to ~55% of the shell model values of (2J+1). This issignificantly lower than spectroscopic factors resulting from other reactions. Generally, the kinematic regions of better agreement between the analysing power data and calculations are similar to those of the earlier $^{16}O(\vec{p},2p)$ experiment. The analysing power for the $2s_{1/2}$ state near t=0 dominance is reasonably predicted whether spin-orbit dependence in the optical model is included or not.

At various kinematic conditions, peaks in the cross section suggest the possible presence of $1p_{1/2}$ and $1p_{3/2}$ 40 Ca single particle states at $\sim\!21$ MeV and $\sim\!30$ MeV separation energy respectively.

NOTICE

AVIS

The quality of this microfiche is heavily dependent upon the quality of the original thesis submitted for microfilming. Every effort has been made to ensure the highest quality of reproduction possible.

If pages are missing, contact the university which granted the degree.

Some pages may have indistinct print especially if the original pages were typed with a poor typewriter ribbon or if the university sent us a poor photocopy.

Previously copyrighted materials (journal articles, published tests, etc.) are not filmed.

Reproduction in full or in part of this film is governed by the Canadian Copyright Act, R.S.C. 1970, c. C-30. Please read the authorization forms which accompany this thesis.

THIS DISSERTATION
HAS BEEN MICROFILMED
EXACTLY AS RECEIVED

La qualité de cette microfiche dépend grandement de la qualité de la thèse soumise au microfilmage. Nous avons tout fait pour assurer une qualité supérieure de reproduction.

S'il manque des pages, veuillez communiquer avec l'université qui a conféré le grade.

La qualité d'impression de certaines pages peut laisser à désires, surtout si les pages originales ont été dactylographiées à l'aide d'un ruban usé ou si l'université nous a fait parvenir une photocopie de mauvaise qualité.

Les documents qui font déjà l'objet d'un droit d'auteur (articles de revue, examens pobliés, etc.) ne sont pas microfilmés.

La reproduction, même partielle, de ce microfilm est soumise à la Loi canadienne sur le droit d'auteur, SRC 1970, c. C-30. Veuillez prendre connaissance des formules d'autorisation qui accompagnent cette thèse.

\ABSTRACT

A 40 Ca(\vec{p} ,2p) experiment was performed at the TRIUMF facility using a 200 MeV polarized proton beam. Data were acquired at eleven independent pairs of angles for separation energies from 0 to 100 MeV over a wide range of recoil momenta. For eight angle pairs, cross sections and analysing powers were extracted from the data as a function of the energy difference of the final state protons for knockout from the valence states ($1d_{3/2}$, $2s_{1/2}$, and $1d_{5/2}$). Cross section and analysing power information was obtained for 3 other angle pairs for only the $2s_{1/2}$ state.

Approximation (DWIA) calculations which incorporated the bound state wave functions of Elton and Swift (EL-67), an optical model potential, with spin-orbit terms, from Schwandt (SC-80), and a half-off-shell prescription for the free p-p scattering matrix element. The £=2 states show strong j-dependence in the analysing power at most measured angles. Such dependence was predicted by Jacob and Maris (JA-73) and has been observed for £=1 states in \$160 (KI-80,KI-76). DWIA calculations agree well with the present analysing powers for equal and near equal angles in the forward direction. The spectroscopic factors resulting from normalizing the calculations to the data are only ~50%

ACKNOWLEDGEMENTS

I wish to express my sincere appreciation to my supervisor, Dr. P. Kitching, and acting supervisor, Dr. W. J. McDonald for their guidance, support, and enthusiasm during the course of this work.

I extend my thanks to the operations staff of TRIUMF for their reliable delivery of beam which enabled the aquisition of all the data for this project on the first attempt and to the director of TRIUMF, Dr. J.T. Sample, for his support and encouragement over the last three years.

I wish to thank Dr. D.A. Hutcheon and Dr. C.A. Miller for their direction and patient explanations of many aspects of experimental and theoretical nuclear physics over the last three and one half years. Thanks also must go to Dr. G. Greenfaus who patiently guided me through the difficulties of the statistical analysis of the data and to Dr. J. Rogers for several especially helpful suggestions on the event analysis.

I also wish to thank the other members of the Experiment 58 group who assisted in the collection of the data including Dr. W.K. Dawson, Dr. G.A. Moss, Dr. G.C. Neilson, Dr. W.C. Olsen, Dr. D.M. Sheppard, Dr. A.W. Stetz, and Dr. E.D. Earle.

I wish to express my gratitude to our excellent technicians, Randy Churchman and Herb Coombes, for their

the experiment and the Eclipse during later analysis and for their explanations of many reconical questions which arose.

Special thanks goes to several University of Alberta post-doctoral fellows - to Al Anderson for his patient explanations of the workings of the Eclipse and for introducing me to mountain-climbing at a time when the long thesis work got me down - to R. L. Liljestrand and H. Wilson for their advice on the project and their companionship on several excellent hiking and skiing trips.

I am indebted to my fellow graduate students, Rick Hooper, Ron Slobods, Tim Cooper, Doug Hasell, and Doug Phillips for their solace and warm fellowship.

A special thanks to Phil Bennett, Arthur Haynes, and Corrie Kost for their special modifications of OPDATA which made the long task of fitting less mind numbing.

My thanks goes to C.W. Bordeaux for allowing me the use of TRIUMF's word processor without which the writing of this thesis would have been an unimaginably dreary task. I also thank Anna Gelbart and Hugh Rogan who did such a fine job drafting and assembling my figures.

Thanks also must go to all the individuals who proofread my thesis including Dr. R. Abegg and Allyson MacBean.

Finally I thank my two very special and dear friends, Keith Corson and Ann Seales whose companionship on many

hiking, skiidg, bicycling, and canoeing trips was greatly appreciated during the last five years.

The financial support of the Matignal Research' Council of Canada, the University of Alberta, and TRIUMF are gratefully acknowledged.

CHAPTER I

Quasi-elastic (p,2p) scattering occurs when the incident proton undergoes a single violent interaction with the nuclear proton; this collision is usually treated as free proton-proton scattering. Thus, although there has been some theoretical investigation of two step processes (KU-79), quasi-elastic scattering is usually viewed as a single step process as represented schematically in Figure I-1. Currently, one of the most immediate aspects of (p,2p) reactions is that they allow a check of the validity of the wave functions describing the propagation of protons through the nucleus. Also, in addition to offering an opportunity to examine the proton-proton interaction in the environment of a nuclear potential, a study of the resulting hole states in the residual nucleus tests nuclear models by providing information on the overlap between the wave functions of the target ground state and excited states the residual nucleus.

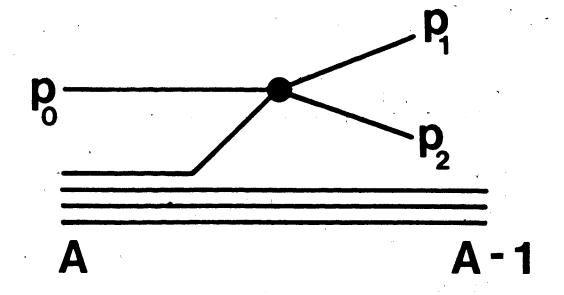

As illustrated in Figure I-2, an incoming proton (mass M) which is instant upon a target nucleus (mass MA) strikes a bound strike and the two protons scatter to detectors without undergoing any other violent interactions. In the shell model, each bound street nucleon is characterized by a well-defined orbital angular momentum and binding energy.

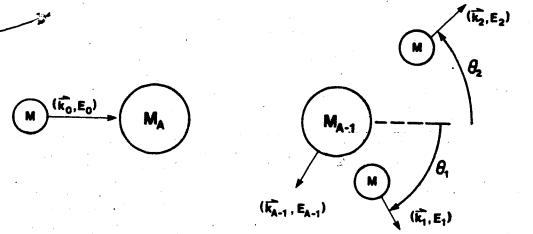

FIGURE I-1

Schematic representation of a (p,2p) reaction as a single step process.

FIGURE I-2

Diagramatic representation of a (p,2p) reaction illustrating the labelling of the various kinematic quantities.

initial state

Final state

Thus the interaction results in the knocking out of a moving nuclear proton which "almost" behaves like a free nucleon. Such "quasi-free" collisions result in a strong angular correlation between the outgoing protons as well as peaks in the summed energy spectrum corresponding to the binding energies of the various single particle states.

A characteristic of quasi-free scattering is that the target nucleon can have an effective initial polarization in the reaction. In asymmetric kinematic conditions, the reaction may be localized. For example, below 400 MeV, the mean free path of protons travelling through nuclear matter decreases strongly as the energy decreases. Consequently, events in which one proton emerges with a large energy compared to the other may tend to originate on the side of. the nucleus in the lirection of the momentum of the lower energy proton. This results in a spatial localization of the reaction. (This is distinct from the localization of the (p,2p) reaction due to radial peaking of the bound state wave function. Surface localization does not occur for the ls_{1/2} state wave function which is mainly concentrated near r=0.) A careful selection of the angles and energies of the outgoing protons determines the magnitude and direction of the momentum of the struck particle which can couple to a localized enhancement of the reaction and this leads to a well-defined sense of orbital angular momentum. Through nuclear spin-orbit coupling, the struck proton is effectively polarized in a direction

normal to the scattering plane. In particular, protons in states of the same ℓ but different j will be polarized in opposite directions. This, coupled with the fact that the free p-p cross section for the scattering of protons with parallel spins is larger than that for antiparallel spins, leads to a j-dependence in the $(\vec{p},2p)$ analysing power. This dependence was predicted by Jacob and Maris (JA-73) and first observed for the ℓ =1 states of ℓ =1 (KI-80,KI-76). Therefore, ℓ =2p) could conceivably be used as a spectroscopic tool to distinguish states of the same ℓ but different j.

A quantitative picture of (\$\vec{p}\$,2p) includes the effect of nuclear distortion of the proton wave functions and is formulated using the Distorted Wave Impulse Approximation (DWIA). In Appendix I, the DWIA description is, discussed and details are given about the manner in which the j-dependence in the analysing power arises. In the present context, the struck particle polarization and hence the analysing power are more promising than the cross section in testing DWIA. This arises because of the particular insensitivity of analysing power to the bound state wavefunction and the spectroscopic factor. Also, the analysing power is less sensitive to the optical potential than the cross section.

From the earliest experiments to the present, analysis of (p,2p) experiments has consisted of organizing the data either on the basis of the summed energy of the outgoing

protons, on the recoil momentum of the residual nucleus. On the outgoing angles, or on some combination of these (KU-71, JA-69, TY-66, WI-55, CH-52). Early interest in (p, 2p) reactions focussed on attempts to study the momentum distribution of bound nucleons by measuring energy distributions for one outgoing proton over a variety of scattering angles (CL-52). In the first (p,2p) coincidence experiment (CH-52), angular correlations for 6Li were measured about an opening angle 90°. The degree to which bound nucleons exhibited free nucleon (quasi-free) behavior was examined in these studies. Later coincidence experiments which measured the energy of one (WI-55) or both (TY-58) outgoing protons gave some of the first direct evidence of the existence of single particle shell model states.

Several features of quasi-free scattering contribute to the interest in this reaction. The kinematics of the (p,2p) reaction allow the recoil momentum to vary over a wide and useful range from zero to several hundred MeV/c. Consequently, it should be possible to distinguish between states of differing 1, particularly 1+0 states (whose momentum distribution, and hence cross section, is at a minimum at zero recoil momentum - as explained in Appendix I) from 1-0 states (whose momentum distribution is at a maximum there). In addition, the same binding energy and recoil momentum region can be examined with a number of different kinematic configurations. This redumdancy allows

one to examine the interaction process for a given nuclear state under a variety of conditions. Comparisons with a DWIA formalism can then be made.

During the quasi-elastic reaction, the binding energy of the struck nucleon together with the recoil momentum of the residual nucleus makes the 2 body t-matrix half-offshell (RE-70). In addition, the distortion suffered by the incoming and outgoing protons causes the t-matrix to be fully off-shell (RE-73). However, if this latter effect can the ignored and the DWIA is a sufficiently accurate description of the (p,2p) reaction, it may be possible to extract off-shell tpp matrix information which can then be compared with the predictions of various phaseequivalent (phenomenological) potentials (BI-76). potentials are equivalent on the energy shell and the hope is that one can distinguish among them by calculations of off-shell processes. Unfortunately, to extract nucleonnucleon information one must perform accurate calculations of the effects of distortion, which can be quite large.

It has been suggested that certain experimental geometries might be particularly propitious for the examination of off-shell effects (IO-78,DE-79). With such geometries an attempt would be made to utilize the variety of kinematic conditions possible for the reaction. The expectation was that the sensitivity of calculations to distortion and the bound state wave functions could be reduced by holding the outgoing proton energies constant

while the initial state of the nucleus being examined was fixed by restricting the value of the recoil momentum. However, calculations comparing off-shell behavior in (p,2p) mometries expected to maximize such differences have shown-disappointingly small sensitivity to the potential used (MI-79).

From the above discussion, the (p,2p) reaction is seen to offer information on nuclear structure, off-shell effects, and propagation of protons through nuclear matter. There are, of course, a number of other reactions which give information complementary to that obtained in (p, 2p). 'Through knockout or pickup reactions such as (,pn), (e,e'p), $(\alpha,\alpha p)$, (p,d), $(d,^3He)$, and (γ,p) , information on nuclear structure through the removal of a single nucleon is acquired. The knockout reactions (p,pn) and (e,e'p) are fairly well described (by a single step DWIA formalism at intermediate energies. Like the (p,2p) reaction, these offer considerable kinematic freedom including wide variation of the recoil momentum. Experimental investigations of (p,pn) reactions can be designed to acquire (p,2p) information simultaneously (JA-79). Such measurements are expected to yield information about bound neutrons wimilar to that from (p,2p) reactions concerning bound protons.

The impulse approximation can be checked by finding quasi-wires processes which have nearly equal distortion and differ primarily in the knock-out process itself. An

example of such a test was an analysis of $^{12}C(p,2p)$ and $^{12}C(p,pn)$ data (MA-79). By taking the ratio of the cross sections for each process, the effects of distortion nearly cancel. A comparison of the ratio of the measured cross sections with the theoretical predictions serves as a check of the impulse approximation.

Information about the momentum distribution for the deeply bound states of several nuclei including 40Ca has been acquired through (e,e'p) measurements (MO-76, NA-76, AM-66). Compared to (p,pN), (e,e'p) with only one strongly interacting particle might be expected to suffer less nuclear distortion and the interaction is presumably well understood. However, cross sections tend to be several orders of magnitude lower and thus harder to extract from background. Enticing evidence for 1s and 1p single particle state strengths in 40 Ca has been published (MO-76) although better statistics would be desirable. reaction can also excite hole states and offers advantages and disadvantages similar to those for (e,e'p), but the range of experimentally accessible recoil momenta is restricted to values >300 MeV/c (MA-75). Apart from the fact that data is limited due to the difficulty of the experiments, questions about the reaction mechanism make an interpretation of the results difficult. A recent $^{16}O(\gamma,p)$ experiment suggests that one-step processes are inadequate to account for the observed differential cross sections and that the inclusion of two-step processes improves agreement

with the data (MA-77).

 $(\alpha, \alpha p)$ quasi-elastic scattering is strongly surface localized compared to (p,2p) due to the strong absorption of α particles in nuclear matter. Some recent $(\alpha, \alpha p)$ measurements on ^6Li and ^{19}F are in fair agreement with DWIA calculations and, in the case of ^6Li , yield a spectroscopic factor consistent with that derived from a DWIA analysis of $^6\text{Li}(p,2p)$ data (NA-79). Measurements of $(\alpha,\alpha p)$ and (p,2p) on ^{40}Ca are currently being analysed (RO-80).

The neutron pickup reaction, (p,d), provides information about high momentum (>300 MeV/c) components of bound neutron wave functions. Recent 40Ca(p,d) measurements show evidence for a number of single particle states up to excitation energies of 18 MeV (LI-80,AL-79,SM-79). In addition, this reaction is potentially useful in probing deep hole states. With the advent of polarized beams, (\vec{p}, d) analysing power measurements have been shown to distinguish strongly between states of the same & but different j (HU-80, AL-79, CH-67). High momentum components are also examined in the $(d, {}^{3}\text{He})$ reaction. States of different & are readily distinguished by the angular distributions of their cross sections (KR-71). High resolution 40 Ca(d, 3 He) measurements at 52 MeV have provided detailed spectroscopic information from the ground state to excitation energies of ~10 MeV (D0-76).

The current investigation of 40 Ca(\vec{p} ,2p) is an extension of the previous 16 O(\vec{p} ,2p) experiment (KI-80,

KI-76) and offers new possibilities. The choice of $^{16}\mathrm{O}$ and $^{40}\mathrm{Ca}$ targets follows from their reputations as good shell model nuclei which should provide relatively pure single particle states.

The separation between any two of the three valence states of 40 Ca (1d_{3/2}, 2s_{1/2}, 1d_{5/2}) is less than 3 MeV making them experimentally more difficult to resolve than, for example, the states of $^{16}\mathrm{O}$ which are 6.5 MeV apart. With improving energy resolution, more recent 40 Ca(p,2p) experiments (TY-66, JA-69, KU-71) have tended to emphasize the nuclear spectroscopy aspect. A recent 40 Ca(p,2p) experiment (RO-78) attained a resolution of 350 keV but examined only the $1d_{3/2}$ and $2s_{1/2}$ states. The best resolution attained in a (p,2p) measurement which examined all three 40 Ca valence states was 4 to 5 MeV (JA-69). Thus, a goal of this experiment was to attain the best possible beam and detector resolution in order to fully or partially resolve all the valence states. A knowledge of excitation energies and relative spectroscopic factors for the removal of protons from a particular single particle state can greatly assist in the analysis and interpretation of nucleon knockout experiments where the resolution may be inadequate to resolve individual peaks. Such factors for 40 Ca have been provided by DWBA analyses of (p,d), (d, 3 He), and $(d, ^3H)$ experiments (DO-76,MA-72) and were helpful in this investigation.

In the present experiment, both the cross sections and

analysing powers for the three valence states of 40 Ca were measured over a large range of recoil momenta. With the kinematics chosen so as to achieve a large effective polarization of the struck proton, the j-dependence of the analysing power of 12 2 states was examined for the first time. The degree to which DWIA could reproduce the data and, in particular, the extent to which the inclusion of spin-orbit distortion affected agreement of the predictions with the data were of major interest. This experiment was the first experimental investigation of $(\vec{p}, 2p)$ on a medium mass nucleus and was also the first investigation of the ability of DWIA to reproduce such data.

In previous 40 Ca(p,2p) experiments, James (JA-69) and Kullander (KU-71) both reported evidence for 1p and 1s strength in 40 Ca. The current experiment also offers the prospect of examining deeply bound nuclear states and provides the possibility for distinguishing between states such as $1p_{1/2}$ and $1p_{3/2}$ on the basis of the behavior of their analysing powers. The measurement of binding energies and widths of deeply bound states provides important data for comparison with nuclear matter calculations from 2-body interactions (CO-74,SP-72,SP-71).

