For instance, the final ultimate oil recovery was found to be 82 % of OOIP for overall 0.3 PV of emulsion injection. Sand packs were examined after experiments to provide additional understanding for the *in-situ* processes. However, it was limited due to the fact that once

pack recovered from the core holder it cannot be placed back. Thus, it was concluded that future studies with utilizing equipment for nondestructive testing, such as two dimensional (2D) core holder, of the *in-situ* process are required for more detailed understanding the interactions between different liquids inside the porous media and how the recovery curve formed during WAE strategy.

Finally, experimental flow visualization and pressure mapping analysis of emulsion flooding with horizontal and vertical wells was carried out as next step of this research project. During preparation to those experiments, it was discovered that the given emulsion has a bi-dispersal structure. A literature review showed that such structure was not previously reported in the literature. This finding leads to the reviewing existing theory about an emulsion, since it effects on *in-situ* processes happening at micro-scale, size of the pore. Testing three different configurations provided initial understanding for the emulsion flooding process at the scale of 2D core holder, which is eight times bigger compared to biaxial core holder. The velocity profiles of front floods, pressure maps and recovery curves of ultimate oil recovery were extracted and used along with collected images of the side wall. It was pointed out that the most efficient configuration for the emulsion flooding is horizontal injection - horizontal production (HI-HP). Field test trials can be now undertaken for similar reservoir conditions and geological formations. However, there is still a broad range of questions which should be answer to get the confidence that emulsion is an economically valuable process for oil recovery.

6.2 Future Work

Further studies can be done as a continuation of the current study and listed below:

- The biaxial holder can be replace with a modified version developed for acoustic measurement technique [1]. Acoustic measurements potentially can provide current saturation levels for each liquid and result in collecting data required for relative permeability curves.

- To be closer to the reservoir conditions, the core block can be modified as it is shown in Chapter 3. Sand packs will have different pore structure and might result in efficiency of emulsion flooding. Collected data can be further applied in field applications.

- In order to reproduce the real world scenario, when the reservoir has non homogeneous strata with residual oil saturation distributed within it, various configurations for strata need to be studied as well. Taking pictures from one side of the 2D visualization cell provide a map for oil, water and emulsion saturations.

- As it was shown in Chapter 5, during emulsion flooding resident oil forms a new front. Having the possibility to install new well during an experiment can be used to study the hypothesis of resuming to traditional water flooding.

- Water-alternate-emulsion (WAE) flooding technique proved to be an efficient method for oil recovery. However, it is still unclear what kind of interactions

[1] Paper in progress. M. Cassiede, A. Baldygin, A. Stephen, J. M. Shaw, D. S. Nobes, and S. K. Mitra, "Acoustic measurement technique in application to the bio-conversion of coal", *Energy & Fuels*, 2014

present inside porous media. WAE flooding can be accomplished in 2D core holder to visualize *in-situ* process.

- Finally, the 3D core holder can be used to study complex porous media, with permeable and non-permeable zones, and complex well configurations, *e.g.* steering well.

Appendix

A-1 1D and 2D core holder

To ensure safe operation for the core holder when the system is pressurized, the components passed strength analysis for safe operation.

A-1.1 One dimensional core holder

Thread

The strength analysis on 2.500 x 4 UNC thread was performed to determine the safety factor at working conditions. Based on available information, the following conservative assumptions were made:

- The material's mechanical properties are homogeneous and isotropic throughout the cross-section;
- The machanical properties of the material are of equal magnitude in tension and compression;
- Cross-sections remain plane under loading conditions;
- The materials have ductile characteristics;
- Simple axial/shear loading results in uniform axial/shear stress distribution across a uniform crosssection;
- Materials obey Hooke's Laws of elasticity;
- The minimum yield strength at 0.2 % offset strain, rather than typical (average) yield strength of a material, is the basis by which stress at yield is defined;

- Shear strength is 50 % to 60 % of the minimum yield strength. Two existing theories are the distortion energy theory (0.577 * Ys) and the maximum shear stress theory (0.5 * Ys);
- The selected material will not be used in an environment that will adversely affect its mechanical or physical properties;
- Calculated stresses are based on static loading conditions if appropriate to the application;
- Material for body is 630 SS, E = 196 GPa.

The tensile strength area of screw thread can be calculated using the following formula:

$$A_t = 0.7854 \cdot \left(D - \frac{0.974}{n} \right)^2 \cdot \text{in}^2 = 4.0 \text{ , in}^2 \qquad \text{(A-1)}$$

where *D* - basic major diameter, *n* - number of thread per inch, and A_t - tensile strength area of screw thread.

