## Abstract

Euryhalinity is the ability to survive in multiple environmental salinities. Full euryhalinity is rare within the elasmobranchs (rays, skates, and sharks), however, marginal euryhalinity is comparatively more common. The physiology underlying these adaptations is relatively understudied in cartilaginous fishes compared to bony fishes. I investigated changes in both gill morphology and the kidney transcriptome in Pacific spiny dogfish (*Squalus suckleyi*), a marginally euryhaline shark, following an ecologically relevant 65% seawater exposure. Furthermore, I explored the evolutionary basis of salinity tolerance using the current literature on phylogenetic relationships in selachimorphs (sharks). Dogfish were exposed to 65% seawater for up to 48hrs and sampled throughout. After 24hrs, gills were excised for light microscopy, revealing a significant increase in the interlamellar cell mass and the appearance of both lamellar clubbing and epithelial lifting, suggesting reduced surface area and increased cellular damage, respectively. Total plasma osmolality was measured during the time course and exhibited a significant reduction. This was primarily attributed to the loss of plasma urea, as both  $\text{Na}^+$  and  $\text{Cl}^-$  showed minimal change. I employed RNA-seq to quantify changes in kidney mRNA expression after 0, 12, and 48hrs in 65% seawater. The role of the kidney in low salinity exposure has been previously studied using physiological methods, however, there is a substantial lack of molecular level studies. This technique revealed 1013 unique and differentially expressed transcripts, of which ~60% were functionally annotated. Generally, transcripts that were upregulated or downregulated after 12hrs remained so after 48hrs. Differentially expressed transcripts were involved in numerous cellular functions including protein chaperones, metabolic processes, cell signalling, and responses to stimuli and stress. Importantly, multiple heat shock protein transcripts were upregulated after 12hrs and numerous

transcripts encoding protein trafficking were downregulated. Overall, I showed that the transcriptomic response of the kidney to 65% seawater was highly integrative and relied on the regulation of a multitude of processes. Lastly, low salinity tolerance within elasmobranchs has arisen in multiple species and I postulate that the phylogenetic distance between these species has no bearing on the limits of salinity tolerance observed in the literature.

## **Preface**

The synthesis of cDNA libraries for sequencing were generated in collaboration with Dr. Andrew Whitehead and Jen Roach at UC Davis. Sequencing of these cDNA libraries and demultiplexing was performed by the UV Davis Genome Sequencing Centre.

## **Acknowledgements**

Firstly, thank you to Dr. Greg Goss. You have been an exceptional teacher and guide during my time at U of A. You allowed me to work independently knowing I always had a safety net if guidance was necessary. You allowed me to go places and perform research I might have otherwise only read about.

Thank you to my parents who have been incredibly supportive and helpful. The science conversations on the couch between gorging on chocolate chip cookies made this work much easier. Meghan Gal, thank you for being patient and encouraging while living in different cities, I am extremely grateful to you.

During my time at U of A I received funding from the Queen Elizabeth II Graduate Scholarship, the Dr. Richard (Dick) E Peter Memorial Graduate Scholarship, the Alberta Graduate Student Scholarship. I received travel funds from the Canadian Society of Zoologists, the U of A Graduate Student Association, the International Conference for the Biology of Fishes, and the Society for Experimental Biology. Funding for experiments was provided by NSERC Research Grant provided to Dr. Greg Goss. I am extremely appreciative of all these funding agencies.

Thank you to my committee member Dr. Warren Gallin, you have been extremely helpful in both the work presented in this thesis and in the technical expertise of oocyte injections outside of this thesis. Thank you to Dr. Andrew Whitehead and Jen Roach at UC Davis for providing the technical expertise while I visited your lab, it was an incredible experience. Thank you to the staff at Bamfield Marine Sciences Centre for providing the most beautiful place for blood sampling at 4 a.m. Thank you to the administration and building staff of the Biological Sciences department and the staff in MBSU.

Thank you to all the members of the Goss lab, past and present, that I was lucky enough to meet and learn from. You are all cherished friends and collaborators and have been a highlight of my time at the U of A.

## List of Abbreviations

AQP4	Aquaporin 4
ATP	Adenosine triphosphate
BAG4	Bcl2 associated athanogene 4
bp	Base pairs
BUSCO	Benchmarking universal single-copy orthologs
BW	Brackish water
CADH1	Cadherin 1
CASP6	Caspase 6
CCD22	Coiled-coil domain containing 22
CCL20	C-C motif chemokine ligand 20
cDNA	Complementary deoxyribonucleic acid
CFTR	Cystic fibrosis transmembrane conductance regulator
CGNL	Cingulin Like 1
CNP	C-type natriuretic peptide
Contigs	Contiguous sequences
CPM	Counts per million reads
CPSI	Carbamoyl-phosphate synthase I
CPSIII	Carbamoyl-phosphate synthase III
DIC	Dicarboxylate carrier (also SLC25A10)
DNase	Deoxyribonuclease
DSC3	Desmocollin 3
E2	Ubiquitin-conjugating enzymes
EKI1	Ethanolamine kinase 1
EPT1	Ethanolaminephosphotransferase 1
ERK1	Extracellular signal-regulated kinase 1 (also MAPK1)
ERK2	Extracellular signal-regulated kinase 2
FADD	Fas associated death domain
FC	Fold change
FTCD	Formimidoyltransferase cyclodeaminase
FW	Freshwater

g	x gravity
GFR	Glomerular filtration rate
GO	Gene ontology
GSase	Glutamine synthetase
HGD	Homogentisate 1,2-dioxygenase
HPETE	Arachidonic acid 5-hydroperoxide
hrs	hours
HSP	Heat shock protein
HSP30	Heat shock protein 30kDa
HSP71A	Heat shock protein 71 A
HSP71L	Heat shock protein 71 L
HSP80	Heat shock protein 80
I17RA	Interleukin 17 Receptor A
IL10	Interleukin 10
ILCM	Interlamellar cell mass
kDa	Kilodalton
KEGG	Kyoto encyclopedia of genes and genomes
kg	Kilograms
L	Litres
LOX5	Arachidonate 5-lipoxygenase
MAPK	Mitogen activated protein kinase
MAP2K5	Mitogen activated protein 2 kinase 5
MAP3K15	Mitogen activated protein 3 kinase 15
mins	Minutes
mL	Millilitres
mOsm	Milliosmoles
MRC	Mitochondria rich cells
mRNA	Messenger ribonucleic acid
NADH	Nicotinamide adenine dinucleotide
NF-kb	Nuclear factor kappa-light-chain-enhancer of activated B cells
NGS	Next generation sequencing