CHAPTER II

EXPERIMENTAL DETAILS

2.1 Overview

The experiment was performed at the TRIUMF facility located near the University of British Columbia. The TRIUMF cyclotron delivered a 200 MeV polarized proton beam with a polarization of ~0.6 + ~0.75 and with an energy resolution better than 1%. The cyclotron accelerates H⁻ions and a proton beam is extracted by removing both electrons from the ions by means of a stripper foil. The proton beam has \$7 ns pulses separated in time by ~43 ns. During the experiment the average beam current was kept at 0.5 to 1.0 nA.

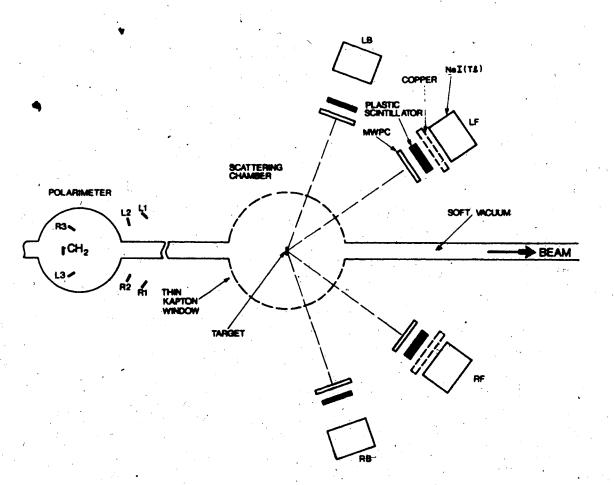

The experimental configuration is illustrated schematically in Figure II-1. Four detector telescopes were mounted on booms which could be positioned independently around a circular scattering chamber with an angular precision of ±0.10°. Beam polarization was measured by means of a polarimeter located upstream of the scattering chamber. Beam current was monitored both by means of the polarimeter and an ion chamber located downstream of the scattering chamber. A more detailed description of various components of the apparatus follows.

2.2 Polarimeter

The polarimeter used in this experiment has been

FIGURE II-1

Experimental configuration of polarimeter, scattering chamber, and detectors.

described in detail in (GR-79, MC-78). Free p-p scattering using a CH₂ target with an average thickness of $3.83\pm.38$ mg/cm² was used for monitor beam polarization and beam current. The polarimeter detectors are illustrated in Figure II-1. On either side of the beamline, a pair of detectors at 17° (L1 · L2 or R1 · R2) acted as a telescope to define the solid angle. coincidences (L1·L2·L3 and R1·R2·R3) are called prompts (consisting of reals and randoms) and are counted. measure the contribution of random events, coincidences between these same sets of detectors but with L3 and R3 delayed by 43 nanoseconds were also counted. This delay ensures that the protons come from different beam bursts and hence different interactions. The rate of accidental events from one beam burst is assumed to be the same as that between two consecutive beam bursts. A schematic diagram of the polarimeter electronics is shown in Figure II-2.

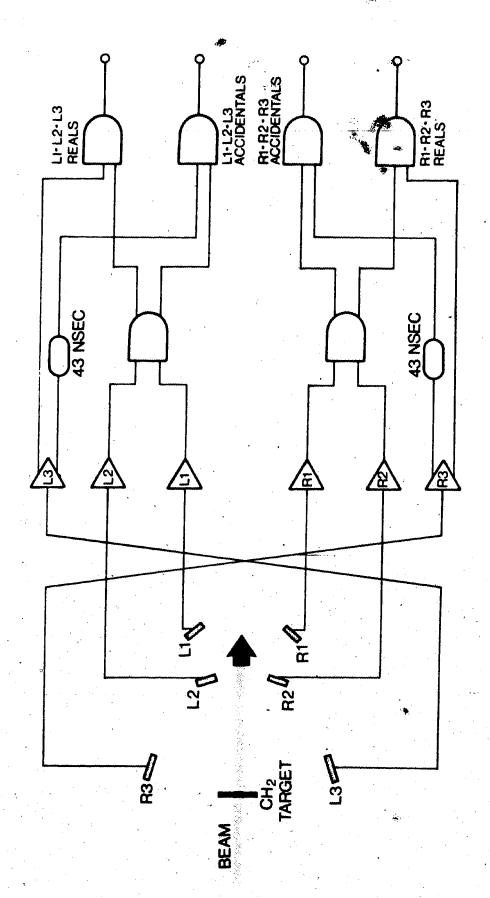

We denote the number of prompt coincidences $L1 \cdot L2 \cdot L3$ (R1 · R2 · R3) as POL[L] (POL[R]) and the number of accidental coincidences as POL[LACC] (POL[RACC]). The beam polarization and number of incident protons (NI_a) are given by

(II.1) Beam Polarization =
$$\frac{1}{PAP} \cdot \frac{(POL[LRE] - POL[RRE])}{(POL[LRE] + POL[RRE])}$$

(11.2) NI = (POL[LRE] + POL[RRE])
$$\cdot \frac{6.2418 \times 10^9}{PC}$$
,

FIGURE II-2

Logic diagram of polarimeter electronics. Logic symbols are defined in Figure III-1.

where POL[LRE] = POL[L] - POL[LACC],

POLM[RRE] = POL[R] - POL[RACC],

PAP is the polarimeter analysing power which equals 0.300 ± 0.015 , at 200 MeV,

PC is the conversion factor from polarimeter counts to nanocoulombs which equals 350 ± 25 counts per nanocoulomb at 200 MeV.

Beam polarization for spin \uparrow (\downarrow) typically ranged from 0.67 to 0.75 (-0.61 to -0.70)° during the experiment. The polarimeter served as the primary beam monitor in the experiment.

2.3 Ion Chamber

A detailed description of the ion chamber, its operation, and calibration appears in (MC-78). In brief, the proton beam passing through the ion chamber ionizes helium gas that is continually flowing through the chamber. The resulting charge is collected by means of high voltage planes in the chamber and a digital signal proportional to the amount of charge is produced. During the experiment the voltage was maintained at -300 Volts. If the number of ion chamber counts is represented by IC, the number of incident protons (NI_b) is given by $(II.3) \quad NI_b = \frac{IC \cdot 6.2418 \times 10^9}{ICC}$

where the conversion factor from ion chamber counts to nanocoulombs (ICC) is 156 ±11 at 200 MeV.

The ion chamber served as a secondary beam monitor, and its

consistency with the polarimeter is discussed in Chapter IV.

2.4 Targets and the Scattering Chamber

A circular scattering chamber with a radius of 25 cm was used. The window of the chamber is 5 cm high, allows the passage of scattered particles from 12° to 168° on either side of the beamline, and consists of 127 µm thick The targets used in the experiment were: (58 mg/cm^{2±5}%), CH₂ (50 mg/cm^{2±5}%), a nætural Ca target (50.88 mg/cm $^2\pm5\%$, of which 96.97% is 40 Ca and we shall refer to it as the 40Ca target), and a ZnS scintillator screen for monitoring the position of the beam. They were mounted, one above the other, on a vertical ladder which can be raised or lowered remotely so as to position the desired target in the path of the proton beam. The target drive mechanism is mounted on a plate which sits on the top of the scattering chamber. The CD2 target is circular with a diameter of 3 cm, while the other targets are ~5 cm square.

2.5 Detector Telescopes

The four booms surrounding the target chamber were designated: Left Front (LF), Right Front (RF), Left Back (LB), and Right Back (RB), where left or right refer to the side of the beamline looking downstream. This labelling is illustrated in Figure II-1. Also shown in the Figure is the arrangement of the components of the detector telescopes on each boom. Each telescope consisted of two

multi-wire propertional counter (MWPC) planes to provide position information in the horizontal (x) and vertical (y) directions, a thin plastic counter, and a NaI(T1) detector. The front (back) wire planes were 134.1 (115.2) cm from the target and were 64(x) by 128(y) (64 by 64) wires. The solid angles were defined using these planes. The construction and operation of these multiwire detectors is reviewed in (MC-78, CA-75).

Each multiwire chamber consists of a plane of high voltage wires kept at -5000 Volts, a sense plane of wires, a second high voltage plane, a second sense plane, and a final high voltage plane. The sense wires are 16 µm in diameter, spaced 2 mm apart, and made of gold-plated tungsten. The high voltage wires are 102 µm in diameter, spaced 1 mm apart, and consist of beryllium (1.9%) and copper. The wire planes are enclosed between sheets of 25.4 µm thick Kapton, and the 4.7 cm spacing between the Kapton sheets is continuously flushed with a gas mixture (75% Ar bubbled through methylal at 0°C, 24.5% isobutane, and 0.5% freen).

A plastic scintillator 12.8 cm square and 0.635 (0.3275) cm thick was positioned behind each front (back) MWPC. Each of these detectors consists of NE110 scintillator and is connected to a plastic light guide which directs the light flashes through a 90° bend to a 5 cm RCA 8575 photomultiplier. The scintillators acted as passing counters providing timing and energy loss (dE/dx)

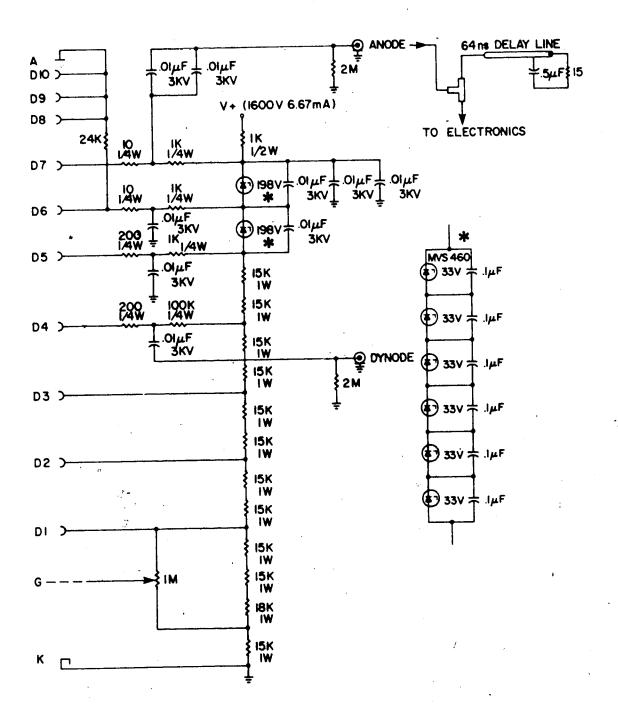

information. The energy deposited in these detectors was used in the calculation of a mass parameter to separate deuterons from protons.

NaI detectors served as stopping counters to measure the kinetic energies (T) of the protogs. A detailed description of these detectors and their efficiency appears The large quantity of light generated by in (CA-77). detected particles in intermediate energy experiments commonly results in a gain shift in the photomultiplier tube with detected flux. This problem arises because the current flow in the photo-cathode induces a voltage drop across it, which distorts the electric field collecting the photo-electrons. The electronics of the base of the 12.5 cm photomultiplier tube were specifically designed to minimize this problem and are sketched in Figure II-3. The 4 tube bases were fed through a common 10 pF capacitor kept at +1600 V. Normaily, the outputs from the photomultiplier are passed through a pulse shaper before integrating with an analogue to digital converter (ADC). exponential tails of such shaped signals are quite long (10 um) and the possibility arises that the tail of a previous pulse may overlap a pulse of interest. Also a second pulse may arrive during the integration of the first pulse. either case the undesirable result is that the total. integrated signal contains contributions from more than one pulse (a condition referred to as pile-up). To overcome this concern, devices called pile-up monitors which note

FIGURE 11-3

i de

Diagram of NaI photomultiplier tube base.

the arrival of two signals within a specified gate (length of time) were used. Pile-up monitors with inputs from the plastic scintillators recorded instances when two signals from a plastic detector were sufficiently close in time that the corresponding NaI signals would overlap. Signals from the plastics were used as they are sharp (~10 ns) and thus allow the pile-up monitor to resolve between signals close in time. Beam current was kept low enough that pile-ups did not exceed 20% of the signals processed. Pile-ups were rejected in later analysis of the data.

In principle, the long exponential tails from the NaI tube base can be brought back to zero voltage (the baseline voltage) quickly by adding an attenuated, inverted, and delayed component of the original signal to the original Such a cancellation was attempted by means of a signal. clip line connected to the tube anode in parallel with the signal cable. As shown in Figure II-3, the clip line was terminated with a $0.5 \mu F$ capacitor and a resistance (15 Ohms) which is lower than the characteristic impedance of the cable (50 0hms). The resulting output signal was directed to an ADC with no pulse shaping and could be integrated in approximately one-tenth the time. Although it was expected that such clipping would decrease energy resolution while allowing significantly higher event rates, tuning of the electronics at the start of the experiment indicated that the resolution remained constant whether the terminators were connected or not. Subsequently it was

decided to proceed without the terminators and to live with longer integration times and necessarily lower event rates.

Each NaI(T1) crystal and tube base was encased in an antimagnetic shield (Mu metal) which sat in an iron pipe. This pipe was, in turn, mounted in a lead pig to shield the NaI detector from background radiation. The NaI detectors were positioned 2.5 cm behind the plastic scintillators. $NaI(T\ell)$ crystals are cylindrical with a 12.7 cm diameter and a 7.62 cm thickness capable of stopping 150 When the front detectors (LF, RF) were MeV protons. operated forward of 29°, a 0.631 cm thick copper plate was inserted behind each of the front plastic scintillators to degrade the proton energies sufficiently to stop them in the NaI detectors. Taped to the detection surface of each NaI and plastic was a light-emitting diode (LED) driven by a pulse generator. The pulser also fired one wire in each of the MWPC planes. The response of the NaI detectors to the pulser signal had an ~ 50 ns rise time and a fall time of ~300 ns.

CHAPTER III

EXPERIMENTAL PROCEDURE

To process the information from the detectors a combination of fast NIM and CAMAC electronics was employed. The electronics were divided into two sections: one near the scattering chamber and detectors, the other in a remote counting room. A Honeywell H316 computer located in the counting room received event information processed by the electronics via a CAMAC network. A data acquisition program, ORION, controlled the data processing in the Honeywell. A detailed description of the structure and operation of this data acquisition system has been given in a series of internal reports (RO-74,RO-75,RO-75a,RO-77).

A schematic diagram illustrating the electronics located near the scattering chamber is shown in Figure III-1 while those located in the counting room are shown in Fi/gures III-2 and III-3. A coincidence between a left and a right plastic detector generated an EVENT FAST signal. This requested the multiwire controller to preserve any multiwire information in a set of memory registers (this action is called a strobe) and also caused the EVENT FAST logic unit to be latched so that no other coincidences could be registered until a CLEAR signal was issued. The electronics in the counting room determined whether the event was to be processed further. A coincidence between a left and right plastic and NaI detector telescope generated an EVENT SLOW

FIGURE III-1

Logic diagram of electronics located near scattering chamber.

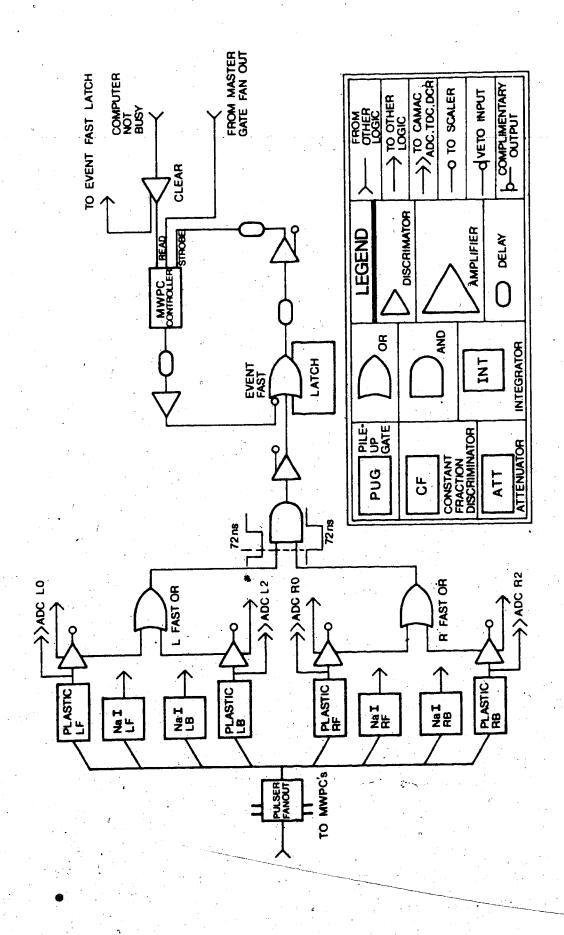

FIGURE III-2

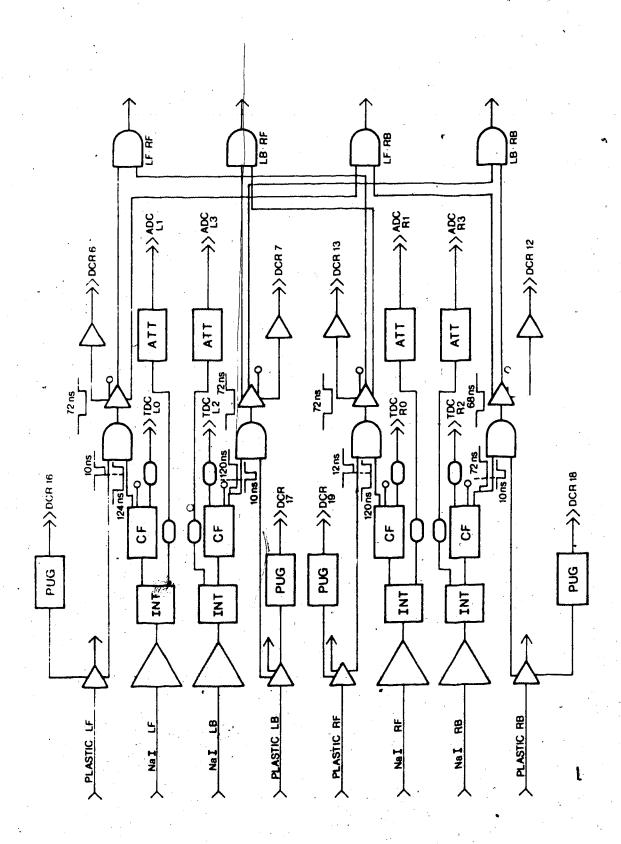

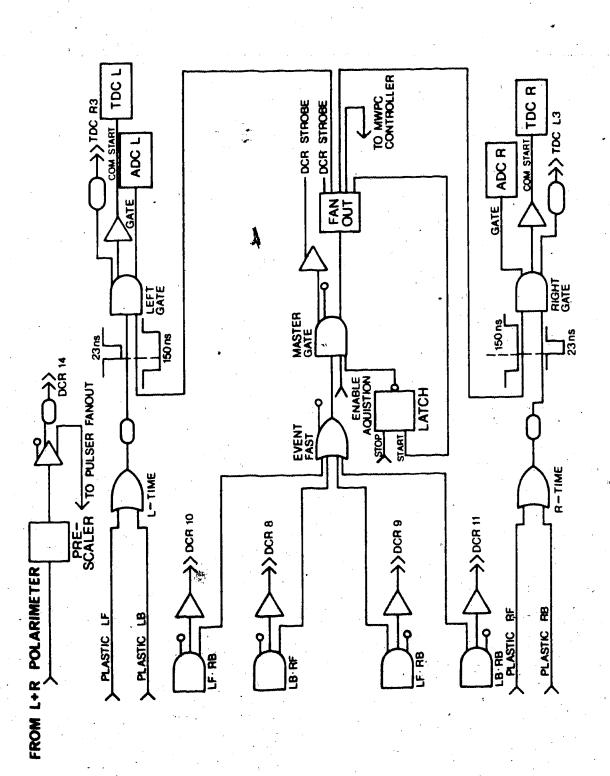

FIGURE III-3

Second of two logic diagrams of electronics located in remote counting room.