Pressure on a thread is a result of pressure applied on end plug (1,500 psi) with outside diameter equal to 1.5 in. Resulted force on a thread is 2.651 x 10^3 lbf, and shear stress on thread can be found as:

$$\tau_{cut} = \frac{Q}{A_t} = \frac{2.651 \cdot 10^4 \text{ lbf}}{4.0 \text{ in}^2} = 662.9 \text{ , psi} \qquad \text{(A-2)}$$

so that safety factor is:

$$sf = \frac{0.577 \cdot Ys}{\tau_{cut}} = \frac{9.791 \cdot 10^4 \text{ psi}}{662.9 \text{ psi}} = 147.7 \qquad \text{(A-3)}$$

Obtained number for safety factor can guarantee safe operation at 1,500 psi.

Wall thickness

The strength analysis on a wall thickness was performed to determine the safety factor at working conditions. In order to estimate safety factor for body's wall, the ASME B31.3 standard has been used. The input parameters are:

- Outside diameter (D), 3.346 in.
- Inside diameter (ID), 2.550 in.
- Wall thickness (t), 0.398 in.
- Wall thickness in weakest point (next to thread) (t_{low}), 0.280 in.
- Stress value for material for Grad 316; 304; 321 (S), 20,000 psi
- Quality factor (E), 1
- Coefficient (function of material and temperature) (Y), 0.4
- Internal gauge pressure (P)

Formula from maximum allowed pressure from ASME B31.3 standard is:

$$P = \frac{2tSE}{D - 2tY} = 5258.3 \text{ , psi} \qquad \text{(A-4)}$$

or for the thinnest point:

$$P_{low} = \frac{2t_{low}SE}{D - 2t_{low}Y} = 3587.4 \text{ , psi} \qquad \text{(A-5)}$$

Taking into account working pressure, P_w, as 1,500 psi, safety factor is:

$$sf = \frac{P}{P_w} = 3.5 \qquad \text{(A-6)}$$

or for weakest point:

$$sf = \frac{P_low}{P_w} = 2.4 \qquad \text{(A-7)}$$

Both safety factors are above 2; thus, current dimensions for the core holder can safely be used up to 1,500 psi.

A-1.2 Two dimensional core holder

Wall thickness and deformation

The required thickness for the cast acrylic wall was estimated using commercial software to guarantee least deformation at the center of the sand pack at 300, 400 and 500 psi. The following boundary conditions have been chosen for model in SolidWorks Simulations:

- No penetration between parts;
- Holes for brackets were fixed;
- Pressure was applied on internal surfaces;
- "Counterbore with Nut" condition with head diameter (0.625 in), nominal shank diameter (0.4375 in) and axial load 100 lbf. for nut and bolt connections at front panel
- "Counterbore Screw" condition with head diameter (0.5 in), nominal shank diameter (0.3125 in) and axial load 80 lbf. for screws used to tight top cap.

For 1.5 in. wall thickness the deformations are 0.109, 0.145 and 0.181 in, respectively, as it is shown in Figures A-1 - A-3.

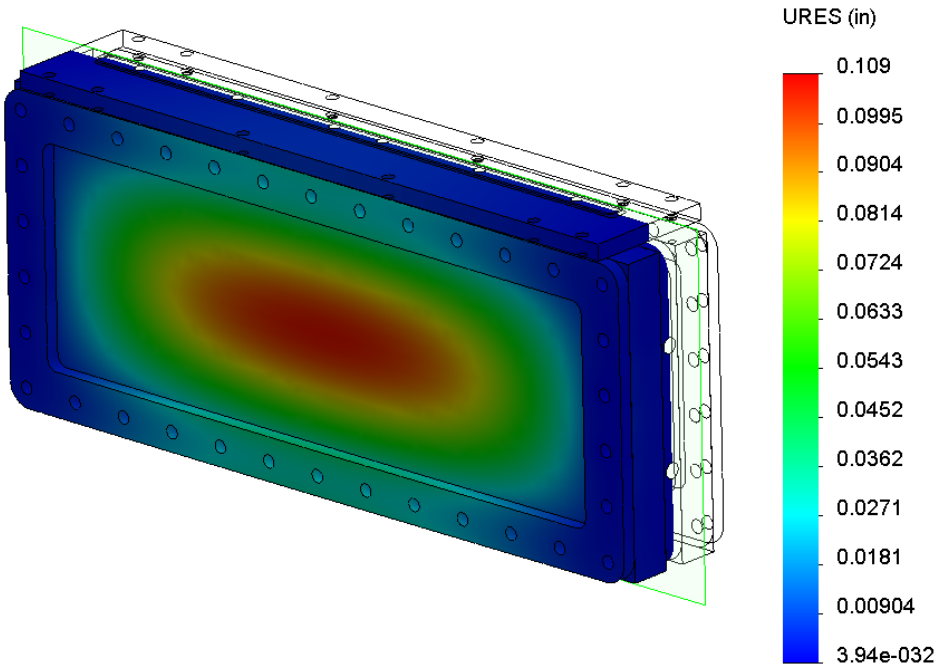

Figure A-1: Cast acrylic wall deformation at 300 psi.