NHE	Sodium-hydrogen exchanger (also SLC9)
NHE2	Sodium-hydrogen exchanger 2
NHE3	Sodium-hydrogen exchanger 3
NKA	Sodium-potassium ATPase
NKCC	Sodium-potassium-2 chloride
NO	Nitric oxide
nt	Nucleotides
ORFS	Open reading frames
OSTF1	Osmotic stress transcription factor 1
OUC	Ornithine-urea cycle
P53	Tumor protein 53
PCA	Principal component analysis
PE	Phosphatidylethanolamine
PFA	Paraformaldehyde
PISD	Phosphatidylserine decarboxylase
ppt	Parts per thousand
PSA7	Proteasome subunit alpha 7
PTSS2	Phosphatidylserine synthase 2
RAB7	Ras associated protein 7
RBBP6	RB Binding protein 6 ubiquitin ligase
REVIGO	Reduce and visualize gene ontology
Rhag	Rh associated glycoprotein type A
Rhbg	Rh associated glycoprotein type B
Rhcg	Rh associated glycoprotein type C
RhoA	Ras homology family member A
Rhp2	Rh protein 2
RIN	RNA integrity number
RNA	Ribonucleic acid
RNA-seq	RNA-sequencing technology
RSEM	RNA-seq by expectation-maximization
SARDH	Sarcosine dehydrogenase

shUT	Shark urea transporter
SLC	Solute carrier family
SLC25A10	Solute carrier family 25 member 10 (also DIC)
SLC6A18	Solute carrier family 6 member 18
SLC6A5	Solute carrier family 6 member 5
SLC9A9	Solute carrier family 9 member 9
SNX14	Sorting nexin 14
SNX4	Sorting nexin 4
SW	Seawater
TJAP	Tight junction associated proteins
TMAO	Trimethylamine N-oxide
TNF6B	Tumor necrosis factor receptor superfamily member 6B
TPM	Transcripts per million reads
TRPV4	Transient receptor potential cation channel subfamily V member 4
TSC22D2	TSC22 Domain family member 2
UB2J1	Ubiquitin conjugating enzyme E2 J1
UBC12	Ubiquitin conjugating enzyme E2 M
UBE2C	Ubiquitin conjugating enzyme E2 C
UBE2T	Ubiquitin conjugating enzyme E2 T
UFR	Urine flow rate
UHRF1	Ubiquitin like with PHD and ring finer domains 1
UT-A1	Urea transporter 1
UT-A2	Urea transporter 2
VPS36	Vacuolar protein sorting 36 homolog
ZO1	Tight junction associated protein 1

## List of Definitions

**BUSCO score** - A measure of the completeness of a transcriptome. Vertebrates possess 2586 orthologs that should be present only once in the transcriptome, thus if all are present in a dataset it is likely more complete than one without all.

**Chondrichthyes** - All cartilaginous fishes, including elasmobranchs and holocephalans.

**Concordant alignment** - Successfully mapping both paired reads to a single location on the transcriptome.

**de Bruijn graphs** - A method of presenting the sequence variations in overlapping contigs.

**Disconcordant alignment** - Mapping of paired reads to separate locations, or, mapping of only a single contig of the pair.

**Elasmobranchs** - A subclass of Chondrichthyes consisting of sharks, rays, and skates.

**Euryhalinity** - The ability of an animal to survive in a wide range of environmental salinities.

**Ex90** - Represents the subset of transcripts that comprise 90% of the most highly expressed transcripts of the TMM normalized data.

**Ex90N50 value** - The N50 value calculated using only the Ex90 subset as the input, rather than the entire transcriptome.

**N50 value** - A weighted median statistic that represents a transcript length such that 50% of the assembly is equal to or greater than this value.

**Phred score** - The probability that a base is sequenced incorrectly, ranging from 0-40. A score of 40 has a 1 in 10000 chance of being identified incorrectly.

**Selachimorphs** - A superorder of elasmobranchs that contains only the true sharks.

**TPM** - Normalized expression values where raw counts are first divided by the length of genes in kilobases to get reads per kilobase (RPK), followed by dividing the sum of all RPK values by 1 million to get transcripts per million.

**TMM normalization** - Normalization method of TPM values which removes mRNA composition bias.

## Introduction

### *Osmoregulatory strategies in fishes*

Osmotic stress is an innate challenge for all aquatic organisms that is imposed simply due to physiochemical properties of the environment. Fishes are the most abundant vertebrate within the aquatic environment and have evolved multiple physiological strategies to overcome osmotic challenges (Kultz, 2015). Actinopterygians (ray finned, bony fishes) are the largest class of fishes and have evolved to simultaneously osmoregulate and ionoregulate, maintaining an internal plasma osmotic pressure of roughly 300-400 milliosmole (mOsm) (Kultz, 2015). The evolution of this strategy has supported widespread habitation in both marine and freshwater environments by many species. Actinopterygians living in a freshwater environment are hyperosmotic, resulting in simultaneous water influx and ion efflux. Inversely, Actinopterygians living in marine environments are hyposmotic and thus are constantly inundated with ion influx and dehydrating conditions. In both environments, the osmoregulatory systems are tailored precisely to maintain ion balance and total osmotic pressure. In contrast to the diverse Actinopterygians, the Myxini class (hagfish) employ a strategy in which they osmoconform and ionoconform causing the osmotic pressure within to match the surrounding water. These fishes are restricted to a marine environment and are unable to survive any freshwater exposure (Martini, 1998).

Another osmoregulatory strategy in the fishes is present in Chondrichthyes, or cartilaginous fishes, and in the rare, extant fossil clade Coelocanthiformes (Griffith, 1980). Marine elasmobranchs (sharks, rays, and skates) are naturally isosmotic (or slightly hyperosmotic) with the surrounding water, maintaining an extracellular osmolality of ~1000 mOsm (Wright and Wood, 2015). This has greatly reduced the need to imbibe water, contrary to their marine Actinopterygian counterparts. Together, plasma  $\text{Na}^+$  and  $\text{Cl}^-$  account for approximately 500-600 mOsm, producing an inward gradient for these electrolytes that must be excreted. The remaining 400-500 mOsm is primarily attributed to the unique addition of two nitrogenous compounds, urea and trimethylamine N-oxide (TMAO)(Yancey, 2015). Therefore, this is termed a ureosmotic strategy. Urea typically exerts an osmotic pressure of approximately 300-500 mOsm, while TMAO is substantially less at 50-100 mOsm (Yancey, 2015). Other

organic methylamines and amino acids such as betaine,  $\beta$ -alanine, sarcosine, and taurine also contribute to total osmotic pressure however in smaller quantities (totalling <50 mOsm). Early studies on elasmobranch physiology (reviewed in Smith, 1936) indicated urea was critical for proper cardiac function in a variety of species. *in vitro* experiments using four elasmobranch species (*Raja clavata*, *Raja blanda*, *Scyllium canicula*, and *Rhina squatina*) demonstrated the vital role of urea in cardiac contractions, while experiments on *Squalus suckleyi* cardiac tissue revealed an increase in irregular heart rate following replacement of urea with sucrose or thio-urea (Mines, 1912; Simpson and Ogden, 1932). It has since been concluded that almost all elasmobranchs require urea, with the exception being a small number of obligatory freshwater stingrays of the Myliobatiformes order (Ballantyne and Robinson, 2010). No teleosts species to date have shown to be ureosmotic, making the Chondrichthyes and Coelocanth unique. However, some such as Lake Magadi tilapia (*Alcolapia graham*) are known to be ureotelic, as opposed to the majority that are ammonotelic (Randall et al., 1989).