(MASTER GATE) signal. This latched the MASTER GATE and signaled the system to transmit the MWPC information to the computer through CAMAC. If a MASTER GATE was not generated within 1 µs of the strobe, the MWPC controller would generate an internal CLEAR which cleared the multiwire memories and disabled the EVENT FAST latch so that further coincidences could be processed. If a MASTER GATE occurred, the system processed the information until it was ready for the next event at which time the computer issued a COMPUTER NOT BUSY signal. This generated a CLEAR which was sent to the MWPC controller and which released the latches on the EVENT FAST and SLOW logic.

Following a MASTER GATE, CAMAC ADC's were turned on for a fixed length of time (a GATE) to integrate the signals from the plastic and NaI detectors, and time-to-digital converters (TDC's) were started. The ADC's were multi-input (12-fold) charge integrating types with 256 pC corresponding to full scale (1024 channels). The ADC gates used were 400 ns wide. The constant fraction devices shown in Figure III-2 provided a sharp timing signal when the height of the NaI signal had risen a pre-specified fraction of the full peak height (0.2 in this experiment). The widths of the pile-up gates were 9.0 to 9.4 µs. There were separate sets of ADC's and TDC's for the left and right detectors. To ensure that a left (right) detector gated or started the left (right) ADC's or TDC's respectively, the signals to initiate these processes were derived by ANDing the MASTER GATE signal with

a suitably delayed signal from the left (right) plastic. This is called retiming.

A TDC unit has a number of inputs each of which is stopped by a separate signal and all of which have a common In addition to using timing signals from the plastics and NaI detectors as stops, every second signal from the radio-frequency (rf) oscillations of the cyclotron was employed as well. The resulting timing right versus rf (start=right, stop=every second rf pulse) spectrum encompassed two beam bursts. A typical spectrum is shown in Figure III-4. If the cyclotron becomes slightly mistuned, some of the accelerated HT ions that pass the stripper foil slip out of phase with the rf by ~180°, emerience deceleration, and are subsequently extracted by the stripper foil resulting in a decelerated beam. Data acquired during periods having large amounts of decelerated beam have a spectrum such as the one shown in Figure III-5. discussed in Chapter IV, decelerated beam data had objectionable features and was not treated differently from other data. One of the stopping signals on the left (right) TDC consisted of a suitably delayed signal from the right (left) side. A typical left-right timing (start=left, stop=right plastic) spectrum is shown in Figure III-6. first and third peaks are random coincidence events consisting of protons from successive beam bursts". middle peak consists of prompt (real+random) events (from the same beam burst).

The DCR units shown in Figures III-2 and III-3 are

FIGURE III-4

CAMAC digital coincidence registers (or bit pattern units) consisting of 24 bits. For each MASTER GATE, the contents of the register were sent to the computer with each bit representing the status of its input. Table I shows the DCR assignments used in the experiment. To record the total number of counts from certain devices over the course of the experiment, CAMAC scalers were used. The quantities scaled in this experiment are listed in Table II, and the positions of some of these scalers are indicated in Figures III-1, III-2, and III-3.

While the computer is processing a previous event, the latch on the MASTER GATE could result in the loss of new events. This computer dead-time must be taken into account. In addition, the electronics preceding the MASTER GATE could contribute to the overall dead-time (although this effect is usually negligible compared to computer dead time). For the purposes of monitoring both the electronic and computer dead-times and to present a constant amplitude signal for calibration, pulser pulses, which were scaled (1 pulse for every 25) L+R polarimeter counts, were fed to the plastic and NaI LED's.

The information received by the computer was processed and, for each MASTER GATE, an event record was written on magnetic tape. A list of the contents of an event record is shown in Table III. In the table, LAM PATTERN refers to the CAMAC look-at-me signal issued when a CAMAC crate required the attention of the computer. The events written on tape

were organized into runs. At the beginning (end) of each run, a header (trailer) block was written which included the contents of the scalers listed in Table II. By subtracting the header block scalers from the corresponding trailer block scalers, the accumulated values for the run were obtained. For a given run, the angles of the detector booms were kept constant as was the polarization direction of the Successive runs recorded on a single tape were beam. separated by an end of file (EOF) mark, while the last run was followed by a double EOF mark. As well as processing the information and writing events on tape, the acquisition program recorded the scalers and kept a set of histograms for on-line analysis of the data. The spectra stored in memory are listed in Appendix II, along with their DCR gating requirements.

During the experiment, the detectors were positioned at various angles by remotely controlling the booms. The pairs of detector angles for which coincidence data were acquired are shown in Table IV. Data for each row of angle pairs in this table were acquired simultaneously. CD₂ and ⁴⁰Ca data were acquired for the same angle pairs in order to allow further calibration of the NaI detectors using (p,2p) on ¹²C or deuterium. Data were taken with the CH₂ target to provide calibration points for the NaI detectors from free p-p scattering. Only the angle pairs 57°-30°, 30°-57° and 44°-44°, from the various CH₂ angle pairs, provided calibration information.

Using the 40 Ca target, typically 3 to 5 tapes were acquired at each set of angle pairs and each polarization direction. Approximately two tapes (one third of a tape) of data were acquired for each set of angle pairs for the CD_2 (CH₂) target. One tape contains roughly 150,000 events divided among the 4 detector coincidence combinations.

CHAPTER IV

EVENT ANALYSIS

4.1 Introduction

The reduction of the information on the tapes to the final results can be divided into two phases. In the first phase, all events for a given beam polarization direction, detector coincidence combination, and angle pair were binned into two dimensional histograms containing prompt (reals+randoms) or random events. The histogram axes were T_1+T_2 (ESUM) and T_1-T_2 (EDIF). T_1 and T_2 are the kinetic energies of the protons at the target. With appropriate corrections, these numbers were converted into cross sections. This chapter discusses the first phase of the analysis in considerable detail. Readers who desire only a general understanding of this phase are advised to read sections 4.1, 4.2, and 4.14.

The quantity EDIF for three of the four detector coincidence combinations (LF-RB, LF-RF, LB-RB) was defined as Tleft-Tright. Since some of the angle pairs for the RF and LB detectors were the same as those for the LF and RB detectors, data for LB-RF was binned as TRF-TLB. With this convention and for similar angle pairs, a spin + run for LF-RB would be equivalent to a spin + run for LB-RF - thus spin + (+) LB-RF data was treated as spin + (+) data. Due to different ESUM resolutions and accuracy of the energy calibrations between LB-RF and LF-

RB, events from these detector combinations were always binned in separate histograms.

The data are organized in ESUM versus EDIF histograms because a single particle state is characterized by a unique binding energy, BE. If T_0 is the incident energy and T_3 is the energy of recoil for a (p,2p) reaction, then (IV.1) $T_1+T_2=T_0-BE-T_3$.

As the recoil energy of the residual nucleus (T₃) is quite small for ⁴⁰Ca(p,2p) (less than 0.55 MeV for recoil momenta less than 200 MeV/c), the cross section for a single particle state should peak at a nearly fixed value of ESUM independent of EDIF. Varying EDIF while keeping ESUM fixed changes the recoil momentum allowing the examination of the momentum dependence of a single particle state. As the cross section for a state changes rather slowly as a function of recoil momentum, the EDIF bin size is 20 MeV. The ESUM bin size is chosen to be 1.0 MeV since this is 1/3 to 1/4 of the summed energy resolution (FWHM) attained in this experiment.

In the second phase of the analysis, which is discussed in the next chapter, cross sections for each of the $\mathrm{ld}_{3/2}$, $2s_{1/2}$, and $\mathrm{ld}_{5/2}$ single particle states were extracted by fitting Gaussian peaks to ESUM spectra for the different 20 MeV EDIF ranges. As there were data for both polarization directions, the results of the fitting were converted into unpolarized cross sections (σ_0)

and analysing powers (A_y) for each single particle state as a function of EDIF and angle pair.

4.2 Overview

An outline of the first phase of the analysis follows the data analysis was performed on a Data. 00 computer. The tape reading software is MN-78) while the remainder of the event analysis sortware was developed specifically for this experiment. For a given run, the data were subjected to a number of cuts and the surviving events were binned into eight ESUM versus EDIF histograms. By means of windows on the left-right timing (start=left, stop=right plastic), events were binned either into a prompt event histogram (corresponding to the central peak of Figure III-6) or a random event histogram (corresponding to the left and right peaks of Figure III-6) for each of the four detector coincidence combinations. The assumption was made that the energy distribution for random coincidence originating from two beam bursts was the same as that for random coincidence events arising from a single beam burst. Since both random coincidence peaks were included to increase statistical accuracy, the random event histogram contained twice the actual random background correction. The counts (divided by two) in the random event histogram were subtracted from the counts in the corresponding prompt event histogram before the cross sections were computed.

Criteria (cuts) used to reject events from the data

were applied equally to the prompt and random data. Some of these cuts, although necessary, eliminate valid events and compensating corrections were necessary to avoid biasing the final cross sections. For this reason, during the reduction of each run, statistics and correlations were acquired from which correction factors were calculated.

4.3 NaI Detector Efficiency and Solid Angle Definition

For a given particle energy, the efficiency of a NaI detector is nearly constant over its central region and drops off sharply near the outer circumference due to outscattering (CA-77). The radius of the central plateau decreases with increasing particle energy. The energy dependence of the NaI efficiency in the plateau is given in Table V. For energies greater than 150 MeV, these efficiencies include the effect of inserting enough copper to degrade the energy to ~135 MeV. A correction factor consisting of the product of the NaI efficiencies for the detector energies of the two protons has been incorporated into the calculation of the cross sections.

The MWPC coordinates were used to define circular windows centered on the faces of the four NaI detectors. The center of each of these windows was established by examining the distributions of "Ca(p,2p) events on x versus y histograms. The radius of these windows was chosen on the basis of histograms such as the one shown in Figure IV-1. This illustrates the radial distribution of (p,2p) events per unit area from the center of the detector

FIGURE IN-1

Counts per unit area for each of the 4 NaI detectors as a function of distance (in wires, wire spacing = 2mm) from the center of the detector. Counts are LF-RB (30°-54°) and LB-RF (49°-35°) events with a 40Ca target. Events falling outside a radius of 26 wires (indicated by arrows) were rejected in the analysis.

the abscissa has units of wires (where the wire spacing is 2 mm). For each of the detectors, the central region is flat (as expected) and falls off beyond 26 wires. Thus, a common window radius of 26 wires was chosen for each of the detectors. The resulting solid angles are LF=4.72msr, RF=4.72msr, LB=6.36msr, and CRB=6.43msr. Events outside these, windows were rejected. The front (back) detectors

4.4. Multiwire Efficiency

Wires away from the edges of the multiwire planes are quite efficient (bypically 599.5%). However, any event for which one (or more) of the four wire planes fails to register a hit must be rejected. For a certain fraction of these events, this missing coordinate would be within the window. Consequently, a correction consisting of the product of the efficiencies of the four participating multiwire planes is included in the calculation of the cross sections. For the x and y planes on one arm, the efficiencies are given by (IV.2). MWEFF += 1 - MMISS

where THIT, YHIT are the number of events within 26 wires of the center in X (Y),

XMISS, YMISS are the numbers of missings in X (Y) whose corresponding Y (X) coordinates were within 26 wires of the center.

Typically, the product of the efficiencies of the foot

planes was ~0.99.

4.5 Pile-Ups and Multiple Hits

In the event analysis, events with a pile-up TiR bit set for either etector arm were rejected. These represented ~13% of the total number of events. Approximately 0.5% of the events had pile-ups in both arms. In adjusting the cross sections for the pile-up cut, each pile-up was counted as representing a single (p,2p) event. Any double (p,2p) events rejected by the pile-up criteria were automatically accounted for in the computer dead-time correction.

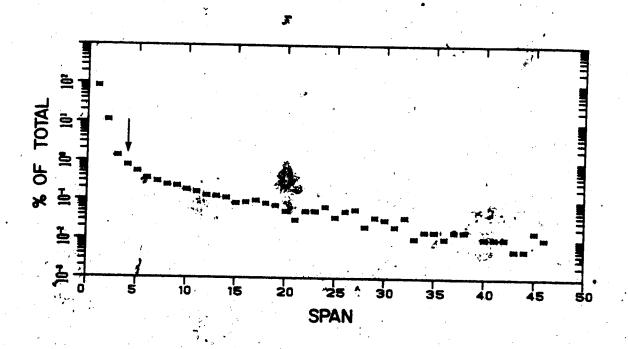

When a proton passes through a MWPC, it is most likely that a single wire will be struck, although it is possible that two or more wires (not necessarily consecutive) will be struck. It is also possible that two particles may pass through the plane within the resolving time, Thu, of the plane (~100ns) causing two distincts sets of struck wires. Furthermore, two particles passing through the telescope sufficiently close in time will fail to be resolved by the pile-up monitor and thus the pile-up DCR bit will not be set.

The span of a struck plane is defined as the number of wires from the leftmost (or topmost) struck wire to the rightmost (or bottommost) struck wire. Thus, a single struck wire has a span of one, two struck wires separated by a gap of two wires has a span of four and so on. If the assumption is made that only a single particle passes

through each wire plane per event, then a reasonable definition of the position of this particle is the sum of struck wire coordinates divided by the number of struck wires (centroid). However, for large spans, the concern arises whether two particles have in fact passed through the plane or whether a single particle has produced a large span (for example, by ejecting a 6-ray to one side). In either case, as the span increases, confidence that the calculated centroid represents the actual cast of the particle(s) rapidly erodes as there is no reason to assume that the span is symmetrical about the position by the particle(s).

The distribution of events for the y plane of the LF MWPC is plotted as a function of span in Figure IV-2. This distribution is typical of all the wire anes and it was decided to reject events for which any one of the 4 planes recorded a span greater than 4 wires. Such events are referred to as multiple hits. After pile-up events were rejected, 12% of the remaining events were found to be multiple hits including 0.5% which had spans greater than four on all four wire planes (quadra-multiple events). No account was taken for the fraction of the quadra-multiple events which may have been double (p,2p) events and all multiple hit events were treated as single (p,2p) events with the final cross sections being corrected accordingly.

Distribution of events (expressed as the percentage of total) passing through y plane (LF at 25°) as a function of span. Events with spans greater than 4 (indicated by the arrow) were considered multiple hits.

4.6 Elimination of Free p-p Events

The calcium target used in the experiment contained substantial amounts of hydrogen ($H/^{40}$ Ca ~ 0.23 in atoms) as discussed in section 4.13. All the angle pairs for LB-RF and LF-RB (with the exception of 47°-29° and 29°-47°) overlapped with free p-p scattering angles. The relatively large free p-p cross section (~10.6 mb/sr at 200 MeV at 43.6°) resulted in the presence of considerable numbers, of free p-p events in the data. The peak for free p-p events As well separated from the (p,2p) data as shown in Figure Tright is plotted for 30°-54° (LF-RB). However, energy losses suffered by elastic protons undergoing nuclear reactions in the NaI crystals result in two p-p reaction tails which extend into the (p,2p) region as can be seen in the figure. Free p-p events were eliminated by means of coplanarity and opening angle cuts applied to the data based on the distribution of Δx versus Δy where

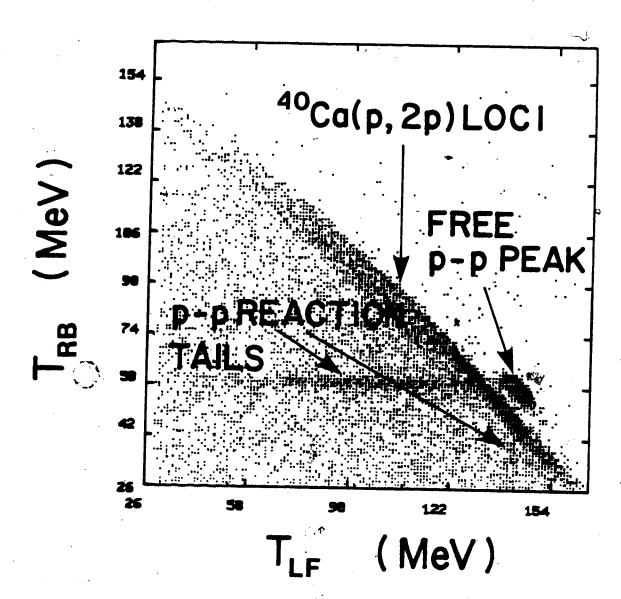

(IV.3) $\Delta x = x_{left}^{-x} right^{+64}$

$$\Delta y = \frac{(y_{left} + y_{right})}{2}$$

Ax and Ay correspond to the opening angles in the horizontal and vertical planes respectively. Such a distribution for events from the free p-p peak (isolated from the 40Ca(p,2p) events by means of applying suitable, windows to the NaI signals from both arms) for 30°-54° is

Scatter plot (logarithmic density scale) for T_{LF} versus T_{RB} . Counts are LF-RB (30°-54°) events with a 40 Ca target. The (p,2p) loci as well as the free p-p peak and reaction tails are labelled. The reaction tail on the low energy side (LB) is only barely visible.

shown in Figure IV-4. Eliminating all events which fell within a rectangular window surrounding this distribution (shown in Figure IV-4) resulted in the Tleft versus Tright distribution shown in Figure IV-5 (which is to be compared with Figure IV-3). This method, which we refer to as the elastic cut, required a different window in Ax versus Ay for each angle pair of LB-RF and LF-RB. It contains the compared of the free p-p events.

However, it also excluded a fraction of the (p,2p) events. To estimate what fraction of (p,2p) events were being rejected, the elastic cuts were applied to runs not containing free p-p events $(47^{\circ}-29^{\circ}$ and $29^{\circ}-47^{\circ})$. By counting the numbers of events eliminated, we obtained a correction factor for each elastic cut. This correction factor was incorporated in the calculation of the cross sections. The size of the correction varied with the Δx versus Δy window size and ranged from 1% to 19% due to varying degrees of overlap with free p-p angles.

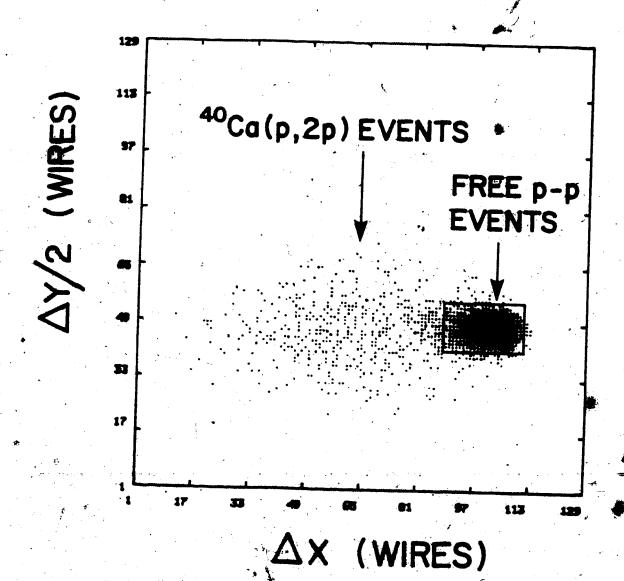

4.7 NaI Calibration and Energy Resolution Optimization

In order to bin events in the ESUM versus EDIF histograms, pulse heights from the left and right NaI detectors were converted into energies. To do this, a number of factors had to be taken into account. The relation of petween NaI pulse height and energy was nonlinear. In addition, the DI ADC pedestals, zero offsets due to a dc level added to mach NaI signal, were not negligible. Since the accuracy in determining the

Scatter plot (logarithmic density scale) for Δx versus $\Delta y/2$ (proportional to opening angles in the horizontal and vertical planes respectively). Counts are LF-RB (30°-54°) events with a 4°Ca target. The free p-p events (selected by software windows) and the few remaining (p, p) events are labelled. Events falling within the rectangular region were rejected in the analysis.