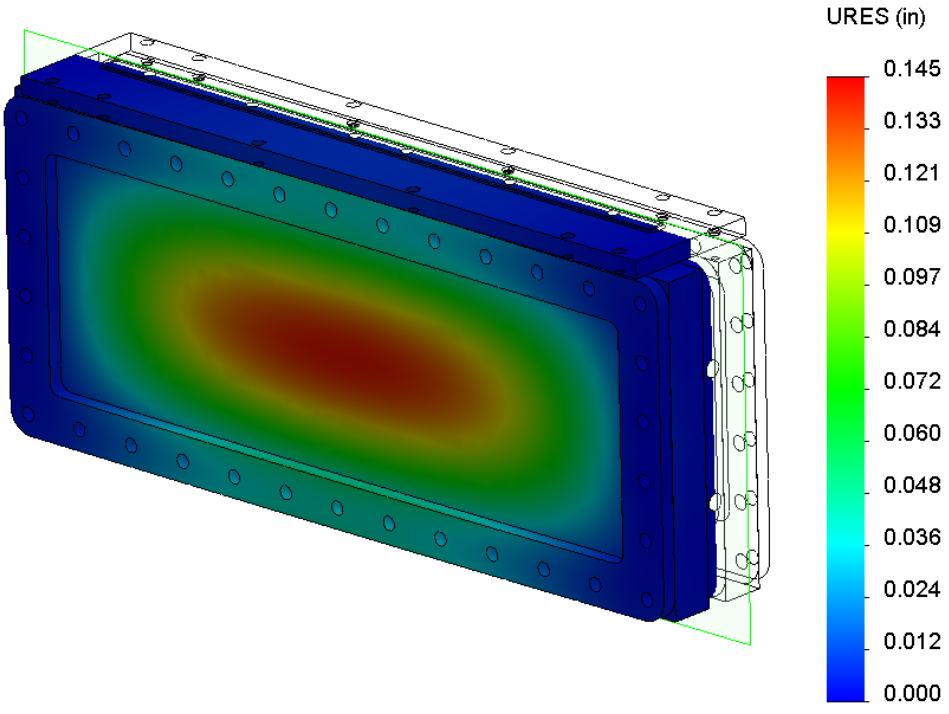

Figure A-2: Cast acrylic wall deformation at 400 psi.

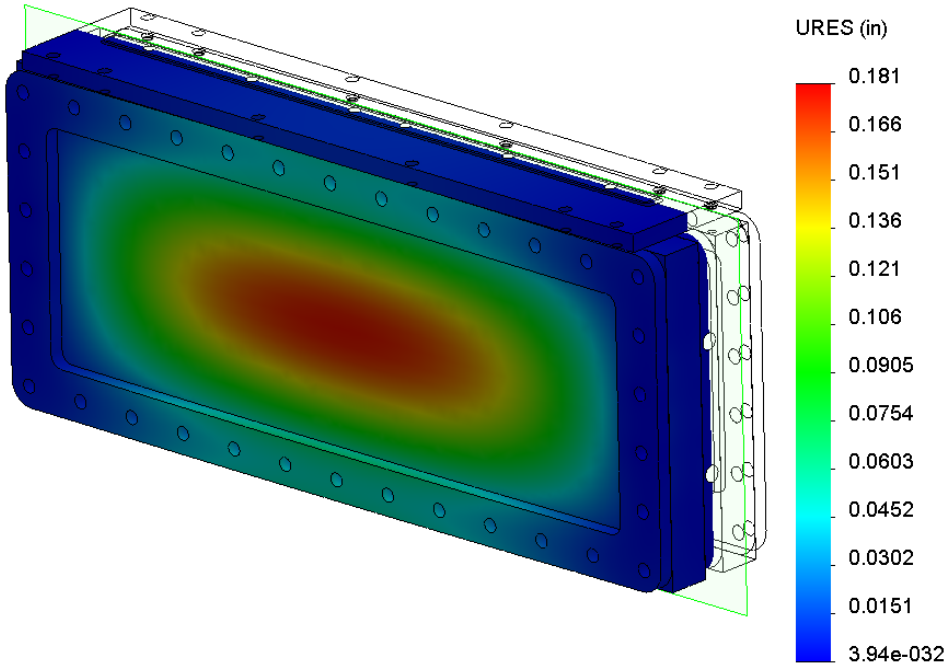

Figure A-3: Cast acrylic wall deformation at 500 psi.

A-2 Error analysis[2]

Here, the error analysis for the components of the system used to carry out experiments and obtained data is provided.

The pore volume and residual water saturation, provided in Chapters 3, 4 and 5, were obtained using the 250 ml graduated glass cylinder (70022-250, Cole-Parmer Canada Inc.) with least count of 2.0 ml. The tolerance specified by the supplier is $\pm$ 2.0 ml.

The ultimate oil recovery was measured using 15 ml test tubes (430055, Cole-Parmer Canada Inc.) with least count of 0.5 ml. As a result, it introduced the error $\pm$ 0.25 ml in measuring recovered fluid, which was accumulated during each experiment. The corresponding error bars are shown on Figures in Chapter 3, 4 and 5.