Retaining urea as a primary osmolyte comes with several major consequences. The first problem is that urea induces destabilizing effects on protein structure. This occurs through both hydrogen bonds forming with the protein amide group and a reduction in the hydrophobic effects that maintain proper protein structure (Zou et al., 1998). To rescue this negative effect, the previously mentioned methylamine compounds (particularly TMAO) act as chemical chaperones to enable proper protein folding and enzymatic function (Yancey and Somero, 1980). The ratio of urea to TMAO (and other organic chaperones) that optimizes protein stabilization is roughly 2:1, however, this is also impacted by depth in the water column, species, and tissue type (Forster and Goldstein, 1976; Laxson et al., 2011; Suyama and Tokuhiko, 1954; Yancey and Somero, 1979).

The second major consequence of the ureosmotic strategy is the metabolic price of urea synthesis. Urea is synthesized through the ornithine-urea cycle (OUC) and this predominantly occurs in the mitochondria (the purine degradation pathway is also present but does not contribute significantly) (Schooler et al., 1966). There are several important differences between the OUC in elasmobranchs and in similar ureotelic animals. First, elasmobranchs rely on glutamine as the initial nitrogenous substrate, rather than ammonia (Anderson and Casey, 1984). Secondly, the reliance on glutamine necessitates a different catalyzing enzyme for this reaction and therefore elasmobranchs employ carbamoyl-phosphate synthetase III (CPS III, substrate is

glutamine) rather than CPS I (substrate is ammonia). Third, both the initial reaction catalyzed by glutamine synthetase (GSase) and the final reaction catalyzed by arginase occur within the mitochondria, rather than in the cytosol (Casey and Anderson, 1982). The functional outcome of this last difference is likely an increase the shuttling of glutamine directly into the urea cycle rather other glutamine dependent processes and increased rate of return of ornithine back into the cycle (Anderson, 1991). The highest rates of urea biosynthesis in elasmobranchs are found in liver, nevertheless, extrahepatic sources are also involved. In particular, white muscle shows relatively low synthesis rates yet contributes significantly to total urea biosynthesis due to its large mass (Steele et al., 2005). Furthermore, GSase in these extra-hepatic tissues (except kidney) is located within the cytosol as opposed to the mitochondria, supporting the key role the liver plays in urea production (Anderson, 1991). The OUC is extremely expensive metabolically, requiring 5 mol of adenosine triphosphate (ATP) to produce a 1 mol of urea (Kirschner, 1993). Since retention of urea across the osmoregulatory organs is not perfect, continuous production of urea is necessary to maintain isosmotic status. A consequence of this constant urea production is that these animals are almost permanently in a nitrogen limited state. It is hypothesized that this high nitrogen demand contributes to the nearly ubiquitous role as carnivores (Ballantyne and Robinson, 2010; Wright and Wood, 2015).

#### *Iono- and osmoregulatory organs in marine elasmobranchs*

The elasmobranchs have evolved numerous sophisticated physiological mechanisms to deal with strong gradients directing salts inward and organic osmolytes outward, all while remaining isosmotic. The four main organs involved in regulating osmolytes are the intestine, rectal gland, gill, and kidney (Wright and Wood, 2015; Yancey, 2015). Briefly, the intestine does not typically play a large role as the drinking rate is almost zero due to their isosmotic status. However, during feeding, osmotic challenge, or alteration of the renin angiotensin via pharmacology, these animals may imbibe seawater and the intestine may become involved (Anderson et al., 2002; Anderson et al., 2007). The rectal gland is present in both elasmobranchs and coelacanth and shares similarities with salt glands found in birds and reptiles (Forey, 1980; Holmes and Phillips, 1985; Shoemaker and Nagy, 1977). It is critical in removing plasma  $\text{Na}^+$  and  $\text{Cl}^-$  and excreting a highly concentrated solution into the lower intestinal tract. It uses a

counter-current system and is populated with numerous mitochondrion-rich cells (MRCs), a hallmark of active ion transport (Wright and Wood, 2015).

The direct interface with the aquatic medium make the gills a principal location for salt influx and urea loss. The gross morphology differs only slightly from teleosts, however, the transport physiology is quite altered. Teleost gills are heavily involved in both acid-base homeostasis and ionoregulation while the elasmobranch gill plays a similar role in acid-base homeostasis, however its role in salt excretion may be secondary to rectal gland, but still functional (Evans et al., 2005; Wright and Wood, 2015). In both clades, salt secretion demands numerous MRCs with high abundance of the trademarks proteins  $\text{Na}^+/\text{K}^+$ -ATPase (NKA),  $\text{Na}^+/\text{K}^+/2 \text{Cl}^-$  co-transporter (NKCC), and cystic fibrosis transmembrane conductance regulator (CFTR)(Silva et al., 1977). Together, this system generates secondarily active NaCl excretion. Interestingly, in marine spiny dogfish, *Squalus acanthias*, surgical removal of rectal gland does not elicit an increase branchial NKA activity (to increase  $\text{Na}^+$  and  $\text{Cl}^-$  secretion) or alter salt homeostasis, suggesting that increased urinary output and the basal level of branchial secretion was sufficient to maintain homeostasis (Wilson et al., 2002). In contrast to this, marine houndsharks (*Triakis scyllium*) challenged with diluted seawater showed an increase in branchial NKA, in addition to NKCC (Takabe et al., 2016). The exact role of the elasmobranch gills in ionoregulation is contentious and remains to be discerned (Wright and Wood, 2015).

In contrast to this disputed ionoregulatory role, the gills undoubtedly contribute significantly to urea osmoregulation and are the primary route for the loss of nitrogenous compounds (Payan et al., 1973; Wood et al., 1995). Elasmobranch gills possess two mechanisms that limit urea loss against a steep chemical gradient. The first is an abnormal basolateral membrane composition in the epithelial cells. This membrane displays an extremely high ratio of cholesterol-to-phospholipids (3.68), promoting the tight packing of the phospholipids and ultimately decreasing the passive urea loss (Fines et al., 2001). The other mechanism of branchial urea regulation is the presence of urea transporters. The location (basolateral vs apical) and transport mechanism (facilitated, co-transporter, or exchanger) remains inconclusive, however, pharmacological inhibition studies using phloretin (NKA inhibitor) and isolated basolateral membrane suggest a  $\text{Na}^+$  dependent back transporter that maintains intracellular urea low (Fines et al., 2001). Alternatively, use of urea analogues thiourea and acetamide suggested an apical localization of a facilitative transporter (Wood et al., 2013). These are not mutually

exclusive and further work needs to be done to conclusively identify the proteins involved. Interestingly, the gills show an ability to acquire  $\text{NH}_3$  from the environment, providing another source of nitrogen (Wood and Giacomini, 2016).