Scatter plot (logarithmic density scale) for TLF versus TRB. Conditions are the same as for Figure IV-3 but with all events falling within the rectangular window shown in Figure IV-4 rejected. Although >96% of the free p-p events have been eliminated, the p-p peak is still visible because of the logarithmic scale.

T_{LF} (MeV)

cross sections of the single particle states depended strongly upon the degree to which the peaks were resolved, it was worthwhile to invest considerable effort in penowing nonlinearities and minimizing effects that degraded the energy resolution.

The free p-p scattering in the La -RF and LF-RB 40Ca runs and in the CH2 runs provided a number of well-defined energy calibration points. Free p-p events were isolated from the 40Ca(p,2p) data by means of NaI pulse height windows and, in addition, the left and-side protons we required to pass through a 6 wire wandow in the x Since, ecattering tantle and energy are direction. correlated for free p-p scattering; to -0.6 served to define precisely the energies of the protons at the target. The position of each x-plane window was chosen and a restriction was applied to the y-coordinates in order to guarantee that the protons in either arm passed within the circular region of constant at efficiency. minimized the reaction tails, making the precise determination of the peak positions easier.

Protons emerging from the target passed through a considerable amount of material (the target itself, the scattering chamber window, air, the MPC's the plastic acintillators, and cope on the fronts of the Mal Satectors) losing obse of their energy before being stopped in the Mal detectors. For calibration purposes, given the energies of the free p-p protons after the interaction in the target,

Once the detectors were calibrated, the energy deposited in the state of was used to obtain the scattered energy at the energe. For both purposes, a table of values representing the energy-degrading materials between the table was compiled and is shown as Table VI. The energy loases experienced by thous passing through these materials were obtained from tables of stupping powers (Sk-67). Energy loases suffered by 14 54 MeV protons at the target reaching the frace (back) Nel detectors were ~8.1

For each CH₂ run and for the p-p elastic events in each "Ca run, the average value of the Ned bulse height for the free p-p year obtained. In addition, the average LED and pedestal pulse heights for each of the NaI detectors for these runs sere obtained. A plot of average pedestal pulse height versus run number for each detector is shown in Figure IV-6. The common fluctuations among the four detectors are believed to be due to a combination of temperature effects, and electronic noise while the origin of the similarity between the left or right pedestals is believed to originate in the ADC's. The fluctuations over the course of the experiment are on the owner of 5 channels ("1.10 to 1.42 Mey espending on the detector) while the resolution (SUND) for a given run ranged from A to 7 channels among the versions detectors.

NaI pedestal pulse height centroids for each detector as a function of run number? Data shown are for "Ca runs while gaps correspond to acquisition of CH2 or OD2 data.

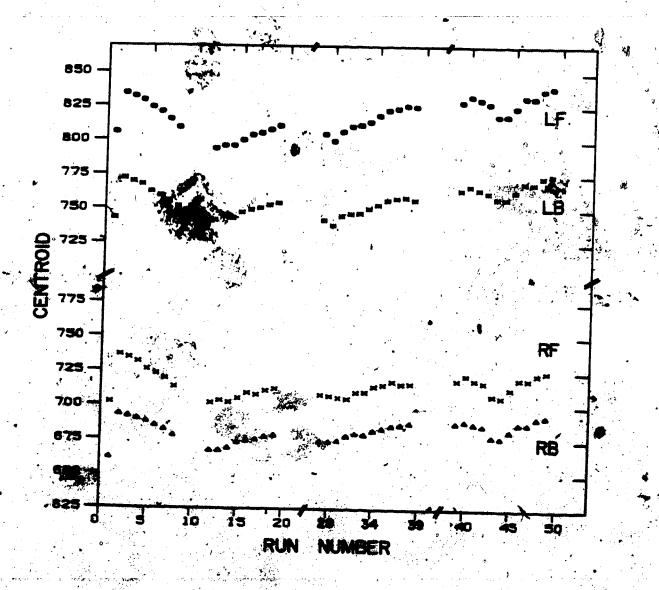

LED pulse height (corrected for the pedestal) versus run number is clotted in Figure IV-7. The large shifts in gain (~20 to 45 channels), which are correlated ong the 4 detectors, are very probably due to stability problems in h the common pulser input to the LED's. The resolution of the the LED peaks (FWHM) for, a given run ranged from 11 tem 16 channels among the four detectors. Finally, the averpulse height of the free pp wevents (corrected for edestal) versus run number is plotted in Figure IV-8. The ESUM resolution (FWHM) varied from 20 to 24 channels. Runs with the same detector angles are grouped together in the figure since the average apulse height for feee p-p scattering varies with angle (data for Figures IV-6 and IV-7 were organized similarly to facilitate comparison). data corresponding to a given set of detector angles, the variations are probably due to a combination of ADC fluctuations and individual detector base noise. changes in the DED pulse heights are substantially larger than, and not obviously correlated with, those of the free p-p events. For the reason, the LED pulses heights were not used in the calibration of the If the signal as output directly from the sulser driving the LED bad been recorded on an event-byevent basis, it might have been possible to remove these variations and the LED pulse heights would then have been quive useful in the energy calibrathon.

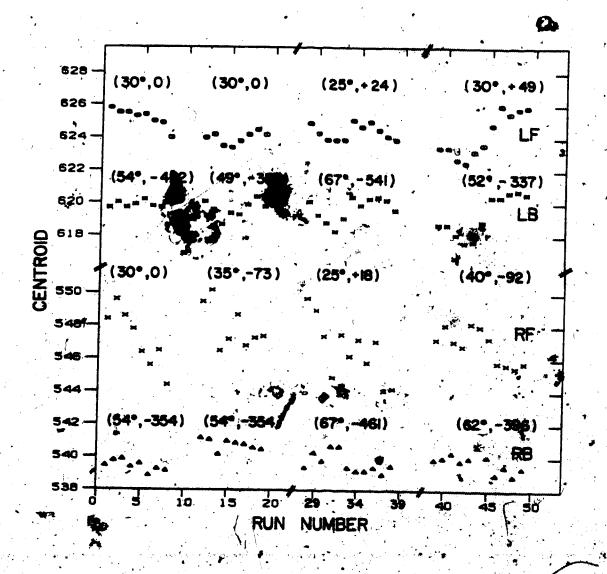

The method of calibration was as follows. Initially,

FEGURE IV-7

Na! LED pulse height (minus pedestal) controlds for each detector as a function of run number. Conditions as for Figure IV-6.

Free p-p NaI pulse height (minus pedestal) centroids for each detector as a function of run number. Data are from scattering from hydrogen contamination in 40Ca target. For each set of data, the detector angle and the difference between the measured pulse heights and the plotted values are given.

the energy at the NaI detector (T_{cal}), as determined from the pulse height, was assumed to be related to the pulse height of the proton (PH_p) and pedestal (PH_{ped}) in a linear fashion, (IV.4) T_{cal} (i) = g(i) · [PH_p (i) - PH_p (i)],

where g(i) is the gain for the ith detector.

The gains were obtained from the librage pulse height for free p-p events, $PH^{el}(1)$; and palestals, PH ped (i), from the p (IV.5) $g(i) = \frac{T_{kin}(1)}{[PH^{el}(1)-PH}(1)]$

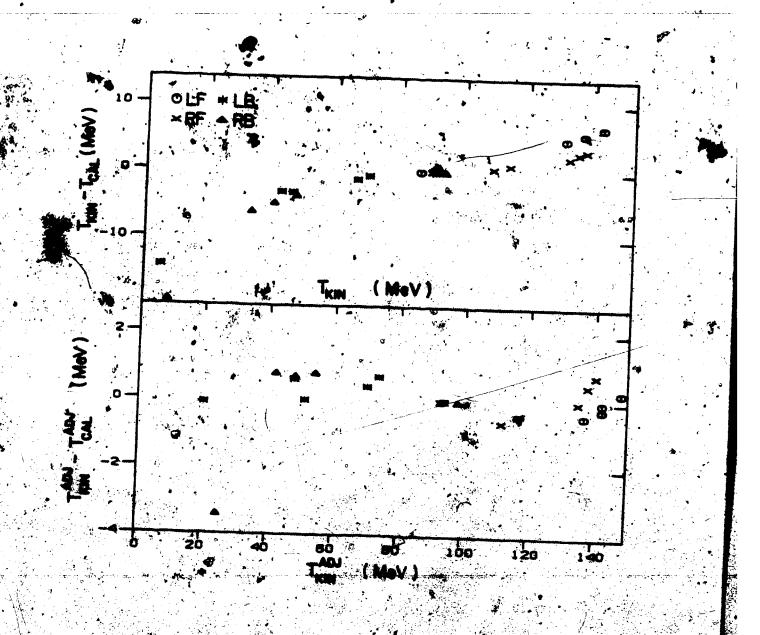

where T_{kin}(i) is the energy at the ith all detector as determined from kinematics at the target (corresponding to the angle of scatter) and corrected for energy logoca.

With this set of gains, a value of energy based upon the average free p-p pulse height and pedestal for each of the detectors for each angle pair of "Ca data containing free p-p scattering was computed using equation IV.4. The result of these calculations is presented in a plot of (Tkin-Tcal) versus Tkin shown in Figure IV-9. The departures from zero at high and low energies are a result of the nonlinearity of the system. A nonlinearity correction, of the necessary energy dependence, was introduced by adjusting the amount of material in front of

minus the energy described from the NaI free p-p pulse heights (Tkin Tcal) for each of the 4 detectors as a function of Tkin. Pulse heights are from CH₂ so well as 40°Ca runs.

FIGURE IV-10

Same as in Figure IV-9 after nonlinearity correction has been applied.

the NaI detectors used in the energy loss calculations. The adjusted values are given in Table VII.

With the same data, the gains were recalculated using equation IV. I where Thin was replaced by Tadj. Tadj is the kin kin.

energy at the NaI obtained from free p-p kinematics at the target and corrected for energy losses using the adjusted densities given in Table VII. The process used to obtain the possess for Figure IV-9 was repeated and the new energy calibration gives the results shown in Figure IV-10. The non-linearities are now seen to be largely removed. Thereafter, energies at the target were obtained from NaI pulse heights and pedestals by means of equation IV.4 (using the adjusted gains) and by performing energy loss calculations with the values from Table VII.

With this procedure, the GD, target data were binned in ESUN versus EDIF histograms. The resulting positions in ESUN of the 12C(p,2p) (BE=15.95 NeV) and 2m(p,2p), (BE=2.225). NeV) loci typically ranged from 3 NeV above to 5 NeV below the expected position of the loci (based on kinematics and taking into account the recoil energies of the 18 and meetron). The expected positions in ESUN of the loci for 12C(p,2p) and 2m(p,2p) ranged from ~182 to ~184 NeV and from ~190 to ~197 NeV respectively. For a given chargy difference and angle pair, the difference between the position of the data and the expected position was the same for the 12C(p,2p) and 2m(p,2p) data. This, along each the Sact these the aims of the hims in ESUN (20 NeV) was target

compared with the error in ESUM, led us to regard uny further adjustment of the energy calibration as unnecessary. The remaining discrepancy was regarded as a linear shift in ESUM which was treated in the fitting of the data.

A further refinement of the pulse height to energy conversion process involved the pedestal values. The pedestal for each detector was continually updated by the average of the last 100 pedestal values for that detector. This resulted in an improvement of 0.2 to 0.3 MeV in the ESUM resolution. The ESUM resolution varied with the angle pair and detector combination and ranged from 3.2 to 4.4 MeV. The variation with detector combination reflects individual detector differences. The variation with angle pair is possibly caused by time-varying temperature effects on the detector electronics.

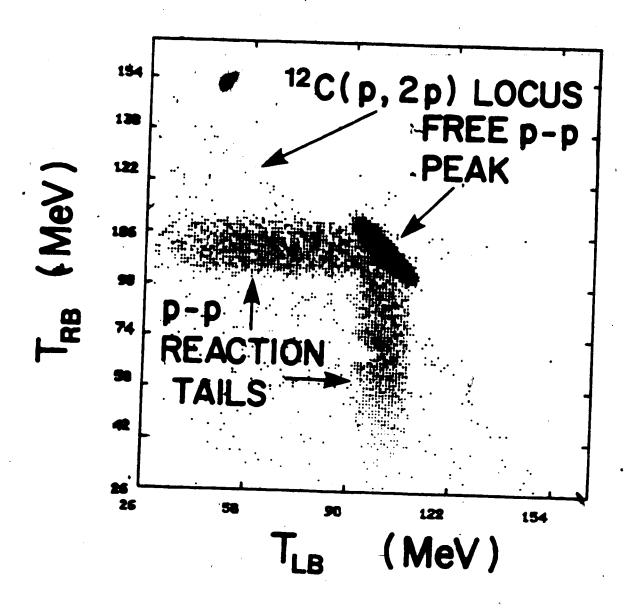

4.8 Reaction Tail Subtraction

Reactions in the NaI(T1) crystals produce tails from every point along a (p,2p) locus similar to those shown for free p-p scattering in Figure IV-11. To easure that the ESUM resolution of the individual valence states was not being seriously degraded and that the heights of their peaks did not have a significant background due to the reaction tails of higher energy protons, an examination of the effect of reaction tail subtraction was performed. The shape of the reaction tails was taken from p-p spectra from the CH2 runs and an attempt to strip away the tails

Scatter plot (logarithmic density scale) for T_{LB} versus T_{RB} . Counts are LB-RB (44°-44°) events with a GH_2 target. The free p-p peak and reaction tails as well as the $^{12}G(p,2p)$ locus are labelled.

.

1. C

from the (p,2p) data was made. For a given angle pair and spin direction, (p,2p) events were binned in a ESUM versus EDIF histogram with bin sizes of 1 MeV by 1 MeV. For each bin of the histogram, the reaction tail contributions due to all higher energy protons were subtracted before proceeding to the lower elergy bins. Once the subtraction process was completed, the remaining counts were rebinned in an ESUM versus EDIF histogram with bin sizes of 1 MeV by 20 MeV and compared with the uncorrected histogram. The reaction tail subtraction made no measurable improvement in the ESUM resolution, and an upper limit for the decrease in the counts for the $1d_{3/2}$, $2s_{1/2}$, and $1d_{5/2}$ region was <2X. Thus, the effect of tail subtraction was small and was not included in the final results.

4.9 Removal of Deuterons

Events from the (p,pd) reaction were acquired concurrently with the (p,2p) events. To eliminate them, a quantity proportional to the masses of the detected particles was calculated. The range, R, of a particle of energy T and mass H in a given material can, be approximated by (SE-64)

(IV.6)
$$R(\frac{T}{H}) = K \cdot (\frac{T}{H})^n$$
,

where K,n are constants, and n=1.8.

From an expression relating the difference in range (AR)

for two particles differing in energy by an amount AT,

(IV.7) WR =
$$R(\frac{T+\Delta T}{H})-R(\frac{T}{H})$$
,

Here AT and T represent the energy deposited in the plastic detector and the emerging particle energy respectively. Thus, plastic scintillator pulse height had to be converted to energy for each of the detectors. Pedestals and free pp scattering pulse heights for the plastic scintillators from CH₂ runs were desed to establish a linear relationship between pulse height and energy. The energy of the particle emerging from the plastic scintillator was obtained from the energy deposited in the Hal detector plus the energy lost in travelling between the plastic and the stopping counter.

In order to resolve protons and deuterons on the basis of mase, it was necessary to correct the pulse heights in the plastic scintillators for an observed dependence on the vertical position of the particle in the detector. This dependence was studied by examining free p-p events from the CH2 runs and the results are plotted in Figure IV-12 as a function of vertical distance (in wires) from the center for each of the plastics.

This behavior probably arises from a wanter of

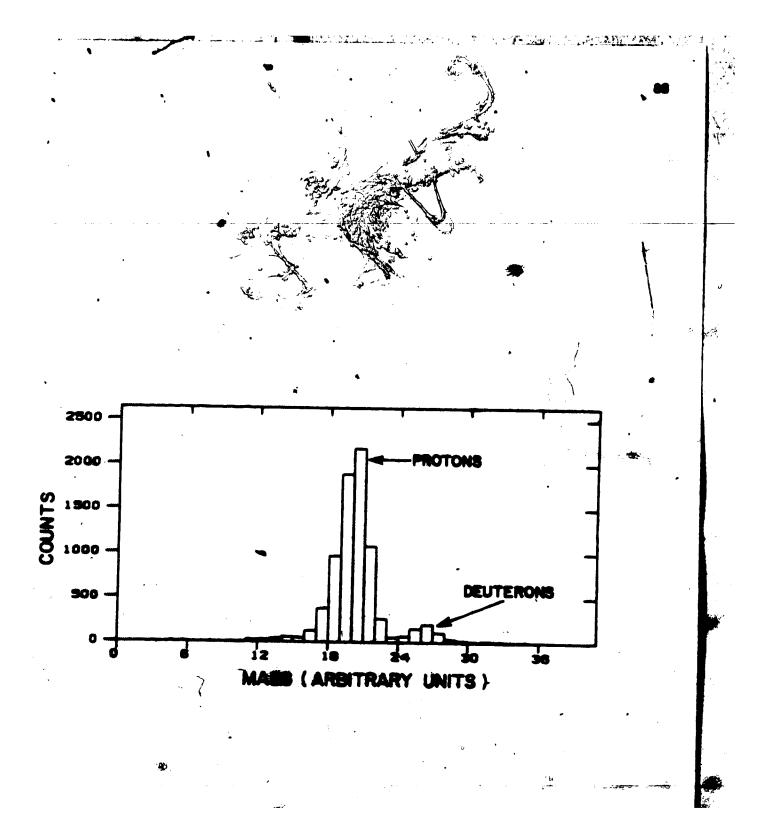

Relative plastic pulse heights for each detector as a function of vertical distance from the center of the event-defining window. Data are from free p-p scattering from the CH₂ target. The position of the light guide and the center of the window are indicated.

effects. The light undergoes attenuation in the scintillator, and the solid angle acceptance of the light guide decreases with increasing distance from the guide. In addition, light signals undergo more reflections from the boundary of the scintillator as they propagate toward the light guide the higher they are generated in the detector, and with each reflection there is some loss of signal strength due to partial internal reflection. This interpretation correctly predicts that the thick front plastics should experience a smaller effect than the thin back plastics (which should require more reflections).