The upstream consists of dual-piston pumps coupled with mass flow meters. The flow accuracy and flow precision at 1 ml/min and 12 MPa are equal to $< 1.0\%$ and $< 0.5\%$, respectively. The mass flow meters have the measurements error equal to $\pm$ 0.2% of the full scale reading + 0.5 g/h, according to calibration certificates. The calibration has been performed by Bronkhorst Cori-Tech BV. Since, the flow rate was set at 0.5 cm^3/min, for half hour the accumulated error would be equal to $\pm$ 0.28 ml.

The densities of injected and produced liquids, provided in Chapter 3, 4 and 5, were measured using a mass flow meter (M13, Bronkhorst Cori-Tech BV). As per obtained data, the uncertainty in measurements of density for water, paraffin oil,

[2]A version of this appendix has been published as conference paper. A. Baldygin, D. S. Nobes, and S. K. Mitra, "Oil recovery from porous media using emulsion", *Proceedings of the ASME 2014 International Mechanical Engineering Congress & Exposition*, 2014

emulsion, recovered oil and produced water were $\pm$ 2.7 kg/m^3, $\pm$ 0.4 kg/m^3, $\pm$ 7.4 kg/m^3, $\pm$ 4.1 kg/m^3, $\pm$ 9.6 kg/m^3, respectively.

The viscosity of injected and produced liquids, provided in Chapter 3, 4 and 5, was measured using a rotational viscometer (Rheolab QC, Anton Paar USA Inc.) which has torque resolution of $< 0.1\mu$Nm. Hence, it would introduce an error into final value of viscosity in a range of $< 1.85 \cdot 10^{-3}\%$ without taking into account the variation of the geometry of double gap cell. As per collected data, the uncertainty in measurements of viscosity for water, paraffin oil, emulsion, recovered oil, produced water, dyed oil and dyed water were $\pm$ 0 Pa·s, $\pm$ 0.024 Pa·s, $\pm$ 16.70 Pa·s, $\pm$ 2.4 Pa·s, $\pm$ 0 Pa·s, $\pm$ 0.00018 Pa·s and $\pm$ 0 Pa·s, respectively. The viscosity of water and produced water was measured near the top limits of the double gap cell, as a result the uncertainty equals to zero.

The surface tension, provided in Chapter 4 and 5, was measured using a drop shape analyzer(DSA 100, Krüs GmbH). As per obtained data, the uncertainty in measurements of surface tension for water, paraffin oil, recovered oil, produced water, dyed oil and dyed water were $\pm$ 1.8 mN/m, $\pm$ 0.04 mN/m, $\pm$ 0.09 mN/m, $\pm$ 0.32 mN/m, $\pm$ 0.11 mN/m and $\pm$ 0.58 mN/m, respectively.

A-3 Consistency in results during 2D core flooding experiments

Here, the comparison of data from complete and incomplete 2D core flooding experiment with horizontal injection - horizontal production (HI-HP) is provided. During incomplete 2D experiment, crashing of the computer operating system has happened during process of emulsion flooding. It caused data lost for an amount of liquid injected into the system and effluent was not collected into the test tubes after 0.35 PV of emulsion injected. The main focus is in understanding the consistency in results from pack to pack for the same well configuration using visual analysis and available test tubes with collected effluent. Relevant parameters for unconsolidated sand pack samples are summarized in Table A-1.

Table A-1: Relevant parameters for unconsolidated sand pack samples used in flooding experiments.

Pack	Well configuration	Porosity, %	Pore volume, cm^3	Mass of sand pack, g	Absolute permeability, Darcy	Permeability with residual water, Darcy	$S^{\ddagger}_{wi}$
Run #10	HI-HP	34.3	820.1	4179.2	0.468 ± 0.074	0.379 ± 0.053	0.057
Run #11	HI-HP*	34.2	818.6	4183.1	0.607 ± 0.064	0.521 ± 0.032	0.03

‡ - Residual water saturation after oil saturation.
$*$ - Failed experiment

The photographs in Figure A-4 (a)-(b) show snapshots of the 2D core holder at different pore volumes of emulsion injection for HI-HP configuration. Injection wells are fully perforate with previously discussed perforation pattern. The flood front pattern has similarities in both experiments. The emulsion fills a region close to the left boundary first and then progresses towards the production well. Starting from 0.6 PV of emulsion injection, channeling is observed in Figure A-4 (b). Also, there is a flow across bottom boundary which allows to lift up oil and redirect towards production well. Overall, these images show repeatability and consistency in

experiments from pack to pack for same well configuration.