#### *Iono- and osmoregulation in the kidney*

The elasmobranch kidney is a critical osmoregulatory organ primarily due to its role in urea homeostasis, wherein it achieves 70-99% reabsorption of the filtered urea (Kempton, 1953). This high rate of renal urea reabsorption is reflected in whole-animal urea excretion measurements where basal renal loss in *Raja erinacea*, a marine skate, only accounted for roughly 4% with branchial loss contributing the remaining 96% (Payan et al., 1973). Reabsorption is suggested to occur through active (primary and/or secondary) transport, or through a countercurrent manner of passive transport, or a combination (Hammerschlag, 2006; Schmidt-Nielsen et al., 1972). Morphologically, the nephron tubules are substantially more convoluted and longer than most other vertebrates, making them unique (Hazon et al., 2003). Tubules begin at the renal corpuscle and typically form a series of 4 hairpin loops that alternate between the bundle zone and sinus zone, before finally emptying into the collecting tubules (Lacy and Reale, 1985). Encasing each bundle tubule is a unique peritubular sheath which shares similarities in cellular arrangement to barrier structures in invertebrates and vertebrates, possibly suggesting a similar role (Lacy and Reale, 1986). The filtered, hyposmotic urine travels from collecting tubules into a duct and is then excreted from the animal through the cloaca. The countercurrent morphology arrangement of tubules in addition to the impermeable peritubular suggests the possibility of a passive renal transport system (Friedman and Hebert, 1990). The proportion of transport that can attributed to this passive movement has not been explored and warrants further analysis. An exception to this complex renal morphology is the Potamotrygonidae family of freshwater rays. These animals have lost the typical ureosmotic strategy present in marine elasmobranchs, and therefore may have no necessity for a complex, renal system to maintain urea and salt homeostasis (Hyodo et al., 2014).

Renal transport proteins are fundamental for the reabsorption of plasma osmolytes, irrespective of the overall transport mechanism (active, passive, or both). Like the rectal gland and gills, basolateral NKA in the renal tubules is a key generator of  $\text{Na}^+$  gradients that can be employed by numerous co-transporters. Renal reabsorption of urea is maintained at a ratio of

1.6:1 to  $\text{Na}^+$  regardless of environmental salinity, suggesting a strong link between the two osmolytes (Schmidt-Nielsen et al., 1972). Both a phloretin sensitive, facilitated urea transporter (shUT) and a phloretin sensitive,  $\text{Na}^+$  dependent transporter have been identified and are hypothesized to be the main participants in urea reabsorption (Morgan, 2003a). The shUT in Japanese-banded houndsharks showed localization restricted only to the collecting tubule and furthermore, this was predominantly in the apical side of the cells (Hyodo et al., 2004; Yamaguchi et al., 2009).

Other transport proteins that play important ionoregulatory roles have been identified in elasmobranch kidney tissues. Two members of the  $\text{Na}^+/\text{H}^+$  exchanger (NHE) family (NHE2 and NHE3) have been revealed, however these were suggested to have a much larger role in acid-base regulation than osmoregulation (Claiborne et al., 2008; Li et al., 2013). Four NKCC2 (a kidney-specific NKCC) variants have been identified (Gagnon et al., 2002). In addition to reabsorbing osmolytes, the kidneys also tightly regulates water balance. Aquaporin 4 (AQP4) has been identified in dogfish shark kidneys, however, that is the only member (Cutler et al., 2012). There is a lack of data about many of the other Solute Carrier (SLC) family transporters that are likely involved in retention of the organic methylamine osmolytes. Ammonia transporter Rhp2 is present in shark kidney and is localized only in the sinus zone (Nakada et al., 2010). In summation, several transporters have been identified, of which some have been localized to particular regions, however, the overall mechanism of osmolyte reabsorption and how each component fits together has not been resolved.

### *Euryhalinity in elasmobranchs*

Euryhalinity is the ability of an organism to live in a wide range environmental salinities. This trait exists as a gradient, ranging from true euryhalinity to marginal euryhalinity. FW habitation in the elasmobranch clade is relatively rare compared to the bony fishes. There are ~1,050 extant elasmobranchs and of this, 171 species are thought to enter BW or live in FW (Dulvy et al., 2014; Martin, 2005). Of these tolerant species, only ~8% are considered truly euryhaline and 21% are obligate FW species, compared to 41% in teleosts (Cohen, 1970; Martin, 2005). Therefore, approximately 120 elasmobranch species can be considered marginally euryhaline. Little is known about the extent of salinity tolerance in the vast majority of these marginally euryhaline species, yet some have been well studied (e.g. *Squalus suckleyi*, *Squalus*

*acanthias*, *Raja erinacea*, *Heterodontus portusjacksonii*, *Triakis scyllium*) The fully euryhaline species include a single shark family, Carcharhinidae (requiem sharks), and several ray and skate families including Pristidae (sawfish), Dasyatidae (whiptail rays), and Rajidae (skates)(Martin, 2005). From the known species, it is clear the rays and skates are considerably more successful at penetrating into freshwater and brackish environments than sharks (Martin, 2005). There may be several factors that limit the extent of FW invasions, however, it is hypothesized that urea physiology, rather than any morphological basis, is responsible due to the common occurrence of unspecialized ecomorphotypes in euryhaline and FW species (Martin, 2005).

Transition from a SW environment to a BW or FW environment induces many acute physiological changes. The most common and well documented change is a reduction of total plasma osmolality, primarily through the loss of plasma urea and TMAO and a similarly, a reduction in urea biosynthesis (Anderson et al., 2005a; Cooper and Morris, 1998; Deck et al., 2016; Guffey and Goss, 2014; MacLellan et al., 2015). This urea loss occurs predominantly through the kidney, as efflux from the gills stays relatively constant (Payan et al., 1973). A common response observed in the kidney is an increased urine flow rate (UFR) and glomerular filtration rates (GFR), both contributing to a decrease in urea reabsorption and an overall decrease in plasma urea (Cooper and Morris, 2004a; Goldstein and Forster, 1971; Payan et al., 1973). Increased GFR also likely contributes to water homeostasis as during this period there is increased water influx (Anderson et al., 2007; Guffey and Goss, 2014).

### *Transcriptomics and physiology*

Genetic sequencing technology and its applications have advanced significantly since its conception with Sanger sequencing, the first generation, low-throughput technique (Sanger and Coulson, 1975; Sanger et al., 1977). Sequencing by synthesis, or next-generation sequencing (NGS), was the next revolutionary technology that allowed high-throughput, parallel sequencing of entire DNA libraries, rather than single targets such as in Sanger sequencing (Heather and Chain, 2016). NGS employs fluorophore-conjugated nucleotides that can be laser stimulated to fluoresce following DNA polymerization, thus revealing the nucleotide identity (Shendure and Ji, 2008). This technology has also been applied to RNA (termed RNA-seq), although it requires reverse transcription to produce a cDNA library prior to sequencing. The development of RNA-seq has greatly benefited the field of transcriptomics (study of the mRNA profile), which

primarily aims to quantify transcript expression after treatment or between different tissue types, measure changes in gene splicing, and identify single nucleotide polymorphisms (Wang et al., 2009).

Prior to RNA-seq, quantification of mRNA expression levels in a high-throughput manner was largely accomplished by microarrays (tag-based methods were also possible however still relied on Sanger sequencing). Microarrays use a set of complementary nucleotide probes, either custom designed or general oligonucleotides, to bind to mRNA and fluoresce upon laser stimulation (Tarca et al., 2006). This hybridization-based method is relatively quick, easy, and inexpensive. However, probe design requires prior genetic knowledge, limiting its applications. Furthermore, some mRNA sequences may cross-hybridize with multiple probes, increasing background levels greatly (Okoniewski and Miller, 2006). Microarrays also possess a limited dynamic range of detection, decreasing the sensitivity (Wang et al., 2009). RNA-seq overcomes many of these issues, as well as providing other advantages. No prior genetic knowledge is necessary for RNA-seq, making it suitable for non-model species. RNA-seq has an extremely large dynamic range, allowing detection of transcripts with differences of >8000 fold, while microarrays are restricted to fold differences in the hundreds (Wang et al., 2009). In addition to its wide detection range, it has also been shown to be accurate in its quantification of transcripts (Mortazavi et al., 2008; Nagalakshmi et al., 2008). This technology is not without its own disadvantages and challenges. It requires extensive use of bioinformatics and computing resources for analysis due to the large amount of data generated. Furthermore, steps in cDNA library synthesis can introduce bias, however, most of these can be measured and corrected (Wang et al., 2009).