After correction for this position dependence, the protons were sufficiently well resolved to allow elimination of the deuterons. Figure IV-13 shows the distribution of events as a function of the mass parameter for the RB detector for 30°-54° +0Ca data. The deuteron peak is to the right of the larger preton peak. Mass parameter windows for protons were established for each detector in a (p,2p) coincidence and events with either particle mass outside these windows were rejected. This eliminated varying fractions of events from ~9% (25°-67°) to ~26% (67°-67°). Generally, the angle pairs for which typical (p,pd) recoil momenta were smaller than typical (p,2p) recoil momenta had the greatest number of events containing deuterons.

0

Counts as a function of the mass parameter of the RB detector. Counts are LF-RB (30°-54°) events with a "Ca target. Proton and deuteron peaks are labelled.

4.10 Decelerated deen Events

The fraction of decelerated protons in the incident bess was large (~12X-78X) in 7 of the 39 40Carruns. In the remaining 32 rune, the decelerated beam component was <2%. As mentioned previously, decelerated bean events could be resolved from normal beam events by means of the timing versus of TBC information. Using the same procedure as in the Wal calibration to isolate free p-p events from **Ca data, the energy spectra for decelerated and accelerated bean events were studied separately. It was concluded that the incident energy of the decelerated component of the beam and the ESUM resolution were indistinguishable from those for the normal beam. Also, the beam polarisations were similar to those of other runs. For these reasons, decelerated beam events were not separated or treated differently from normal events in the subsequent analysis.

4.11 Dead Time Correction

The loss of events due to computer and electronic dead-time must be compensated for in the calculation of the cross sections. Two (correlated) measures of the deadtime, the first (a) including only computer dead-time, the second (b) including that from both sources, calculated from

Pulser events presented to system

These seaferes were usually quite committees (a) were cypically 0.6% see 1.8% Surger than (b). Proceeding of

polarimeter counts caused the interval between subsequent pulser triggers to be very regular. Thus, pulser events could cause dead time for non-pulser data but not subsequent pulser events. This, along with the fact that the electronic dead-time is expected to be negligible, explains the sense of the difference between the two dead times.

The value determined by method (a) was used. In instances when there was serious disagramment between the two methods, the problem was believed to be due to a hardware malfunction in the palaer electronics. In such cases, the ratio of new-pulser meants written on tape to non-pulser events presented was taken as the dead time correction. Typically, this correction ranged from 1.05 to 1.12 for the "Cc runs."

4-11 Man Hornelisation

The number of incident protons during a run could be measured either by means of the polarimeter counts (NI_a) of ion chamber counts (NI_b) using equations II.2 or II.3 respectively. The free p-p scattering cross sections at -63.2° from LF-RF and LB-RB CH, data with a polarization of -0.73 (*) were computed. Using NI_a, the values obtained were completent so within 0.2% and were 5.0% lower than the value expected from phase shift askenistions, then NI_a will appear the RB and La-RB the results were 5.2% and 5.4%

the experiment, expressed to the Series of hydrogen to extend from the first of the series of hydrogen to extend from the first of the series of the series

previously outlined in section 4.7. Then, from known values for the free p-p cross section (from phase shifts), the amount of hydrogen could be deduced.

The source of hydrogen in the target was probably Ca(OH)₂ and residual mineral oil not removed in the cleaning. As previously mentioned, the free p-p peak is well separated from the 40 Ca(p,2p) data and the reaction tails were almost entirely removed by means of the elastic cuts. However, while the free p-p events posed no problem in the analysis of the 40 Ca(p,2p) data, other contaminants such as oxygen (Ca(OH)2, CaO), nitrogen (CaN2), and carbon (CaCO $_3$) have (p,2p) loci which overlap those from 40 Ca to varying degrees. Previously measured binding energies for single particle valence states for 40ca, 160, and 12c are listed in Table VIII. Because of the 3.2 to 4.4 MeV summed energy resolution and the resulting overlap of single particle states from different nuclei, it is impossible to distinguish between the 40Ca(p,2p) peaks and those of the contaminants. Consequently, other analysis methods were employed in an attempt to ascertain the amount of contemination. Since these analysis methods were performed after vanious periods of time had elapsed since the experiment (performed in June 1977), the resulting values serve only as upper limits. Due to a number of difficulties, the methods were not equally sensitive to the various contaminants and the following represents the best estimate for each of the contaminants.

** Spectroscopic factors and binding energies for $^{40}{\rm Ca}$ from (D0-76).

A value for the nitrogen to calcium ratio of 0.091±.004 was obtained (in August 1979) from a 200 MeV (p,d) experiment involving the "OCa target and a 90.2 mg/cm² kapton target (C22H10N2O5, density=1.42gm/cm³) which served as a nitrogen target. The scattered deuterons were detected by the TRIUMF Medium Resolution Proton Spectrometer (MRS) at 22.0°. In the experiment, the peak for 14N(p,d) in the deuteron energy spectrum was identified by means of the Q-value for the reaction (~8.3 MeV). The Kapton target was used to determine the cross section for this process and this in turn was used to determine the amount of 14N in the 40Ca target. Unfortunately, the peaks corresponding to 12C(p,d) and 16O(p,d) were not resolved from 40Ca(p,d) peaks and no reasonably accurate value for carbon or oxygen could be extracted.

A value for the carbon to calcium ratio of 0.054±0.009 was obtained (in August 1979) by means of gas chromatography. The method involved grinding a small piece of the target (~10 mg) into a powder which was then fed to a gas chromatograph. The sample was heated to a temperature of ~1100°C and the expelled gases were carried along by a jet of helium to molecular scrubbers which trapped HgO, CO₂, He, N₂, or O₂. Even though CaCO₃ dissociates at ~900°C, CaO would probably remain as a solid (dissociation point >2850°C). Also the dissociation point for CaN₂ is >1192°C and thus this technique was inappropriate for determining the oxygen or nitrogen

3-

contamination.

The amount of oxygen was measured by scattering 18 MeV protons from the "OCa target (University of Washington, Seattle, September 1979). Elastically and inelastically scattered protons were stopped at 110° in a solid state silicon detector. The ratio of 1-60 to "OCa (RAT) was obtained from

(IV.10) RAT =
$$\frac{N_0}{N_{\text{Ca}}} = \frac{\frac{d\sigma}{d\Omega}}{\frac{d\sigma}{d\Omega}}$$

where $N_{\rm Ca}$, $N_{\rm O}$ were the number of counts in the $^{40}{\rm Ca}$ and $^{16}{\rm O}$ elastic peaks, and the elastic scattering cross sections, $\frac{{\rm d}\sigma}{{\rm d}\Omega}$, for $^{40}{\rm Ca}$ and and $^{16}{\rm O}$ were obtained from (SH-74,VA-71). The elastic peaks for $^{12}{\rm C}$ and $^{14}{\rm N}$ were not resolved in this experiment.

The 40 Ca target was briefly exposed to air in the process of mounting it in the scattering chamber despite attempts to isolate it by means of keeping it in a dry argon atmosphere. Thus, the value obtained for the ratio of 16 O to 40 Ca (0.526 \pm 0.055) represents a very pessimistic upper limit.

In summary, the level of contamination for ¹⁴N and ¹²C appears low enough to be unimportant. However, the situation for ¹⁶O is less clear on the basis of these measurements. Fortunately, an indirect method of measuring the oxygen was found by means of incorporating previously

measured $^{16}O(\dot{p},2p)$ cross sections into the fitting of the $^{40}Ca(\dot{p},2p)$ data. This method is fully outlined in Chapter V and yielded a value of 0.324 ± 0.078 . Furthermore, as detailed in that chapter, the final $^{40}Ca(p,2p)$ results were fully corrected for the presence of ^{16}O .

4.14 Event Analysis Summary and Cross Section Calculations

The cuts and windows applied to the events from each 40 Ca run in the order in which they were performed are summarized below.

- i) Pulser events were rejected.
- 11) The detector coincidence combination was determined.

 Subsequent analysis focussed on information from the two detector arms in coincidence.
- iii) Events not passing through the cincular multiwire windows were rejected.
- angle pairs which contained free p-p events. This eliminated most free p-p events.
- The left-right timing (start=left, stop=right plastic) was examined and events were flagged either as a random (peak 1 or 3 of Figure III-6) or a prompt (peak 2). All subsequent cuts were applied in an identical fashion to both types of events.
- vi) °Events for which pile-up occurred in either detector arm were rejected.
- vii) Multiple hit events (events with spans >4 wires) were rejected.

- viii) The energies deposited in the plastic and NaI detectors were computed. From these the mass parameter for each particle was calculated. If either particle fell outside the mass parameter window for protons, the event was rejected.
- ix) The appropriate random or prompt energy histogram binwas incremented.

The bins of the energy histogram were: 100.5, 101.5, ..., 209.5 for ESUM (where bin 100.5 covers the region [100,101) MeV etc.); -180, -160, ..., 200 for EDIF (where bin -180 covers the region [-190,-170) MeV etc.). After the information from all runs having a given spin direction, detector combination, and angle pair were tombined, the cross sections were calculated. As the incident beam was only ~70% polarized, the resulting spin + and + cross sections are referred to as partially polarized cross sections.

For a bin with energy coordinates ESUM-ES, EDIF-ED, the partially polarized cross section and error were computed as

(IV.11)
$$\frac{d^4\sigma}{dESUM \cdot dEDIF \cdot d\Omega_1 \cdot d\Omega_2} = {NE-NRE \choose 2} \cdot f ,$$

$$\frac{\Delta d^{4}\sigma}{dESUM \cdot dEDIF \cdot d\Omega_{1} \cdot d\Omega_{2}} = \left(\frac{NE + NRE}{4}\right)^{1/2} \cdot f$$

where f is given by

(IV.12)
$$f = \frac{DTC \cdot PUC \cdot MHC \cdot ELC}{\Delta ESUM \cdot \Delta EDIF \cdot d\Omega_1 \cdot d\Omega_2 \cdot N_1 \cdot N_2 \cdot MWEFF \cdot NaIEFF}$$

where NE is the number of events in the prompt histogram

NRE is the number of events in the corresponding randoms bin (includes 2 randoms peaks),

DTC is the computer dead time correction,

PUC is the pile-up correction,

MHC is multiple hit correction,

ELC is the correction factor accounting for the elimination of (p,2p) events in the course of eliminating free p-p events; it applies only to those detector combinations and angle pairs with free p-p events present,

 $\Delta ESUM$ ($\Delta EDIF$) is the dimension of the bins in ESUM (EDIF), 1 (20) MeV,

 $d\Omega_1, d\Omega_2$ are the solid angles subtended by the MWPC windows,

Ni is the number of protons incident on the target (based on polarimeter counts),

 $M_{\rm t}$ is the number of $^{40}{\rm Ca}$ atoms per unit area in the target, [7.44±0.37]×10²⁰ cm⁻²,

MURPY is the product of the efficiencies for the lar multiwire planes for the detector coincidence ins considered,

CHAPTER V

FITTING OF THE DATA

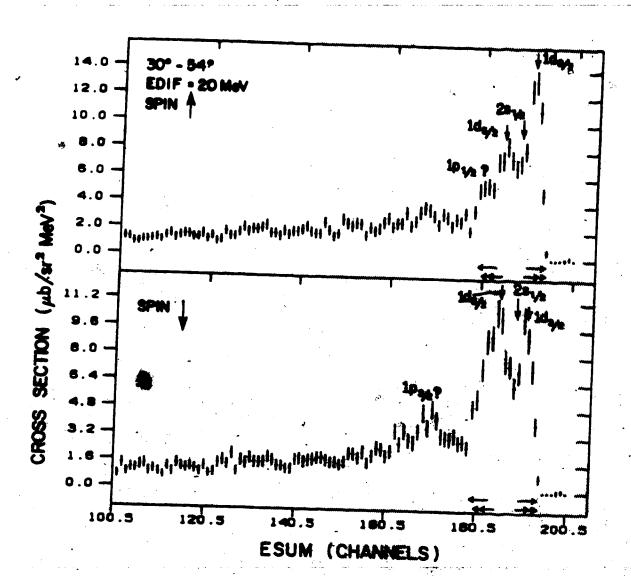

The final stage of the analysis involved extracting unpolarised cross sections and analysing powers for the 40 Ca single particle valence states, $(\mathrm{ld}_{3/2}$, $2\mathrm{s}_{1/2}$, $\mathrm{ld}_{5/2}$), as a function of EDIF from the partially polarised cross sections stored in the ESUM versus EDIF histograms. The functional dependence of analysing power and unpolarised cross section on the partially polarized spin + and + cross sections is given in equation AIII.10 of Appendix III.

The computer software used for fitting were a TRIUMF program (OPDATA) and a CERN program (MINUITS). Notes on some specialized aspects of the fitting and on the calculation of the errors from the results of the fits are included in Appendix III.

In a given 20 MeV EDIF interval, partially polarized cross sections for each of the valence states were obtained by fitting peaks to data over a portion of the ESUM range. Examples of ESUM spectra are shown in Figure V-1 where the spin + and + data for $30^{\circ}-54^{\circ}$ for 'channels' 100.5 to 200.5 in ESUM and EDIF = 20 MeV are presented. Since, as explained in Chapter IV, difficulties with the energy calibration resulted in small errors in summed energy which differed for each EDIF region, the amount of the shift from the correct value was determined in the fitting from the position of the $1d_{3/2}$ state. In Figure V-1, where the ESUM

FIGURE V-1

 40 Ca(p,2p) cross sections as a function of ESUM (in channels) for LF-RB (30°-54°), EDIF=20°7MeV. The positions of the 40 Ca valence states ($1d_{3/2}$, $2s_{1/2}$, $1d_{5/2}$) are indicated along with those of possible 40 Ca lp states. The wide and narrow-fit windows are indicated by horizontal single and double headed arrows respectively.

channel 180.5 to 194.5 were the portions of these spectra fit in the final analysis. For this data, the final enalysis determined the shift to be ~+0.3 MeV. Since the 3.2 to 4.4 MeV ESUM resolution due to detector resolution and other experimental effects is large compared with the expected width of a particle stable state of less than an eV, a Gaussian curve was taken to be an adequate representation of the peak shape.

Spectroscopic factors derived from the analysis of a 40Ca(d, 3He) experiment (DO-76) suggest that most or all of the strength for each of the $1d_{3/2}$ and $2s_{1/2}$ single particle states is concentrated in a single peak while that for the $1d_{5/2}$ state is spread out over a number of peaks (over ~6 MeV in binding energy) as shown in Table VIII. The spectroscopic factors for the 1d3/2, 201/2, and 1d5/2 states (3.7, 1.65, 4.96) are ~93%, ~63%, and ~63% of their expected shell model values of (2J+1) respectively. The peak positions and spectroscopic factors from (30-76) for these 3 states are fairly consistent with results of an earlier 40Ca(p,d) experiment (MA-72) as well as with the Tesuits of a ""Ca(e,e'p) experiment (HO-76). Consequently, our model for fitting the data utilized a single Gaussian peak for each of the $1d_{3/2}$ and $2s_{1/2}$ states and a combination of 15 Gaussian peaks for the 1d5/2 state. For a given spin direction, there were three variable suplitudes, one for each of the valence states (where the

The shift in ESUM energy due to difficulties in the energy calibration was dealt with by allowing the positions of the peaks to shift up or down in ESUM with the spacing between the peaks remaining fixed. By varying the parameter for the position of the 1d_{1/2} peak, at the fitting routine could determine the best position of the peak for the fit. The difference between the best value of XI in the fit and channel 191.67 was the assumed senergy shift over the entire ESUM region fit. Spin + and data have identical energy calibration shifts and thus were fit together.

The height for a single peck at a particular channel in ESUM, XT, was found by evaluating a function of the form

(V-1) A *exp(-C52 2 *(XT-XI+EXC) 2)

where A is the amplitude,

II is the position of the 163/2 peak,

EXC is the excitation energy (relative to the

1d_{3/2} peak) of the peak,

C52 is a peak width parameter related to the standard deviation of the peak position, s, and the PWEN of the peak by

$$(V-2) \quad C52 = \frac{1}{\sqrt{2}\sigma} = \frac{2\sqrt{\ln 2}}{\text{FWHM}} \quad (\text{FWHM in MeV})$$

The area under a Gaussian is given by

(V.3) Area =
$$\frac{A \cdot \sqrt{\pi}}{C52}$$

To remove the contribution of the $^{16}O(p,2p)$ $1p_{1/2}$ and $1p_{3/2}$ states from the ^{40}Ca data, four peaks (two for each spin direction) were incorporated into the model as well. The values and statistical errors for the ^{16}O cross sections, $\sigma_0^{\pm\Delta\sigma}_0$, and analysing powers, $A_y^{\pm\Delta A}_y$, were obtained from the results of a previous 200 MeV experiment (KI-80,KI-76). With the relations

$$(V \cdot 4) \quad \sigma_{\mathbf{P}}(^{16}0) = \sigma_{0} \cdot (1 + \mathbf{P} \cdot \mathbf{A}_{\mathbf{V}}) \quad ,$$

$$\Delta \sigma_{\mathbf{P}}(^{160}) = [(1+\mathbf{P} \cdot \mathbf{A}_{\mathbf{y}})^2 \cdot \Delta \sigma_0^2 + (\sigma_0 \cdot \mathbf{P} \cdot \Delta \mathbf{A}_{\mathbf{y}})^2]^{1/2}$$

where P>0 for spin +, P<0 for spin +, $\sigma_{p}(^{16}0), \quad \Delta\sigma_{p}(^{16}0) \quad \text{are the partially polarized}$ cross sections and errors ($\mu b/sr^2MeV$) for a polarization, P (where equation AIII.1 has been used),

the 160 packs were incorporated into the fit with amplitudes and errors given by

$$(V.5) \quad A(^{16}0) \pm \Delta A(^{16}0) = (\sigma_{\mathbf{p}} \cdot \pm \Delta \sigma_{\mathbf{p}}) \cdot \mathbf{g} ,$$

and with the overall normalization adjusted to the "Ca data by the factor C52 * RAT

$$(V.6) \quad g = \frac{C52 \cdot RAT}{\sqrt{\pi}}$$

where RAT is the ratio of $^{16}\mathrm{O}$ to $^{40}\mathrm{Ca}$ atoms in the target.

The angle pairs of data taken in this previous experiment did not completely overlap with all the angle pairs of the current experiment so that the fitting was performed only for energy differences between -100 and +100 MeV for the angle pairs $54^{\circ}-54^{\circ}$, $47^{\circ}-47^{\circ}$, $30^{\circ}-30^{\circ}$, $30^{\circ}-35^{\circ}$, $30^{\circ}-40^{\circ}$, $47^{\circ}-29^{\circ}$, $29^{\circ}-47^{\circ}$, $54^{\circ}-30^{\circ}$, $30^{\circ}-54^{\circ}$, and $30^{\circ}-62^{\circ}$. Results for three other sets of data where the $2s_{1/2}$ state was dominant (near conditions of zero recoil) were also obtained $(67^{\circ}-25^{\circ}$ and $25^{\circ}-67^{\circ}$ (EDIF=120 MeV), $49^{\circ}-35^{\circ}$ and $52^{\circ}-40^{\circ}$ (EDIF=40 MeV)).

The amount of energy lost to recoil (~0.3 MeV at 150 MeV recoil for \$^{16}\text{O}(p,2p)\$ and ~0.4 MeV at 100 MeV/c recoil for \$^{16}\text{O}(p,2p)\$ (where the \$^{16}\text{O}\$ lp states have maximum cross section)) was small compared with the FWHM resolution of 3.2 to 4.4 MeV. Thus, the shifting of the positions of peaks in ESUM due to varying recoil energy losses as the angles or energy differences changed was ignored in the model, and recoil energy losses were neglected in the positioning of the peaks.