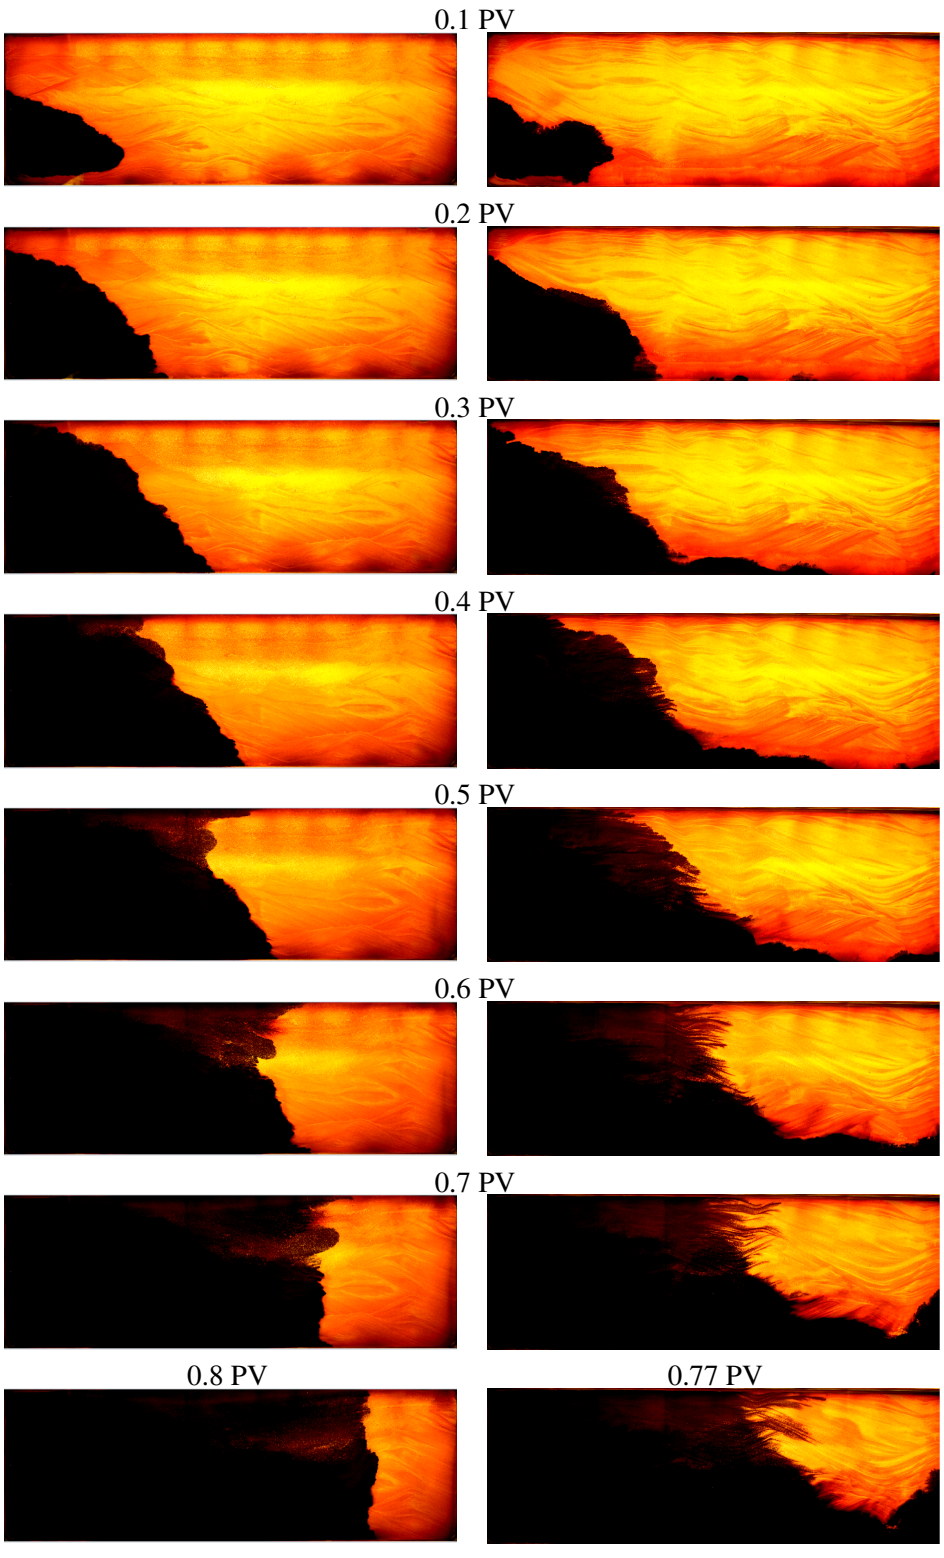

Figure A-4: Cross-section images of the sand pack for different configurations: (a) HI-HP; (b) HI-HP (failed).

Additional Run #11 was added to previously shown Figure 5.21 (a). Figure A-5 shows the ultimate oil recovery curves for three well configurations used in a 2D core holder. The recovery curve for incomplete flooding experiment follows the recovery curve for complete experiment with HI-HP well configuration. It proves repeatability and consistency in experiments from pack to pack for same well configuration.