RNA-seq has become common in a physiological context to understand changes in organisms following treatment or experimental exposure. In teleost fishes RNA-seq has been used extensively to study several phenomena in multiple tissue types, e.g. thermal tolerance, salinity tolerance, hypoxia exposure, stress responses, immune response to infection and metal toxicity (Aballai et al., 2017; Beck et al., 2016; Gibbons et al., 2017; Metzger and Schulte, 2016; Naour et al., 2017; Nguyen et al., 2016; Song et al., 2017; Tomalty et al., 2015; Zhang et al., 2017a; Zhang et al., 2017b). Within elasmobranchs, RNA-seq has seen limited usage. The studies that have been performed have used it to catalogue the transcriptome, rather than performing any experimental treatment to quantify differential expression (Chana-Munoz et al.,

2017; King et al., 2011; Krishnaswamy Gopalan et al., 2014; Mulley et al., 2014; Richards et al., 2013). The potential of future investigation into elasmobranch genomes and transcriptomes using NGS is enormous.

### *Thesis goals*

Currently, there is a broad understanding of elasmobranch renal physiology following a salinity challenge (SW into BW or FW), however it is far from complete. Unsurprisingly, most studies that have examined changes at the molecular level have focused on critical transporters (such as urea transporters), excluding a plethora of other potential responses that may be occurring. Therefore, this thesis primarily sought to explore in greater detail the changes in expression of transcripts involved in ion transport, and ancillary transcripts that also likely contribute to successfully responding to osmotic challenges within the kidney. This was accomplished using RNA-seq technology and the Pacific spiny dogfish, *Squalus suckleyi*. As discussed previously, RNA-seq technology has been limited in its application in elasmobranch species, making the work in this thesis particularly novel. *S. suckleyi*, and its sister species *S. acanthias*, are marginally euryhaline elasmobranchs and have been extensively used in whole body, branchial, and rectal gland physiology studies, largely excluding the kidney (Claiborne et al., 2008; Deck et al., 2016; McMillan and Morse, 1999; Wilson et al., 2002; Wood et al., 1995; Wood et al., 2013). These animals have been previously caught in estuaries where salinity was measured at ~65% SW, and therefore this level was used for experiments. It is hypothesized that an acute salinity challenge will induce a reduction in the transcript expression of urea transporters as previously seen in *Triakis scyllium*, in addition to transcripts involved in organic osmolyte transport, ultimately to allow the conservation of isosmotic status (Yamaguchi et al., 2009). Consistent with this hypothesis, decreases in the expression of tight junction transcripts such as the claudin family is expected, allowing for increased paracellular loss of osmolytes. Furthermore, the abundance of aquaporins transcripts will likely increase to permit water loss and maintain water balance. Responding to any stimulus requires the activation of signal transduction pathways, and therefore transcripts involved in these pathways will likely be differentially expressed following an osmotic challenge, with increases and decreases in expression specific to each pathway (Fiol and Kültz, 2007). Consequently, there will likely be changes metabolic processes to accommodate the activation of these pathways and the extensive

responses these pathways activate or inhibit. The levels of protective osmolytes such as TMAO have an inverse relationship with the levels of heat shock proteins, and thus, as TMAO decreases there will likely be an increase in the expression of heat shock protein transcripts (MacLellan et al., 2015).

Additional to this primary goal, I aimed to characterize morphological changes seen in the dogfish gills following exposure to low salinity. This has not been documented in these sharks previous, however, teleosts have been shown to respond to changes in salinity through alterations to gill morphology (Blair et al., 2018). The last objective of this thesis was to explore the evolutionary history of the selachimorphs to elucidate whether the level of salinity tolerance was evolutionarily related to phylogenetic relationships.

## **Materials and Methods**

### *Dendrogram of marginally euryhaline elasmobranchs*

The literature was searched for publications containing information about the lowest salinity that selachimorphs are found at in a natural setting or tested within the laboratory. A representative dendrogram was generated to visualize the relationships between species based on (Ballantyne and Fraser, 2012) and Naylor et al. (2012). A semi-quantitative measure of the link between salinity tolerance and evolutionary history was performed by measuring the pairwise phylogenetic distance between each euryhaline species and correlating this to pairwise differences in the lowest published salinity. This was done under the hypothesis that species with a greater phylogenetic distance would likely display a greater difference in salinity tolerance. The phylogenetic distances between species were measured using ImageJ software and the phylogeny generated by Naylor et al. (2012) which used NADH2 sequences from 595 elasmobranch species.

### *Animal collection and exposure*

Pacific spiny dogfish (*Squalus suckleyi*) were collected from Barkley Sound (Vancouver Island, B.C., Canada) using hook and line and transported to Bamfield Marine Sciences Station where they were kept in a flow-through, circular housing tank (140,000 L). Dogfish were fed

commercial hake (*Merluccius productus*) to satiation every four days. Experimental animals were transferred to a smaller, flow-through, circular holding tank (1,500 L) to fast for five days. Following fasting experimental animals were transferred to individual, opaque, flow-through exposure tanks (135 L) and allowed to acclimate for at least eight hours. Upon completion of acclimation period, water was drained over 10 mins to ~65% tank volume and refilled with 100% FW to achieve the desired 65% SW (21ppt), an ecologically relevant exposure level (McMillan and Morse, 1999). Simultaneous inflows of 100% SW and 100% FW at different rates maintained the 65% SW exposure level throughout the length of the experiment. Five animals were kept at 65% SW for each time duration (0, 3, 6, 12, 24, and 48hrs) with continuous flow-through and an oxygen air-stone. Water salinity was measured using an electronic probe (YSI) and maintained via adjustments to the SW and FW inflow rates. Water temperature was maintained at environmental levels by the flow-through system. After completion of the full exposure duration, animals were euthanized using tricaine methanesulfonate ( $5 \text{ g L}^{-1}$ ) (Syndel Laboratories, Qualicum Beach, B.C., Canada) followed by severance of the spinal cord. All procedures using animals were approved by the University of Alberta and Bamfield Marine Sciences Centre animal use care committees (University of Alberta AUP#00001126).