Even with the addition of these 160 peaks, an 'extra'

peak (B, for background) was required in the model to account for an additional feature in the spectrum at an excitation energy of 12.4 MeV. Without the inclusion of this peak, the χ^2 increased substantially. The nature of the peak that appears throughout the data at this energy is unknown but one possibility is that it is $lp_{1/2}$ strength from $^{40}Ca(p,2p)$. This peak is part of the shoulder at approximately channels 178.5 to 181.5 in the spin + spectrum of Figure V-1. A second interesting feature appears between channels 160.5 and 178.5 (centered at ~169.5) in the spin + spectrum of Figure V-1. possibly be $lp_{3/2}$ strength from $^{40}Ca(p,2p)$. As this second feature is well outside the region of the data fitted, no account of it was taken in the model. J Both of these features appear throughout the data in regions well away from 2s_{1/2} state dominance and were most prominent in the $30^{\circ}-54^{\circ}$ data which had the best statistics.

The fitting of the data proceeded in two passes. In the first pass, the model was developed. A linear least squares routine (OPDATA) was used to minimize a χ^2 function of the form given in equation AIII.2. In summary, the model consisted of 40 peaks with a common width parameter. For each spin direction, there were seventeen 40 Ca peaks, two 16 O peaks, and a background peak. Ten parameters in the model were always free: four peak amplitudes for each spin direction (three for 40 Ca, one for the background peak), the energy calibration parameter (XI), and the 16 O.

to 40 Ca ratio (RAT). The Fortran functions used to compute the value of the model for a particular spin direction are listed in Appendix IV where the 16 O peaks are in a separate function from the rest. The same functions were used for both spin + and + data.

More 40 Ca data ($\gtrsim 70\%$) were acquired at $30^{\circ}-54^{\circ}$ (LF-RB) than for other angle pairs. For this reason, much of the early development of the model was performed using this data. As the background peak was most prominent in the $30^{\circ}-54^{\circ}$ data, it was used to determine the B peak position relative to the $1d_{3/2}$ peak. The value obtained, 12.4 ± 0.3 MeV, was thereafter adopted as a fixed parameter in the model.

As all the spin † and † data for a given angle pair and detector combination should have the same resolution, the width parameter was established by first fitting several of the ESUM spectra from that data set with the width parameter, C52, free. By statistically averaging the result for C52 from three or four spectra according to equation AIII.3, a value for C52 and its error was established and all subsequent fits for that data set were performed with C52 fixed. These values and errors were also used in the second pass of the fitting.

For a given spectrum, the range used in the fit was the same for the spin \pm and \pm data and was chosen so as to include as much of the region from the B peak (on the low ESUM side) to the $1d_{3/2}$ peak (on the high ESUM side) as

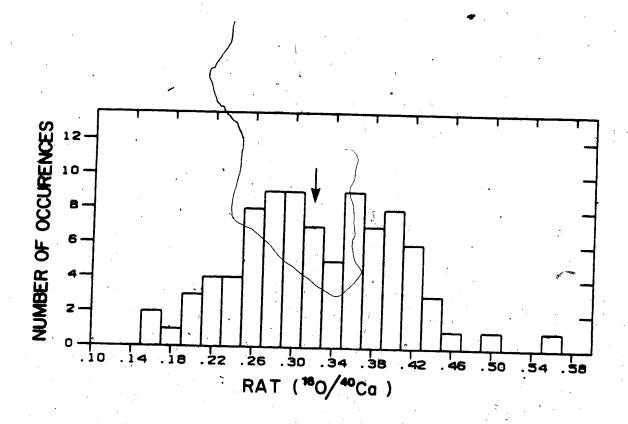

possible without including other background features. The number of channels in these fitting regions (which we call the wide-fit window) ranged from 16 to 19 while the number of degrees of freedom for a fit varied from 22 to 28. The wide-fit limits (inclusive) for 30°-54°, EDIF=20 MeV are indicated by single-headed horizontal arrows in Figure V-1.

All data were fit using the model and the wide-fit windows described above. The values of RAT, except for those from the EDIF=±100 MeV spectra, where the statistics were generally quite poor, were used to determine the \$^{160}\$O to \$^{40}\$Ca ratio in the \$^{40}\$Ca target. A histogram of these values of RAT is shown in Figure V-2. This distribution resembles a broad Gaussian peak. However, the statistics are too poor to make any definite conclusion. A simple average and the sample standard deviation were used as our conservative estimate for RAT and its error. This yielded a value for $^{160}/^{40}$ Ca of 0.324±0.078 which was used in the second pass of the fitting.

In the second pass (performed using the CERN fitting program, MINUITS (JA-75)), the model was basically the same as for the first pass. In addition to the ten free parameters of the first pass, C52 and the four \$^{16}\$O peak amplitudes were free parameters. However, RAT, C52, and the \$^{16}\$O amplitudes were constrained from deviating significantly from their previously determined average values. For each of these six parameters, a constraint

FIGURE V-2

Distribution of RAT's, relative numbers of 160 and 40 ca atoms, produced from first pass fitting of data. The centroid of the distribution is indicated by an arrow.

term of the form given in equation AIII.4 was added to the χ^2 . In this manner, the uncertainties in these six parameters were reflected in final values for all the free parameters, their errors, and the χ^2 .

The upper channel limit for each second pass fit was the same as that for the corresponding first pass fit. However, the lower limit was chosen to be the channel nearest to 11.5 channels below the position of the $1d_{3/2}$ peak (XI) as determined from the first pass. fashion, the second pass 'narrow-fit' windows were chosen in a consistent manner for all of the data. In addition, while the size of this window ensured the inclusion of almost all of the $1d_{5/2}$ state, it excluded a large fraction of the B peak region thus minimizing the dependence of the final results on the accuracy of the determination of the position of this peak. Varying the position of the B peak by amounts equal to its standard deviation (±0.3 MeV) changed the results for the $1d_{5/2}$ and $2s_{1/2}$ states by <2% and had a negligible effect on the 1d3/2 state. Also, the values for XI from the second pass fits differed by <0.5 MeV from those of the first pass. The number of channels within these narrow-fit windows ranged from 14 to 17 and the number of degrees of freedom ranged from 19 to 25. The narrow-fit limits (inclusive) for 30°-54° EDIF=20 MeV are indicated by double headed horizontal arrows in Figure v-

1

The result of fitting the 30°-54° EDIF=20 MeV data is

shown in Figure V-3. The individual peaks are shown (solid lines for 40 Ca-peaks, dashed lines with circles for 160 peaks, dashed line with +'s for background peak) along with the overall fit (dashed line) and the individual data points along with their errors (*'s with bars). Fits which produced negative amplitudes were redone with a penalty function added onto the χ^2 as shown in equation AIII.5. Five spectra gave slightly negative amplitudes (<0.5 μ b/sr 2 Mev) for the B or $2s_{1/2}$ peak and were re-fit.

From the 40Ca amplitudes, C52 values, and their errors as determined from the fits, the partially polarized cross sections and errors were calculated according to equation AIII 6. These values, in turn, were used to derive the unpolarized cross sections, analysing powers, and their errors by means of equations AIII.10 and AIII.11. The results for 29°-47°, 47°-29° (LF-RB, LB-RF), 30°-54°, 54°-30°, and 25°-67°, 67°-25° were averaged statistically according to equation AIII.3. The final results for the 40Ca unpolarized cross sections and analysing powers are presented and discussed in the next chapter.

A general overview of the quality of the fits is illustrated in Figures V-4 and V-5. These figures contain the distributions of the percentage points and the χ^2 per degree of freedom respectively for all of the second pass fits. A percentage point is the fractional probability of obtaining a value for χ^2 equal to or less than the value obtained in the fit; its interpretation is discussed in

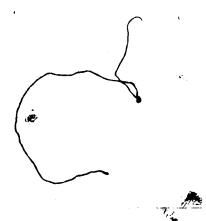

FIGURE V-3

Results of fitting LF-RB (30°-54°) EDIF=20 MeV data. Data points and their errors are indicated by asterisks and bars and the overall fit by a dashed line. The $^{+0}$ Ca (1 d $_{3/2}$, 2 s $_{1/2}$, 1 d $_{5/2}$) and 16 O (1 p $_{1/2}$, 1 p $_{3/2}$) peaks are shown as solid lines and dashed lines with circles respectively while the background peak is denoted by dashed lines with pluses (+). The energy calibration shift has been applied to the ESUM scale.

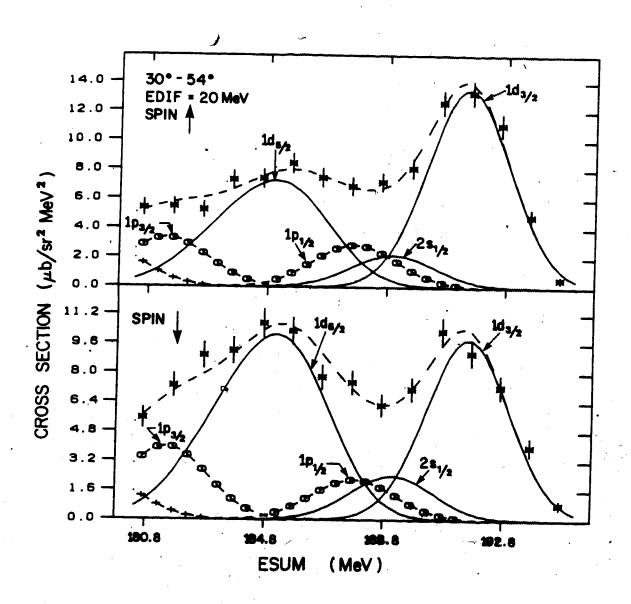

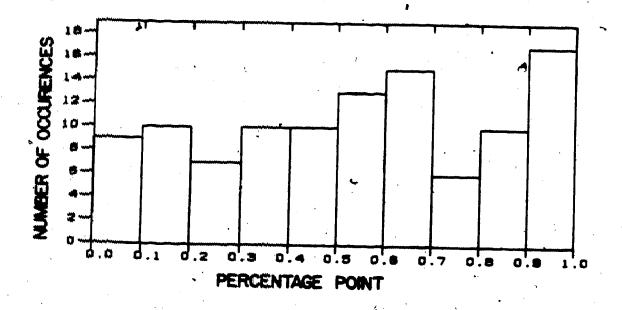

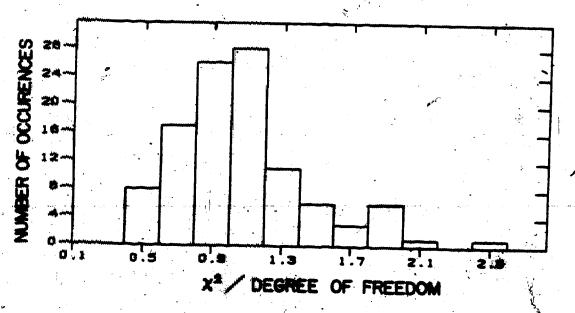

FIGURE V-4

FIGURE V-5

Distribution of χ^2 per degree of freedom from the second pass fitting of the data.

Appendix III. The percentage points are fairly evenly distributed with a small amount of skew toward the high and. The χ^2 per degree of freedom histogram exhibits a χ^2 -like distribution with a peak at a value of ~1.2. Weither distribution contains may disturbing features.

CHAPTER VI

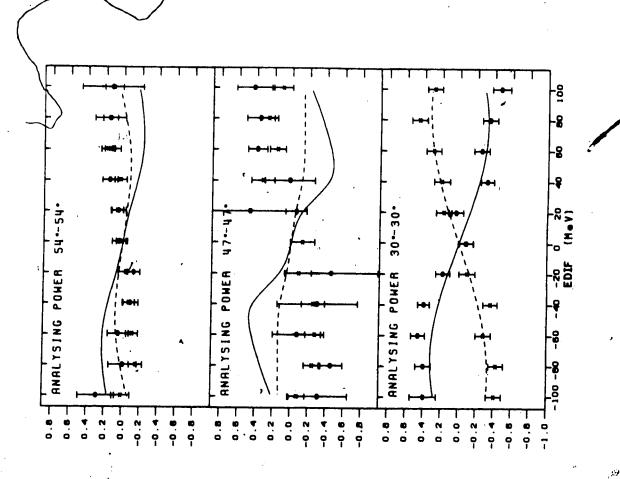

COMPARISON OF RESULTS WITH DWIA CALCULATIONS

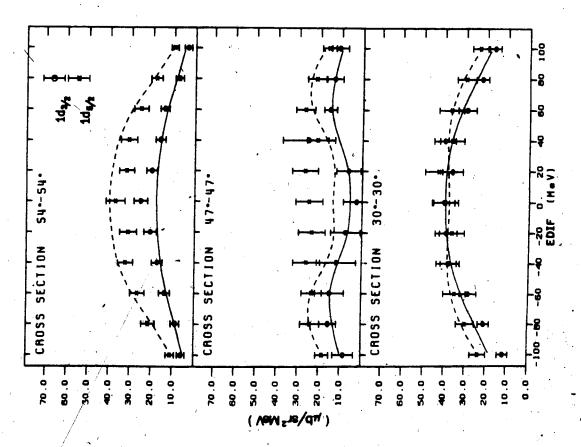

The values of the cross sections and analysing powers for the $1d_{3/2}$ (circles) and $1d_{5/2}$ (crosses) states obtained from the fitting are presented in Figure VI-1. For each angle pair, the data are plotted as a function of EDIF. In addition, the $2s_{1/2}$ cross sections and analysing powers are plotted as a function of $THETA_{pp}$ (the p-p scattering angle in the center of mass of the two protons) for conditions where the recoil momentum is at or near zero which includes: 25°-67°, EDIF=120 MeV (THETApp=52.1°); 30°-62°, EDIF=100 MeV (62.1°); 30°-54°, EDIF=80 MeV (66.5°); 35°-49°, EDIF=40 MeV (77,7°); and 40°-52°, EDIF=40 MeV (81.5°). Away from zero recoil momentum, the $2s_{1/2}$ strength was small compared with that of the $\ell=2$ states; consequently, its cross sections and analysing powers were poorly determined, and are not shown.

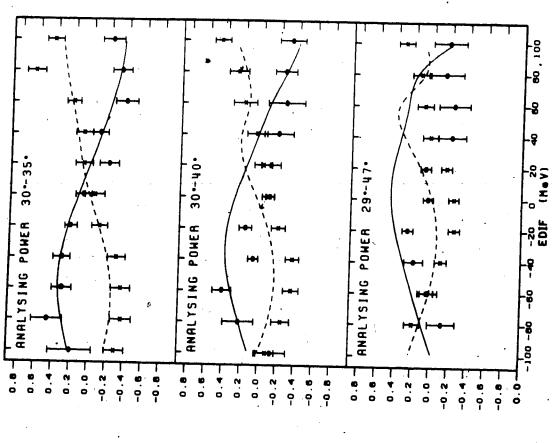

The curves in Figure VI-1 are the results of DWIA calculations performed with the code THREEDEE (CH-79). This code performs the calculations according to equation AII5 and employs a direct 3-dimensional numerical integration avoiding the use of angular momentum coupling coefficients. This represents a substantial improvement over previous codes which did not include the effects of spin-orbit distortion. The calculations were performed at the kinematic conditions for which the data were obtained

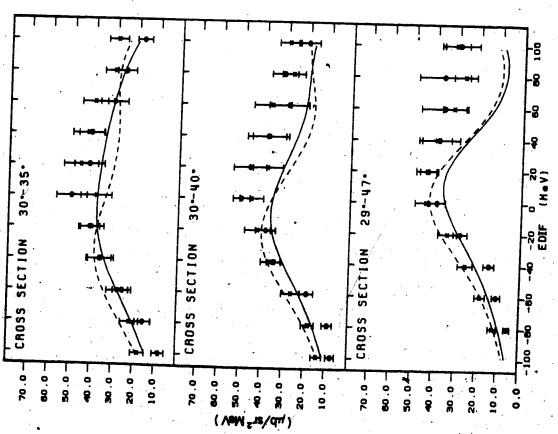

FIGURE VI-1

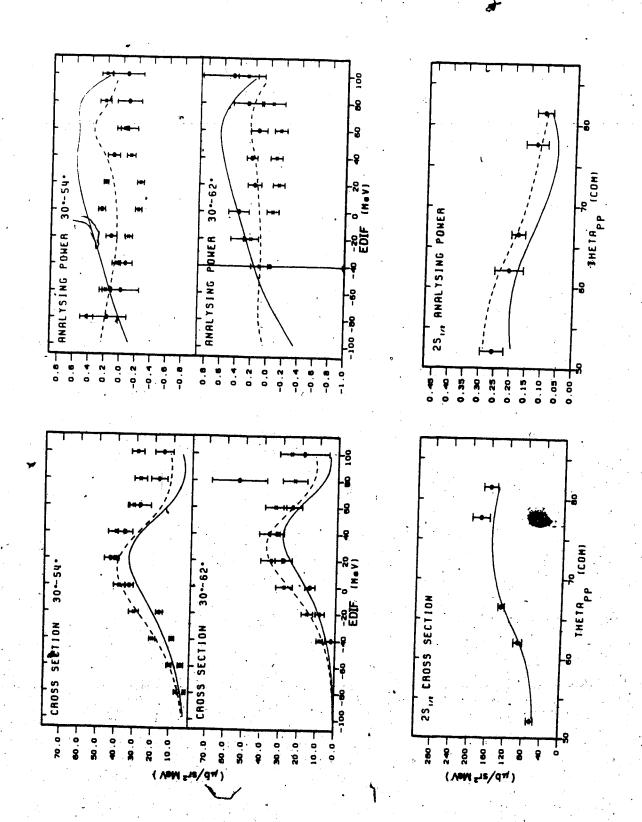

Cross sections and analysing powers for the $1d_{3/2}$, $1d_{5/2}$, and $2s_{1/2}$ states. Results for the $ld_{3/2}$ (circles) and $ld_{5/2}$ (crosses) are presented as a function of energy sharing (EDIF) for the angle pairs indicated while the $2s_{1/2}$ results are presented as a function of the free p-p center of mass scattering angle (as calculated using a half-off-shell prescription). The calculations for the $ld_{3/2}$, $ld_{5/2}$, and $2s_{1/2}$ states are given as solid, dashed, and solid lines respectively while the dashed line in the plot of $2s_{1/2}$ analysing powers corresponds to the free p-p analysing powers. The DWIA calculations were performed using spectroscopic factors onehalf the simple shell model values of 2J+1.

and the dashed and solid curves are interpolations between the calculated values. In the plots for the $1d_{3/2}$ and $1d_{5/2}$ states, solid and dashed curves are used respectively while solid curves are used in the plots for the $2s_{1/2}$ state. All calculations were done with an optical potential including spin-orbit terms. In addition, the dashed line in the plot of $2s_{1/2}$ analysing powers corresponds to the free p-p analysing powers resulting from excluding the spin-orbit terms in the optical potential. The cross sections are in units of $\mu b/sr^2 MeV$ and, in order to plot the DWIA values and the measurements on the same scale, spectroscopic factors one half the shell model values of (2J+1) were used in the DWIA calculations.