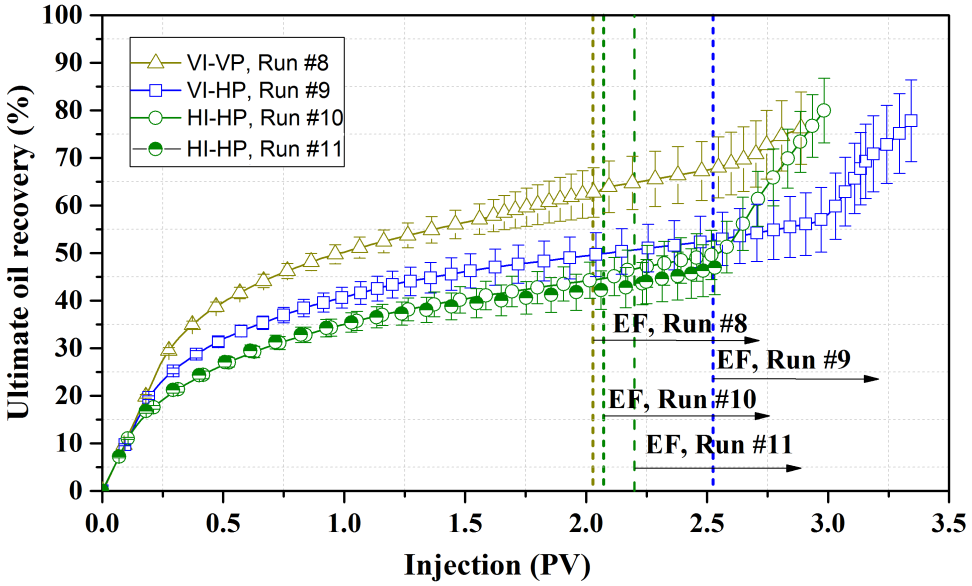

Figure A-5: Ultimate oil recovery curves for water flooding followed by emulsion flooding at different well configurations.

A-4 Image processing source code

The following code was developed using commercial multi-paradigm numerical computing environment (MATLAB R2014a, MathWorks). In order to reduce number of lines in code, due to similar procedures for each section of the core holder, the function to find profile was written into separate file, profilefinder.m. Main file, mainprogram new ref.m, recalls it for every location. Each file has detailed comments.

A-7 Software flowchart

The algorithm for the further software was developed and drawn as flowchart using diagramming software(Microsoft Visio Professional, Microsoft, Co.). It was modified and edited along project time, since new features were introduced from experiment to experiment. Final version is shown in Figure A-1.