#### *Plasma measurements and tissue sampling*

Whole blood (2mL) was sampled at each time point via caudal puncture using a 20 gauge needle rinsed beforehand with heparinized dogfish saline (in  $\text{mmol L}^{-1}$ : NaCl 280.0, KCl 6.0,  $\text{CaCl}_2$  5.0,  $\text{MgCl}_2$  3.0,  $\text{Na}_2\text{SO}_4$  0.5,  $\text{Na}_2\text{HPO}_4$  1.0,  $\text{NaHCO}_3$  4.0, Urea 350.0, TMAO 70.0, and glucose 5.0 at  $\text{pH} = 7.8$ ) (Guffey and Goss, 2014). Blood was immediately centrifuged at 12,000 xg for 2 min to obtain plasma. Plasma  $\text{Na}^+$ ,  $\text{Cl}^-$ , and urea were measured via, respectively, a Thermo Scientific model iCE 3300 Atomic Absorption Spectrometer, a Buchler digital chloridometer, and a colourimetric urea assay (urea diluted to 1:5000) (Rahmatullah and Boyde, 1980). Total plasma osmolality was measured using a Vapro vapour pressure osmometer. Tissue samples (gut, kidney, brain, heart, gills, white muscle, liver, and rectal gland) were excised at each time point immediately upon euthanasia and placed into appropriate solutions (e.g. RNAlater™ (Ambion) and then into liquid nitrogen or prepared for gill morphology).

### *Gill morphology*

Gills from three animals at both 0hrs and 24hrs were extracted and fixed in 4% PFA overnight at 4 °C and subsequently washed twice with ice-cold 70% ethanol. These were then dehydrated via a series of ethanol washes. Tissues were embedded in paraffin, sectioned at 5 µm and stained with hematoxylin and eosin before being imaged on Zeiss Scope A1 microscope combined with an optronic camera for imaging. Images were loaded in ImageJ and the line tool was used for measurements using a reference scale bar added during image capturing. Gill lamellar width measurements were performed by taking the average of ten random measurements along the length of a lamellae on five different lamellae. Five interlamellar cell mass (ILCM) measurements were made on each side of a gill by measuring from the outermost side of the ILCM to border.

### *RNA extraction, cDNA library preparation, and sequencing*

Total kidney RNA was extracted using TRIzol (Invitrogen) according to manufacturer's guidelines from sharks exposed to low salinity for 0hr, 12hr, and 48hr. RNA integrity and purity were analyzed on an Agilent 2100 Bioanalyzer and Nanodrop 1000, respectively, for quality control prior to cDNA library synthesis. All RNA integrity numbers (RINs) were above 8 (mean = 9.32). RNA concentration was measured using a Qubit fluorometer (Invitrogen). The cDNA libraries were produced using the NEBNext<sup>®</sup> Ultra Directional RNA Library Prep Kit for Illumina<sup>®</sup> and indexed using the NEBNext<sup>®</sup> Multiplex Oligos for Illumina<sup>®</sup>. The quality of the cDNA libraries was measured using an Agilent 2100 Bioanalyzer. Samples were pooled after indexing and sequenced on an Illumina HiSeq 4000 with 150bp, paired-end sequencing parameters at the UC Davis Genome Centre. Following sequencing, raw reads were demultiplexed by the UC Davis Genome Center.

### *Processing of reads and transcriptome assembly*

The quality of the raw reads was assessed using FastQC v0.11.5 and subsequently trimmed using Trimmomatic v0.36 software to remove both primer and adaptor sequences, low quality reads at the leading and trailing ends (Phred score <15), and reads that are <50 bp in length (Andrews, 2010; Bolger et al., 2014). Reads were also trimmed using the sliding window

function set at a window of 4 and a minimum Phred score of 10. Post-trimming quality was assessed again using FastQC to verify that all non-biological sequences were removed and remaining sequences were of high quality. These trimmed reads were *de novo* assembled using the Trinity v2.4.0 software (Grabherr et al., 2011). In short, Trinity is comprised of three modules that together generate a transcriptome. The Inchworm module assembles the trimmed reads into contiguous sequences (contigs) based on overlapping k-mers. The Chrysalis module then clusters similar contigs together and creates de Bruijn graphs for each cluster. Finally, the Butterfly module reconstructs transcript isoforms from each cluster de Bruijn graph. Reconstructed transcripts were filtered based on a minimum threshold of 1 transcript per million reads (TPM) in any sample. Following assembly and filtering of the transcriptome, numerous scripts within the Trinity package were run to analyze assembly statistics such as sample correlation, calculation of N50 and Ex90N50 value, and principal component analysis. BUSCO (Benchmarking Universal Single-Copy Orthologs) scores were calculated using online software gVolante v1.0.1 to estimate the completeness of the transcriptome (<https://gvolante.riken.jp/>; Nishimura et al., 2017). The Trinity script *align\_and\_estimate\_abundance.pl* wrapped Bowtie2 v2.3.2 for alignment of samples to the *de novo* transcriptome and RSEM v1.3.0 (RNA-seq by Expectation-Maximization) for alignment-based estimation of transcript abundances (Langmead and Salzberg, 2012; Li and Dewey, 2011). This script produced matrices of both transcript and gene counts, in addition to CPM normalized expression values, in each of the 15 samples. Gene level expression is the sum of all transcript isoform expression values.

#### *Annotation, differential expression analysis, GO enrichment, and KEGG pathways*

TransDecoder v5.0.0 was used to predict likely open reading frames (ORFs) in each transcript (Haas et al., 2013). Both nucleotide and predicted protein sequences were used with the Trinotate v3.0 pipeline (<http://trinotate.github.io/>). Briefly, this pipeline wraps multiple querying programs and databases together (including Blast+, SwissProt, HMMER/PFAM, and GO annotations) to extract homologous annotations from other species. Differential expression analysis was performed using the Trinity script *run\_DE\_analysis.pl* which wrapped edgeR, an analysis package within R (Robinson et al., 2009). Transcripts that showed significant differential expression (cutoff of  $P_{adj} < 0.05$  and  $\log_2FC > 1$ ) were extracted using the Trinity script *analyze\_diff\_expr.pl* (McCarthy et al., 2012). Similar analysis was also performed to find

changes in expression at the gene level. Heatmaps were produced in R Studio v1.0.143 using the “gplots” package. The Trinity script *run\_GOseq.pl* wrapped the R package GOseq to determine enriched GO terms (biological processes, molecular function, and cellular component) in the differentially expressed transcripts (Young et al., 2010). REVIGO online software was used to collapse semi-redundant biological process terms, cluster these terms and plot them (<http://revigo.irb.hr/>; Supek et al., 2011). Custom labels were added to these GO plots to summarize the general functional role of the major clusters. Functional annotations from differentially expressed transcripts were converted into *H. sapiens* homologs to identify and visualize enriched KEGG pathways using online software DAVID v6.8 (<https://david.ncifcrf.gov/>; (Huang et al., 2009a; Huang et al., 2009b).

### *Statistical analysis*

Significant differences in plasma osmolality and osmolyte concentrations were tested using a one-way ANOVA followed by a Tukey’s post hoc test which compared the data from each group to every other group. This was done with a p-value threshold of 0.05. Analysis of the gill morphology was performed using an unpaired T-test, with a similar P-value threshold of 0.05. Differential expression within RNA-seq was performed by the edgeR program and corrected for using the Benjamini-Hochberg correction.