In the calculations, the bound state wave functions were calculated from a Woods-Saxon potential with spinorbit terms. The radius, diffuseness, and well depth parameters are taken from values derived from fits to elastic electron scattering data as well as the binding energy of the particular single particle state (EL-67). The binding energies used in the calculations for the $\mathrm{Id}_{3/2}$ and $2\mathrm{s}_{1/2}$ states are those given in Table VIII while a value for the $\mathrm{Id}_{5/2}$ state of 15.07 MeV (based on an average of the binding energies of the various $\mathrm{Id}_{5/2}$ components weighted by their spectroscopic factors) was used. As the calculations are not especially sensitive to small changes in the binding energy, this is an adequate approximation for the $\mathrm{Id}_{5/2}$ binding energy. The optical potential

(SC-80) used was derived from a global for to angular distributions of p-40Ca elastic scattering cross sections and analysing powers including recent TRIUMF (200 MeV) and Indiana (80,135,160,181 MeV) data. This phenomenological optical potential utilized relativistic kinematics and a semi-relativistic Schrodinger-type equation. The potential does not contain an isospin-flip component which would result in a charge exchange contribution to the calculation. The functional form of this potential, its energy dependence, and the modifications necessary implement it in the code are outlined in Appendix V. difference between p-40Ca total reaction cross sections (σ_r) predicted using this optical potential and measured. values is <9% at energies <140 MeV. Although the difference increases slightly to 14.5% at 181 MeV, distortion plays a relatively less important role in this energy region for an incident energy of 200 MeV.

In the plane wave limit, the p-p interaction is halfoff-shell. If an on-shell prescription is used, the halfoff-shell nature of the interaction leaves some ambiguity
as to the momentum at which to evaluate the p-p t-matrix.
Two on-shell prescriptions are the initial and final state
prescriptions. They correspond to evaluating the t-matrix
at the momentum in the center of mass of the initial and
struck protons (initial state) or in that of the two
outgoing protons (final state). More recently, a half-offshell prescription in which the t-matrix is evaluated

between the initial and final state momentum (to account for the momentum and energy mismatch) has been incorporated into the calculations in a manner detailed in (MI-79). The t-matrix is factorized into two parts: the on-shell t-matrix (in the form of partial wave amplitudes) which is evaluated from experimentally determined phase shifts (AR-77), and a real off-shell extension function calculated from the Mongan potential (MO-69) - a separable nonlocal phenomenological nucleon-nucleon potential. The results of calculations employing the initial and final state prescriptions differed slightly from those of the half-off-shell prescription by <±10% in cross section and <±0.08 in analysing power. All results shown correspond to the half-off-shell prescription.

The modification of the free p-p interaction in the presence of the nuclear medium is manifested in part, through off-shell behavior. The effect of the distorting potentials taking the interaction fully off the energy shell has been investigated (using the Mongan potential) for \$^{16}O(\vec{p},2p)\$ (MI-80) according to a method outlined in \$^{28}E-73). Compared to the half-off-shell calculations, there were significant changes only for forward angles (30°-30°) where the analysing powers are reduced by <0.05 and cross sections increased by <10%.

A second effect of the nuclear medium on the interaction is through Pauli blocking. Pauli blocking refers to the suppression of amplitudes for p-p scattering

that leave one of the protons with a momentum equal to that of one of the protons of the core. Calculations incorporating Pauli blocking performed by Miller and Thomas (MI-80) on \$^{160}(\vec{p},2p)\$ indicate a change of \$\sim 0.05\$ in analysing power and an increase of \$< 10% in cross section compared with the half-off-shell calculations. Because they do not appear to affect the results of the calculations strongly, neither Pauli blocking or fully-off-shell calculations were performed in the present analysis.

. A careful comparison of the present DWIA calculations with the data reveals a number of trends. At equal proton angles and energies, the symmetry of the kinematics precludes the existence of a preferred direction. Consequently, the analysing power should and does vanish under such conditions in the data. Throughout the data, when the cross section calculations are normalized to the data, the resulting spectroscopic factors are \$50% to \$55% of the shell model values of (2J+1). In contrast, studies of other reactions (D0-76,MA-72) have yielded spectroscopic factors lying in the range of the shell model values which is more consistent with naive expectations. For 47°-47°. as the EDIF is varied, the recoil momentum reaches a minimum of ~ 60 MeV/c and here one expects a dip in the $\ell=2$ strength while the L=0 strength peaks. This is confirmed by both the data and the calculations. The agreement between the data and calculations for the 1=2 analysing powers is quite good for forward angles (30°-30°, 30°-35°,

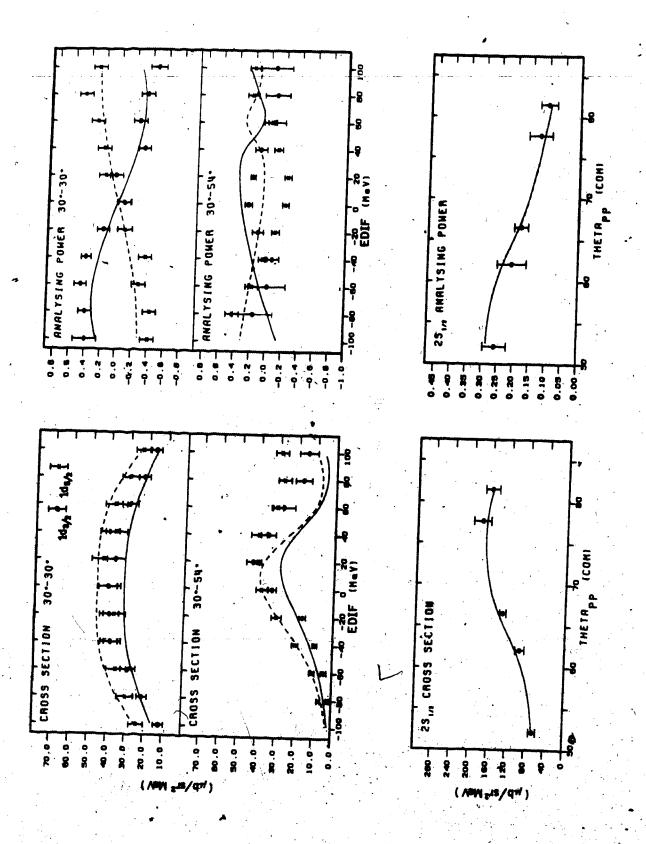

30°-40°) but deteriorates steadily as one or both angles increases in the backward direction. For the analysing powers the difference between the DWIA predictions and the free p-p analysing powers is small and the data do not favor either set of values. The results of the previous $^{16}O(\vec{p},2p)$ experiment at 200 MeV have been similarly compared with predictions from DWIA (KI-80). this case the cross sections and analysing powers of the lp_{1/2} and lp_{3/2} states were calculated without spin-orbit distortion. The results were quite similar to the present case in that the cross sections were overestimated (by 1 ~80%) and the agreement with the analysing powers was good $_{4}$ for forward angles but poor as one or both angles increased.

For 30°-30° and 30°-54° (t=2) and the $2s_{1/2}$ cases, the calculations were redone with the real and imaginary spin-orbit terms in the optical potential set to zero. This caused an increase in the p=40Cs σ_r of <7% at the highest energy with no change at the lowest energy. The results are shown in Figure VI-2. There were small but non-negligible changes in the (p,2p) cross sections and small changes in the analysing powers which produced no general improvement in the agreement with the measured analysing powers.

The optical model potential describing the interactions when a proton passes through a nucleus can be calculated from the nucleon-nucleon (N-N) potential.

FIGURE VI-2

As in figure VI-1 except that the spin-orbit term has been turned off in the DWIA calculations.

In this context, the intrinsic nonlocality of the N-N potential leads to a nonlocal optical potential. As well, nonlocality may be caused by antisymmetrization, as in the Hartree-Fock method of constructing self-consistent potentials for antisymmetric wave functions, or because the proton in the elastic channel moves under the influence of coupling to the other channels (AU-65).

Nonlocality is partly accounted for by means of energy-dependent local optical potential, the calculated wave functions of which are asymptotically equivalent to those of its nonlocal counterpart. However, inside the nucleus; such local potential wave functions are not equivalent to the corresponding nonlocal wave functions. Calculations have shown that the amplitudes of wave functions derived from an attractive nonlocal potential are significantly reduced inside the nucleus compared with the corresponding amplitudes from a local potential which produces asymptotically equivalent wave functions. In the $^{16}O(\vec{p},2p)$ analysis, an investigation of this effect was performed by multiplying each of the distorted wave function amplitudes by a factor dependent upon the nuclear matter density, [1/2] m is an effective mass characterizing the nonlocality of the potential. Values for this factor come from (JE-77) as does the radial dependence of the nuclear density. This nonlocality correction (method i) was included calculations for 30°-30°, 30°-54° (1-2) and the 201/2

values and the results are illustrated in Figure VI-3.

A second method (ii) of adjusting the distorted wave functions to correct for nonlocality has been investigated using the WKB method (80-80, AU-65, PE-63, PE-62) and is incorporated in the present DWIA code. In this method, the degree to which the amplitude of the wave function changes as a result of having a nonlocal component (such as the real central part) in the optical model potential is parametrized by a range parameter, \$. With \$ set to 1.0 fm and applying the correction corresponding to having a nonlocal real central potential to each of the distorted proton wave functions, calculations were performed for 30°-30°, 30°-54° and the 2s_{1/2} cases. The results are shown in Figure VI-4.

The two methods of incorporating conlocality produce virtually indistinguishable analysing powers while the cross sections from method (i) are "61 higher than those from method (ii). The nonlocal analysing powers differ by <0.03 from those of the local calculations. The nonlocal cross sections (method ii) are generally 201 to 501 lower than the corresponding local values. A increases, the cross sections decrease and at a value of "1.15 fm the spectroscopic factors for the fa2 states, as obtained by normalizing the calculations to the data, increase to "(2j+1) in regions where the struck particle momentum is >55 MeV/c. In the 160(β,2p) analysis, method (i) produced effects similar to those observed here.

FIGURE VI-3

As in figure VI-1 except that a nonlocality correction (method i) has been incorporated in the DWIA calculations.

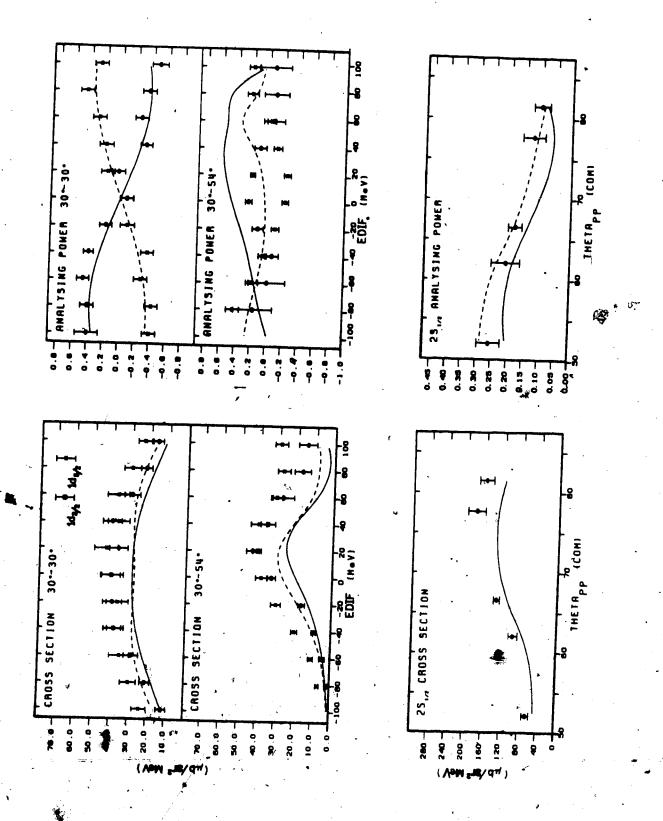

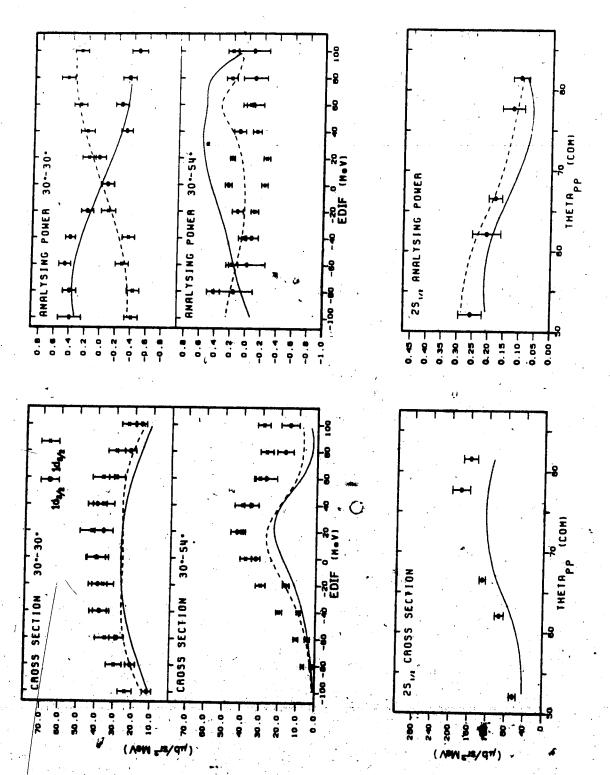

FIGURE VI-4

As in figure VI-1 except that a nonlocality correction (method ii) has been incorporated in the DWIA calculations.

While the inclusion of nonlocality in the calculations improves agreement with the cross sections, the inability to reproduce analysing powers for \$\frac{1\pmo}{1\pmo}\$0 states in certain kinematic regions remains. In response to these concerns, Miller (MI-80) has recently pointed out that the directions of the protons at the interaction point can be altered by the refractive effects of the optical potential. Consequently, the use of the asymptotic center of mass angle between the emerging protons in the calculation of the free p-p observables may be inappropriate. This, along, with reaction localization in the target nucleus, may lead to a shift in analysing power the magnitude and direction of which would be correlated with kinematics and which would be the same for states of the same & (1#0) but different j. Preliminary studies of these effects indicate shifts in the $1d_{3/2}$ and $1d_{5/2}$ analysing powers producing closer agreement with the data. The effect on the $2s_{1/2}$ state is thought to be negligible. Detailed calculations are planned.

For good shell model nuclei, if the spin-orbit term in the binding potential was zero so that the j=1+1/2 and j=1-1/2 states were degenerate, then the net polarization of the subshell would be zero and the following relation between the effective polarizations, Peff, of protons of the same 1 but different j would be expected to hold to a good approximation:

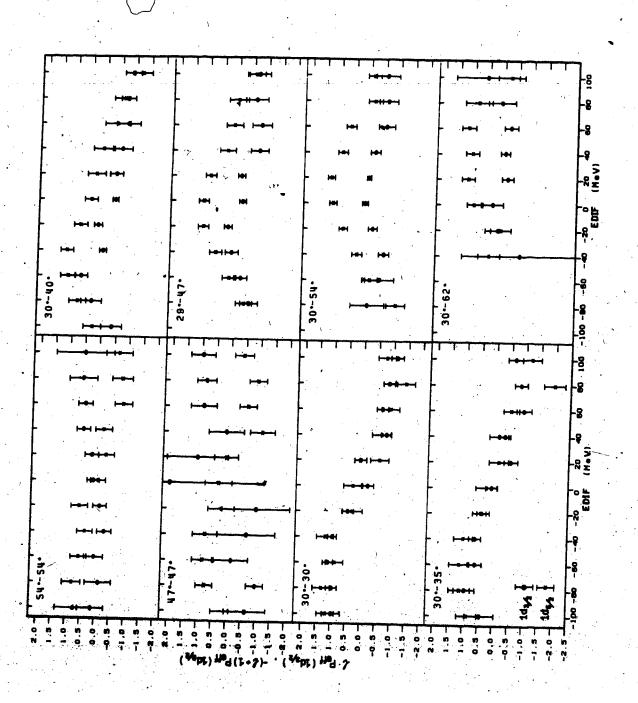

(VI.1) $t \cdot P_{eff}(j=k-1/2) = -(k+1) \cdot P_{eff}(j=k+1/2)$

The effective polarization is, in fact, insensitive to the details of the bound state wave function. Consequently, turning on the spin-orbit term in the binding potential should not affect the validity of equation VI.1 (MA-79a).

In the absence of spin-orbit distortion; the effective polarization for a state may be obtained simply from its $(\vec{p}, 2p)$ analysing power by means of equation AI.4. Using the free p-p analysing powers, A, and correlation parameters, CNN, obtained from phase shifts with a halfoff-shell prescription, the values of Peff for the $1d_{3/2}$ and $1d_{5/2}$ states were determined. The resulting values of $2 \cdot P_{eff}(1d_{3/2})$ (circles) and $-3 \cdot P_{eff}(1d_{5/2})$ (crosses) are plotted as a function of energy sharing in Figure VI-5. The results are consistent with equation VI.1 when both angles are in the forward direction. However, poorer agreement is observed as one or both angles increase in the backward direction. A similar analysis of the $^{16}O(\vec{p},2p)$ data (MA-79b) yielded comparable results.

FIGURE VI-5

Plot of $l \cdot P_{eff}(ld_{3/2})$ (circles) and $-(l+1) \cdot P_{eff}(ld_{5/2})$ (crosses) as a function of EDIF for the angle pairs indicated.

CHAPTER VII

This experiment has yielded extensive information on the behavior of the cross sections and analysing powers of the $\mathrm{ld}_{3/2}$, $2s_{1/2}$, and $\mathrm{ld}_{5/2}$ states of $^{40}\mathrm{Ca}$. The pattern of agreement between the DWIA calculations and the measured l=2 cross sections and analysing powers is remarkably similar to that observed in the earlier analysis of l=1 states from the $^{160}(\vec{p},2p)$ experiment. The inclusion of nonlocality in the DWIA calculations reduces the cross sections, allowing the spectroscopic factors to increase toward values expected of these nuclei.

Although the inclusion of spin-orbit distortion in the present analysis has a marked effect upon the DWIA calculations, it does not significantly affect the quality of the agreement with the data. For the $2s_{1/2}$ state, the data are consistent with either the inclusion or exclusion of spin-orbit dependence in the optical model potential.

Evidence for the existence of 40 Ca $1p_{1/2}$ and $1p_{3/2}$ strength at 21 MeV and 20 MeV separation energy appears throughout the data although the energy resolution and statistical accuracy of our measurements in these regions is too poor to reach any definite conclusions.

DWIA has proven capable of successfully predicting analysing powers for medium and light weight nuclei like 40 Ca and 16 O in restricted angular regions. The strong j-

dependence of the analysing power has been clearly demonstrated in these measurements. Given the current state of agreement between DWIA and experiment, $(\vec{p}, 2p)$ reactions can be used as a spectroscopic tool to identify new pairs of states of the same t but different j provided one limits oneself to appropriate kinematic regions. The results of this experiment thus serve as an incentive for future efforts in both the theoretical and experimental investigation of quasi-elastic scattering with protons.