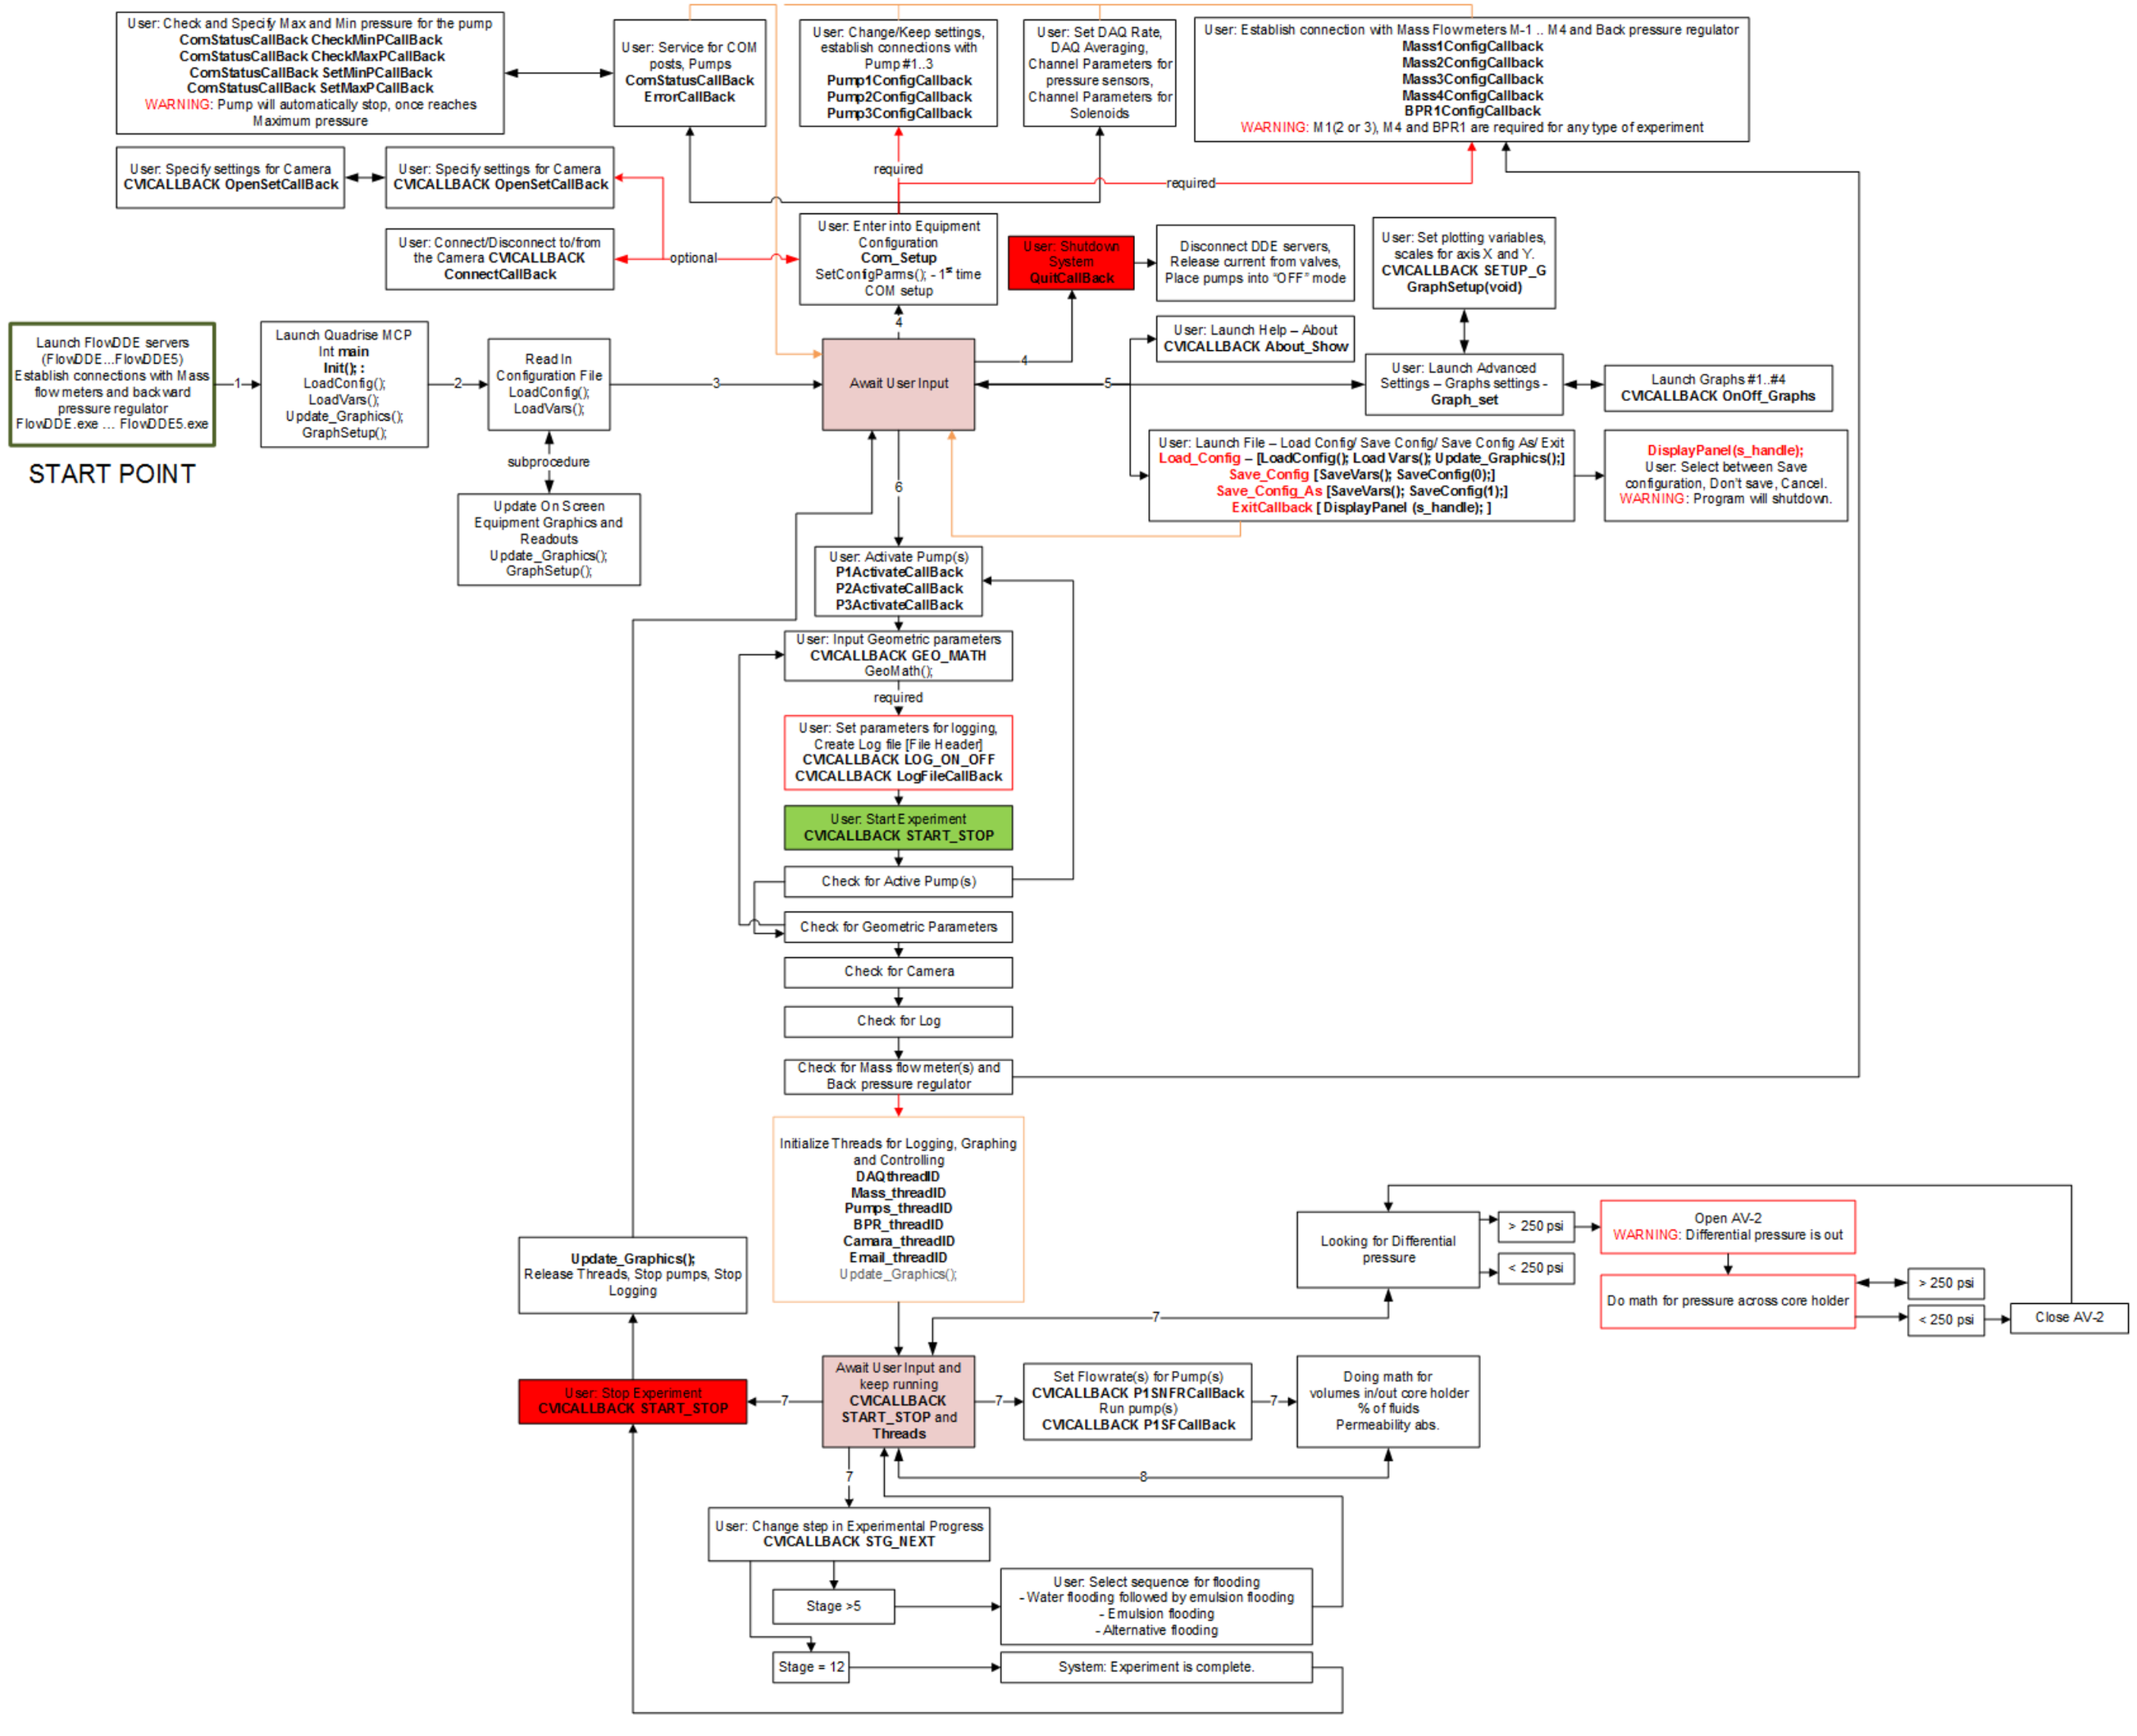

Figure A-1: Software flowchart.

A-8 Software source code

The following code was developed using custom design software (LabWindows CVI 10.0, National Instruments Inc.). The code consists of the five threads which allow to control and collect data from four mass flow meters, three dual piston pumps, 17 inline pressure sensors and one differential pressure sensor, one web-camera and single fraction collector. The code was developed based on source code presented earlier by Marc Evans in his MSc Thesis[3].