## **Results**

### *Phylogeny of marginally euryhaline selachimorphs*

The literature of selachimorphs was reviewed to investigate both the prevalence and limits of salinity tolerance in elasmobranchs. The occurrence of marginal euryhalinity is much more common than what has previously been suggested by Ballantyne and Fraser (2012). The bullshark, *Carcharhinus leucas*, remains the only completely euryhaline selachimorph. There are six orders of marginally euryhaline selachimorphs, including Sphyrnidae, Triakidae, Heterodontidae, Squalidae, and Hemiscyllidae, and Scylorhinidae. The Triakidae order contains the greatest number of marginally euryhaline animals, possessing four species that can tolerate salinity from 10 ppt up to 26 ppt. Of this group, *Triakis scyllium* exhibits the greatest salinity tolerance, capable of surviving as low as 10 ppt water (Yamaguchi et al., 2009).

This dendrogram (Fig. 1) highlights the diverse clades that exhibit marginal salinity tolerance, however, it doesn't distinguish whether there is a relationship between the phylogeny of these species and differences in salinity tolerance. This is essential for understanding whether salinity tolerance is an ancestral trait shared by all members within an order or whether it has evolved multiple times both within orders and between orders. Therefore, using the phylogeny created by Naylor et al. (2015) the pairwise phylogenetic distance between each known euryhaline (marginal and full) species was measured and plotted against the pairwise difference in lowest salinity experienced in either a lab or natural setting (Fig 2). There was no observable correlation between these two parameters, suggesting salinity tolerance is not dependent on phylogenetic relationships and has likely evolved multiple times independently.

#### *Plasma osmolytes and total osmolality*

Dogfish transferred from 100% SW to 65% SW exhibited a time-dependent, significant decrease in total plasma osmolality from  $843.8 \pm 1.6$  mOsm/kg to  $662.2 \pm 15.3$  mOsm/kg over 48hrs ( $P < 0.05$ ,  $n=5$ ) (Fig. 3a). This decrease was non-linear and approached an asymptote at 650 mOsm/kg, roughly equivalent with the environment. No significant alterations were seen in plasma  $\text{Na}^+$  as concentrations in control animals was  $325.7 \pm 8.8$  mmol  $\text{L}^{-1}$  and decreased minimally to  $308.1 \pm 12.7$  mmol  $\text{L}^{-1}$  following 48hrs of exposure (Fig. 3b). However, plasma  $\text{Na}^+$  reached the lowest levels at  $298.3 \pm 6.5$  mmol  $\text{L}^{-1}$  after 24hrs (Fig. 3b). Similarly, resting plasma  $\text{Cl}^-$  was  $248.6 \pm 5.9$  mmol  $\text{L}^{-1}$  and decreased to  $221.4 \pm 6.0$  mmol  $\text{L}^{-1}$ , with a significant decrease after 24hrs (Fig. 3b). Urea levels demonstrated larger changes than both  $\text{Na}^+$  and  $\text{Cl}^-$  however no significant changes were detected (Fig. 3b). Control plasma concentration was  $358.0 \pm 73.6$  mmol  $\text{L}^{-1}$ , which decreased after 6hrs to  $184.3 \pm 73$  mmol  $\text{L}^{-1}$ . Interestingly after 24hrs, urea had risen to  $254.6 \pm 31.3$  mmol  $\text{L}^{-1}$  before levels decreased again to the lowest concentration measured of  $118.1 \pm 42$  mmol  $\text{L}^{-1}$ . The osmolyte concentration data was reformatted to provide a measure of the change from control which highlighted the large change in urea and the tight link between  $\text{Na}^+$  and  $\text{Cl}^-$  (Fig. 3c).

### *Gill morphology*

Changes in gross gill morphology were quantified in control animals and animals after 24hrs in 65% SW. Lamellar widths of control and experimental animals was measured, however no significant differences were detected (Fig. 4c). Conversely, there was a ~2-fold significant increase in ILCM of exposed fish (Fig. 4d). There were notable changes to the lamellar structures after 24hrs in 65% SW, including both epithelia lifting and lamellar clubbing (Fig. 4a & b). Furthermore, there appears to be the development of pyknosis (nucleus and chromatin collapse), a process associated with apoptosis and necrosis.

### *RNA-seq analysis*

#### *Assembly statistics and annotation*

The total number of fragments for each sample ranged between ~2 million up to 18 million (Supp. Fig. 1). These were used in the *de novo* assembly, which after filtering of low expression transcripts, 479,976 transcripts were retained, contained within 361,284 genes (Table 1). This number of transcripts and genes assembled is likely an overestimation of the true numbers, possibly caused by the process of *de novo* assembly. Most of the transcripts and genes identified were expressed at very low levels and if these low-expression contigs (<10 TPM) are excluded from calculations, then 15,082 transcripts were assembled (Supp. Fig. 2). The quality of the assembled transcriptome was assessed in a variety of ways. The assembly had a N50 value of 361bp and a Ex90N50 value of 1855. The average contig length was 407 bp, however there were 79 transcripts that were longer than 10,000 bp and 30,843 transcripts longer than 1,000 bp. BUSCO score analysis showed that of the 2,586 BUSCO groups searched, 1,935 (74.8%) were found as complete sequences within the transcriptome (Table 2). Of these 1,935 groups, 1,202 (46.5%) were found as complete and single-copy while 733 (28.3%) were found as complete and duplicated. The total mapping coverage of aligned reads to the *de novo* transcriptome also served as an indication of assembly quality (a higher alignment suggests a better assembly). Approximately 27% of paired reads did not align concordantly (of which 18% aligned discordantly, and the remaining 9% never aligned), 16% aligned concordantly once, while 56% aligned more than once, with an overall alignment rate of 92.75% (Supp. Table 4).

Correlation between sample expression profiles using were also computed and suggested minimal correlation (Fig 5a). Furthermore, PCA showed that global expression patterns did not separate into distinct clusters based on sampling times (Fig. 5b).

### *Differential expression and annotation*

Analysis using edgeR revealed 1013 transcripts that underwent significant differential expression ( $P_{\text{adj}} < 0.05$  and  $\log_2\text{FC} > 1$ ). Only 179 genes were differentially expressed under matching parameters. A heatmap including each biological replicate shows within treatment variation is quite high (Fig 6). Therefore, the expression of biological replicates was averaged and centered on control values (Fig 7). This produced more distinct clusters of upregulated and downregulated transcripts. The heatmap highlights a general trend over time; most transcripts that were upregulated in the short term, stayed upregulated to later time points, and similarly, those downregulated in the early response remain downregulated. Of the 1013 transcripts, there were 240 that showed a reversal in the direction of change; undergoing upregulation at 12 hrs to downregulation at 48hrs, or *vice-versa*. Furthermore, 63 transcripts show expression values equal to control levels at 12hrs or 48hrs. At the gene level, similar trends exist in the expression pattern over time (Fig 6). Pearson correlation analysis and principal component analysis on the differentially expressed transcripts show similar patterns of expression and low variance within treatments (Fig 7). Only ~15% of all transcripts were annotated using Trinotate, however, ~60% of the differentially expressed transcripts were annotated. At the gene level, 45 out of 179 differentially expressed genes were annotated. A full listing of differentially expressed transcripts and genes can be found in Supplementary Material, but below I will review results with respect to specific physiological functions.