A new measurement of $^{40}\text{Ca}(\vec{p},2p)$ would help to resolve a number of the questions left outstanding in this experiment. With better energy resolution (~1 MeV), a quantitative investigation could be performed upon the feature which may be a ^{40}Ca $1p_{1/2}$ state. Better statistics should enhance the broad feature which may possibly be ^{40}Ca $1p_{3/2}$ strength. The analysing powers of these two features could then be compared with DWIA calculations to determine if they exhibit behavior consistent with $1p_{1/2}$, and $1p_{3/2}$ states. This identification would be facilitated by taking measurements at forward angles, for example $30^{\circ}-30^{\circ}$, where DWIA has demonstrated its ability to reproduce the data.

The current experiment has stimulated the beginning of an examination of the effect of reaction localization coupled with refraction of the distorted waves in the nucleus on the calculations. Such investigations may extend the reliability of DWIA analysing powers to any kinematic region.

"forgiving" when the data includes polarisation data in that more stringent constraints are placed upon the theory. There is some indication that as the quality of the optical model in input to the DWIA calculations has improved the spectroscopic factors have changed significantly in this light. Only when DWIA is able to predict, analysing powers and cross sections simultaneously will one be confident in the resulting nuclear structure information.

APPENDIX I

DWIA DESCRIPTION OF (方,2p)

The description of quasi-elastic (p,2p) reaction with the Distorted Wave Impulse Approximation (DWIA) been reviewed by Jacob and Maris (JA-66, JA-73a). The inducation is shown in Figure I-2. Assumptions made in DWIA treatments of quasi-elastic scattering include the following:

- incident proton and struck nucleon and there are no other strong interactions between the incident proton and the residual nucleus,
- ii) the violent interaction can be related to free proton-proton scattering,
- iii), the distortion factors (defined as the ratio of plane wave functions to distorted wave functions) do not change appreciably over the range of this interaction.
- (ii) and iii) are collectively a statement of the impulse approximation)
- iv) the core interacts with the incoming and outgoing nucleons as a refractive and absorptive medium. This is described in terms of an optical model potential which distorts the wave functions of the incoming and outgoing protons.
- v) the single particle shell model wave functions are

taken as an adequate representation of the overlap integral between the target and residual nuclei.

In the present context of generating distorted waves for protons with energies from 50 MeV to 200 MeV, the best optical model potentials available are empirically obtained from fitting elastic cross section and polarization data. A more desirable approach would be to generate optical potentials from multiple scattering theory, such as KMT (KE-59), utilizing the fundamental nucleon-flucteon interaction. However, at the current time such an approach has not yielded optical potentials for energies less than *400 MeV which are consistent with the energies cross section and polarization data (NA-80).

The differential cross section under the assumption of no spin-orbit dependence in the optical potential was shown by Jacob and Maris to be given by a product of a factor (K) involving the phase space and spectroscopic factors, the distorted momentum distribution of the struck nucleon (G), and the free proton-proton scattering cross section,

(AI.1)
$$\frac{d^3\sigma}{d\Omega_1 d\Omega_2 dE} = K \cdot G \cdot \frac{d\sigma^{fr}}{d\Omega}$$

If there is a single value for the initial orbital angular momentum quantum number, 1, of the struck proton, then G is given by

(AI.1.1)
$$G = \sum_{m=-L}^{L} ||\mathbf{r}||^2 ||\mathbf{r}||^2$$

The W_m are weight factors involving Clebsch Gordan coefficients. With the further assumption of zero distortion (the plane wave limit), G_L^m is the Fourier transform of the initial bound state wave function of the struck proton, ϕ_L^m :

(AI.1.2)
$$G_{\ell}^{m} = \int \exp(ik_{A-1} \cdot r) \cdot \phi_{\ell}^{m}(r) dr$$

Here k_{A-1} is the momentum of the recoil nucleus.

In spherical coordinates, the momentum dependence of G_L^m enters via a spherical Bessel function, $j_L(k_{A-1}r)$. (ME-66). For small values of the argument of j_L , (AI.1.3) $j_L \sim (k_{A-1}r)^L$.

Consequently, at zero recoil momentum, the momentum distribution for \$1\pm\$0 states goes to zero while that for \$1\pm\$0 states is at a maximum since \$j_0\$ is at a maximum. In practice, the minimum in the momentum distribution for \$1\pm\$0 states at zero resoil is somewhat filled in due to the effects of distortion and the finite angular acceptance of the detectors.

The cross section for scattering free protess with parallel or entiparallel spins is given by

Here P and Personal the polarizations of the incident and struck protons, respectively while A and Com are the free p-p analysing powers and correlation parameters

respectively. P, Peff, and A are measured with respect to an axis perpendicular to the scattering plane and the polarizations are >0 for spin +, <0 for spin +.

At intermediate energies, CNN is large and positive. Thus the cross section for protons with parallel spins is 3 to 5 times larger than that for protons with antiparallel spins. Bound protons with the same £ (£#0) but different j can be effectively polarized in opposite directions in quasi-elastic reactions. Expression (AI.1) leads one to expect states of the same £ but different j to exhibit different behavior in their (p,2p) analysing powers. For £=0 states, the effective polarization vanishes, and thus the (p,2p) analysing power reduces to that for free p-p scattering.

The (\$\delta,2p) analysing power, Ay, for a particular state is obtained from the spin + and spin + cross sections by

(AI.3)
$$A_y = \frac{\frac{d^3\sigma}{d\Omega_1 d\Omega_2 dE} (+) - \frac{d^3\sigma}{d\Omega_1 d\Omega_2 dE}}{\frac{d^3\sigma}{d\Omega_1 d\Omega_2 dE} (+) + \frac{d^3\sigma}{d\Omega_1 d\Omega_2 dE} (+)}$$

Substituting equations AI.1 and AI.2 into AI.3 and solving for $P_{\mbox{eff}}$, one obtains

Thus, by measuring the analysing power, A_y , for a state and given the free p-p values A and C_{NN} , the effective

polarization of the struck nucleon can be determened.

The inclusion of spin-orbit dependence in the optical model potential seems to be important in fitting elastic and reaction cross section as well as polarization data (NA-80). If included, spin-orbit distortion upsets the factorization of the cross section and expression (AI.1) is no longer valid. Rather, as shown by Jackson (JA-76), the cross section is factorized in the amplitudes and calculations become considerably more complicated, $\frac{d^3\sigma}{d\Omega_1 d\Omega_2 dE} = C \cdot S_{1f} |T_{1f}|^2.$

Here C is a phase space factor and Sij represents the appropriate sum and average over initial (i) and final (f) states. In DWIA, Tfi is given by

$$\begin{array}{lll} \text{(AI.6)} & \text{$T_{\text{fi}} = \sum_{\ell, j \in \mathcal{N}} \sum_{i=1}^{N} \sum_{j=1}^{N} \sum_{i=1}^{N} \sum_{j=1}^{N} \sum_{j=1}^{N} \sum_{i=1}^{N} \sum_{j=1}^{N} \sum_{j=1}^{N} \sum_{i=1}^{N} \sum_{j=1}^{N} \sum_{j=1}^{N} \sum_{i=1}^{N} \sum_{j=1}^{N} \sum$$

where k_0, k_1, k_2, k_{A-1} are the lab momenta of the incident proton, the outgoing protons and the recoil nucleus, q_0, q_1, q_2 are the momenta in the A+1 center of mass (JA-65) conjugate to the spatial coordinates appearing in the Schrodinger equation for the distorted wave functions;

 $\frac{1}{2}(\vec{k}_0 + \vec{k}_{A-1})$, $\frac{1}{2}(\vec{k}_2 - \vec{k}_1)$ are the relative momenta of the protons in their c.m. system before and after

scattering,

and a=(A-1)/A.

(....) are Clebsch Gordan coefficients,

\(\xi_{J_1} \int_{J_2}^{(1)} \) are fractional parentage coefficients,

\(\sigma_{J_1} \int_{J_2}^{(1)} \) are spin quantum numbers,

\(\xi_{J_2} \int_{J_2}^{(1)} \) are the distorted wave functions,

\(\text{N} \) is the spectroscopic factor corresponding to the final state (=2J+1 in the single particle shell) model where J (or j) is the total angular momentum quantum number of the state),

Omitting isospin, the overlap integral (Y_p) of the initial and final nuclear states is given by $(AI.7) \quad \begin{array}{c} Y' = & LJ_M (J_f M_f JM | J_1 M_1) \cdot \xi_{J_1} J_f \\ \end{array}$ where

(AI.8)
$$Y_{LJ}^{M}(\hat{\mathbf{r}}) = \sum_{\mathbf{m} \sigma_{1}} (t \mathbf{m} \frac{1}{2} \sigma_{1} | \mathbf{J} \mathbf{M}) \cdot \phi_{LJ}^{\mathbf{m}}(\hat{\mathbf{r}}) \cdot \chi_{\mathbf{m}_{1}}^{\sigma_{1}}$$

Here s_1 and σ_1 are the spin quantum numbers for the struck proton and $\chi_{s_1}^{\sigma_1}$ is a spinor. In the context of our $^{40}\text{Ca}(p,2p)$ calculations, the overlap integral is taken to be a pure single particle state with a single value of £ and J. Thus, all configurational mixing is ignored and there is only a single non-zero value of $\xi_{J_1J_2}$.

A simple statement about the result of the complication arising from the inclusion of the spin-orbit term is difficult to make, but one can make a few generalizations. The relative sizes of various p-p

amplitudes determine the polarization of the final state protons resulting from the free elastic scattering. This polarization of the particles after the interaction can affect the probability of their emergence from the nucleus resulting in a selection of specific p-p amplitudes. Hence, the spin-orbit distortion results in a modification of these relative strengths through the differing absorption and distortion of particles with opposite polarizations. In addition, the polarization of the incoming proton may be affected strongly (SC-78).

APPENDIX III

STATISTICAL TREATMENT OF ERRORS, STATISTICAL AVERAGING, DEFINITION AND INTERPRETATION OF χ^2

Counting statistics in a spectrum are given by Poisson statistics which become Gaussian when the number of counts per bin, c, becomes large (c\20). The condition, c\20, was satisfied for all data analysed in this experiment and hence all statistical quantities were assumed to follow Gaussian statistics. Was taken as adequate estimate of the statistical error in the measured number of counts, c.

Consider a function of n parameters, $F(p_1, p_2, \dots, p_n)$. Some of the parameters will have corresponding uncertainties and may be correlated with other parameters. Still others will be pre-determined and have no uncertainty and no correlation with other parameters. The uncertainty in F is given by

(AIII.1) $\Delta F = \begin{bmatrix} \frac{n}{2} \left(\frac{\partial F}{\partial p_1} \cdot \Delta p_1 \right)^2 + 2 \cdot \frac{n}{2} & \frac{n}{2} \\ \frac{n}{2} & \frac{\partial F}{\partial p_1} \cdot \frac{\partial F}{\partial p_2} & \frac{\partial F}{\partial p_2} & \frac{\partial F}{\partial p_3} & \frac{\partial F}{\partial p_3} \end{bmatrix} \cdot \Delta \begin{pmatrix} p_1 p_3 \end{pmatrix}$

+ higher order terms $]^{1/2}$,

where the summations extend over the parameters which are not pre-determined,

 $\Delta p_{\underline{i}}$ is the error in the ith parameter,

Δ(p₁p_j) is the covariance between the ith and jth

In general, a mathematical model which is to be fit

to a set of measurements, $y_1 \pm \Delta y_1$ (i=1,m), must make a prediction, F_1 , corresponding to each measurement, y_1 . The predictions come from the evaluation of a function, $F(p_1,p_2,\cdots,p_n)$. Some of the parameters will be determined and thus fixed while others are free to be varied by a fitting program. The purpose of the fitting program is to find a set of values for the free parameters which minimize the value of a function called χ^2 . In the simplest case, χ^2 may be computed from

(AIII.2)
$$\chi^2 = \sum_{i=1}^{m} \left(\frac{F_i(p_1, p_2, \dots, p_n) - y_i}{\Delta y_i} \right)^2$$
.

This expression for χ^2 , when applied to a spectrum where m is the number of bins, is approximately true if the number of counts is not too small (>5). Strictly speaking, the y₁ should be independent, normally distributed random variables and Δy_1 must be their standard deviations.

As a special case, if a series of measurements, y they (i=1,m), are made of a single quantity, y, the statistically weighted average for y and the corresponding error are given by

(AIII.3)
$$\bar{y} = \frac{\sum_{i=1}^{\Sigma} y_i \cdot (\Delta y_i)^{-2}}{\sum_{i=1}^{\infty} (\Delta y_i)^{-2}}$$

$$\Delta \bar{y} = \left(\frac{z}{4z_1}(\Delta y_1)^{-2}\right)^{-1/2}.$$

In addition to returning a set of values for the parameters which minimize χ^2 , the fitting routine also returns a symmetric matrix variously referred to as the covariance, variance, or error matrix. The ith diagonal element of this matrix is the variance (or the square of the standard deviation) of the ith free parameter. Changing one of the parameters, by an amount equal to its standard deviation and refitting with this parameter fixed would result in χ^2 increasing by 1. These standard deviations are taken as the errors in the parameters, Δp_1 . The (i,j)th element of the matrix is the covariance between the ith and jth parameters, $\Delta (p_1p_4)$.

In the course of developing a fitting model, a parameter may be used which has previously been determined independently to a certain accuracy, p_c top. In this case, it may be desirable to let the parameter remain free while constraining it with this additional information. This constraint is implemented by including a term in the χ^2 function,

(AIII.4)
$$\left(\frac{P_{c}-\overline{P}_{c}}{\Delta\overline{P}_{c}}\right)^{2}$$

Another situation that arises is the desire to restrict the value of a parameter to a particular region . This is done by means of adding a penalty term into the χ^2 . An example of a χ^2 function with both a constraint iterm and a penalty term is

(AIII.5)
$$\chi^2 = \sum_{i=1}^{n} \left(\frac{P(x_i, p_1, p_2, \dots, p_n) - y(x)}{\Delta y(i)} \right)^2$$

Here the third term (the penalty term) helps to constrain the dth parameter to non-negative values. Penalty terms may help to prevent the fit from producing unphysical values for parameters such as negative amplitudes for peaks.

The value of x2 may be used to determine the degree to which the date was successfully fit by the modal. One measure for this is the value of x2 per desire of freedom. The number of degrees of freedon in the the number of data points winus the number hot uncapatrained free pareneters. A sessed (aut Ind Stanfat) passes based be the x2 and number of degrees at profitor to called the percentage point. Training of percentage points are available in standard methematical handbooks (38-76). Its value ranges from 0 to 1 and it represents the fractional probability of obtaining a value for x2 equal to or less then the value of a chastvet. For a single fit, a definite conclusion bened on either of these two quantities is difficult to outline but very general statements can be made. Mile with a X2 Mile degree of transport particular points of M. (D.2) indicate a resident con the

very large values, $\gtrsim 4$ ($\gtrsim 0.95$), indicate a poor fit and put the valuelty of the model into question; very small values, $\lesssim 0.4$ ($\lesssim 0.1$), indicate a fit that is "too" good and may suggest that the errors in the data have been overestimated.

For a number of sets of data fit by a single model, if the model describes the data and the data and variances follow a normal distribution the histogram of percentage points should be flat.

The model used in the fitting involved Gaussian peaks of the form given in equation V.1. The result of fitting a set of data were two amplitudes for man peak in the model (one for each spin direction). In addition, for some fits, the width, C52, was a variable parameter. Let

A+#AA+ be the amplitude for the spin + peak

C52±AC52 be the fidth parameter

P+,P+ be the beam polarizations of the spin

(where noth values are hetween 0 and 1).

In terms of these parameters, the partially polarized spin

(AIII.6)
$$\sigma_p^+ = \frac{A^+ \cdot \sqrt{\pi}}{C52}$$
 , $\sigma_p^+ = \frac{A^+ \cdot \sqrt{\pi}}{C52}$

$$\Delta \sigma_{p}^{+} = \sqrt{\pi} \cdot \left[\left(\frac{\Delta \Delta + 1}{C52} \right)^{2} + \left(\frac{\Delta + 1}{C52} \right)^{2} + 2 \cdot \left(\frac{\Delta + 1}{C52} \right)^{2} + 2 \cdot \left(\frac{\Delta + 1}{C52} \right)^{2} \right]^{1/2}$$

$$\Delta \sigma_{1}^{+} = \sqrt{\pi} \cdot \left[\left(\frac{\Delta \Delta +}{C52} \right)^{2} + \left(\frac{\Delta + + \Delta C52}{C52} \right)^{2} + 2 \cdot \left(\frac{\Delta}{C52} \right)^{2} + 2 \cdot \left(\frac{\Delta}{C52} \right)^{2} \right]^{1/2}$$

where equations V.3 and AIII.1 have been used.

Let of and of represent the cross sections for 100% polarizations. The relations between the partially polarization and 100% cross sections are:

$$\sigma_{p}^{+} = \frac{1}{2} \cdot (1+p+) \cdot \sigma_{1}^{+} + \frac{1}{2} \cdot (1-p+) \cdot \sigma_{1}^{+}$$

$$\sigma_{p}^{+} = \frac{1}{2} \cdot (1 - P +) \cdot \sigma_{1}^{+} + \frac{1}{2} \cdot (1 + P +) \cdot \sigma_{1}^{+}$$

Solving for gt, of we have

The unpolarised cross estion and analysing powers are defined as

and in terms of the partially polarized results, these quantities become

Finally from equations AIII.1. AIII.10 and recalling that of and of are independent quantities, the errors in σ_0 and A_{τ} are given by

(AIII.11) $+ \Delta \sigma_0 = \frac{1}{P + \Phi_0} + [(P + \Delta \sigma_1)^2 + (P + \Delta \sigma_1)^2]^{1/2}$

$$\Delta A_{y} = \frac{p + p + \cdots}{(p + \sigma_{1}^{2} + p + \sigma_{2}^{2})^{2}} \cdot [(\sigma_{p}^{+} \cdot \Delta \sigma_{p}^{+})^{2} + (\sigma_{p}^{+} \cdot \Delta \sigma_{p}^{+})^{2}]^{1/2}$$

to be ignared. The special due to the polarimeter p-p calibration does not affect the fits.

APPENDIX V

OPTICAL MODEL POTENTIAL FOR p- 40Ca SYSTEM

The optical potential used in the calculations consisted of a Coulomb term, a complex valued nuclear central term, and a complex valued nuclear spin-orbit term

(AV.1)
$$U(r) = U_{coul}(r) - Vf_{0}(r,R_{0},a_{0}) - i[W_{s} - 4a_{w}W_{d} \frac{d}{dr}]f_{w}(r,R_{w},a_{w}) + i[W_{so} \frac{1}{r} \frac{d}{dr}f_{so}(r,r_{so},a_{so})] \stackrel{?}{L} \stackrel{?}{\sigma}$$

where the form actors, f, have Woods-Saxon shapes,

 (AV_{2}^{2}) f = f(r,R,a) = $\frac{1}{m_{2}(r-R)/a}$

The values of the various parameters as a function of energy are listed in Table X. The details of the analysis method used to derive this potential are given in (NA-80).

The applyers used to obtain the optical potential was based on a semi-relativistic Schrodinger-type wave equation derived from the Dirac equation for, a fermion moving in a localized central potential, U(r). As the spin-orbit term arising from the Dirac equation is negligible, the one used in this assigns is purely phenomenological. With the least transfer is purely phenomenological. With the least transfer to the latest transfer to the latest selection for the target non-