### *Transcripts involved in trans- and paracellular transport*

The significant role of the kidneys in osmoregulation suggests an osmotic stress would induce changes in the expression of a variety of transporters and tight junctions (NKA, urea transporter, members of the SLC family, aquaporins, claudins, etc) to regulate transcellular and paracellular ion/molecular flux. Transcripts and genes encoding proteins in the NKA complex showed no significant changes in expression over the exposure. Only a single NHE, SLC9A9, was upregulated after 12hrs, but returned to control levels after 48hrs. Other members of the

SLC family such as SLC6A18 (neutral amino acid transporter) SLC6A5 (glycine transporter), SLC22A2 (polyspecific organic cation transporter) were all upregulated after 12 hrs. Multiple transcripts encoding SLC25A10 (mitochondrial dicarboxylate carrier, DIC) was significantly upregulated and exhibited one of the high fold changes in the annotated transcripts. Interestingly only a single contig was annotated as CFTR, and showed no change in expression levels. NKCC transcripts were identified however expression remained constant throughout the exposure. Calcium ATPase Type 2C was also downregulated after 48hrs. Numerous aquaporins were detected in the transcriptome however none showed significant changes in expression. The urea transporter, UT-A1, was not detected, however, UT-A2 (mammalian UT-A2 is 66% amino acid homologous to shUT) was detected at low levels and showed no change in expression levels. No changes were present in transcript expression of the ammonia transporters Rhag, Rhbg, or Rhcg, although they were detected. A number of transporter transcripts were among the most highly altered following 65% SW exposure such as mitochondrial dicarboxylate transporter, thiamine transporter 2, cationic amino acid transporter 3, and mitochondrial calcium uptake 1 (Table 3, Table 4, Table 5).

Paracellular leakage is another route of possible osmolyte loss. Two transcript isoforms of claudin 10 were differentially expressed. Both showed a significant reduction, however one was reduced at 12hrs and one at 48hrs compared to control. No changes were seen in the expression of occludin transcripts. Tight junction protein 1 (ZO1) was significantly upregulated from 12hrs to 48hrs. No changes were seen in any transcripts encoding tight junction associated proteins (e.g. TJAPs, and CGNLs). Transcripts of the cell adhesion protein cadherin 1 (CADH1) and the desmosome adhesion protein desmocollin 3 (DSC3) were both downregulated after 48hrs. In conclusion, most transcripts related to tight junctions and paracellular leakage were either downregulated or unchanged.

#### *Protein chaperones, degradation and transport*

The highly conserved family of heat shock proteins (HSPs) act as molecular chaperones in a similar method to the chemical chaperones (i.e. TMAO) to reduce stress associated protein misfolding and promote correct protein maturation (Georgopoulos and Welch, 1993). This family has been implicated in the response of elasmobranchs to osmotic challenges (MacLellan et al., 2015; Morash et al., 2016). Transcripts within this family that were differentially

expressed were all upregulated following the salinity challenge, including HSP70, HSP71A, HSP71L, and HSP30.

Damaged proteins that cannot be rescued through the action of chaperones or proteins that are no longer needed must be degraded. This can occur through the ubiquitin-proteasome pathway or transport into lysosomes for hydrolysis. Transcripts within the ubiquitination-proteasome pathway were detected, however, only transcripts encoding E2 enzymes (UB2J1, UBE2T, UBE2C, UBC12) and E3 enzymes (UHRF1, RBBP6) were differentially expressed (both up and downregulated). A single subunit of the 20S proteasome (PSA7) was significantly downregulated, however, this may be of little consequence as there are a total of 28 subunits within this complex (Tanaka, 2009). Numerous lysosomal peptidases (including cathepsins, carboxypeptidases, dipeptidyl peptidase) were detected however none were differentially expressed following exposure.

An essential function within cells is the distribution of newly synthesized proteins in addition to the removal and recycling of mature proteins from the plasma membrane or organelles. An abundance of transcripts (e.g. RAB7, SNX4, SNX14, SNX6, VPS36) involved in protein transport were differentially expressed following exposure to 65% SW. The majority of these were downregulated, particularly those related to early-to-late endosome transport and endosome to lysosome.

#### *Metabolism and signal transduction*

Several transcripts of interest involved in metabolic processes were differentially expressed. Interestingly, sarcosine dehydrogenase (SARDH) was downregulated after both 12 and 48hrs, suggesting an accumulation of sarcosine. Transcripts for formimidoyltransferase-cyclodeaminase (FTCD), an enzyme involved in amino acid degradation, were also downregulated after both 12 and 48hrs. Inversely, another amino acid catabolizing enzyme, homogentistate 1,2-dioxygenase (HGD), was upregulated after both 12 and 48hrs. Multiple transcripts involved in oxidative phosphorylation (NADH dehydrogenase, cytochrome C oxidase, V-type ATPase, ubiquinol-cytochrome C reductase complex) were differentially expressed but showed no distinct pattern of co-expression.

Signal transduction is an essential component in eliciting a response to a stimulus, including salinity stress (Fiol and Kültz, 2007). Within the dogfish kidney, numerous MAP

kinases were identified, however only MAP2K5 and MAP3K15 were differentially expressed; the former was consistently upregulated and the latter was consistently downregulated. Nitric oxide synthase 2 (NOS2) produces NO, a potent signalling molecule, was upregulated after 12hrs. Transcripts encoding various targets in fish signalling cascades (including 14-3-3 proteins, c-Jun N-terminal kinases, osmotic response elements, TSC22D2, and TRPV4) were detected yet none showed significant changes in expression (Fiol et al., 2007; Kültz et al., 2001; Liedtke et al., 2000; Lopez-Bojorquez et al., 2007; Marshall, 2005; Wang and Kültz, 2017). Osmotic stress transcription factor 1 however was not detected.

### *Immune related function*

Salinity induced stress response is common in fish and many of the proteins involved in this response have immunological functions (Cuesta et al., 2005; Gu et al., 2018). Cytokines play an important role in propagating immune response. Multiple transcripts encoding the cytokine C-C motif chemokine ligand 20 (CCL20) were upregulated after 12 hrs. Importantly, interleukin 10 (IL10), an inhibitor of cytokine production, was downregulated after both 12 and 48hrs (de Waal Malefyt et al., 1991). Another major mediator in regulating cytokine production and stress responses is NF- $\kappa$ b complex. The coiled-coil domain containing protein 22 (CCD22) is an activator of the NF- $\kappa$ b complex and was downregulated after both 12hrs and 48hrs (Starokadomskyy et al., 2013). NF- $\kappa$ b was detected however no significant changes occurred. Expression of select cytokine receptors were also changed. Tumor necrosis factor receptor member 6b (TNF6B) was upregulated while inversely interleukin 17 receptor A (IL17RA) was significantly downregulated. A regulator in the signal transduction from the death receptors on the cell surface, Fas associated death domain (FADD), was down regulated after 48hrs (Kim, 2002). Transcripts for Bcl2 associated athanogene 4 (BAG4), a protein involved in suppressing activity of death receptors via interactions with HSPs, were upregulated after both 12hrs and 48hrs (Briknarová et al., 2002). In contrast to the general pattern of downregulation in cytokines and receptor transcripts, caspase 6 (CASP6), a promotor of apoptosis, was upregulated after both 12 and 48hrs (Riedl and Shi, 2004). Another pro-apoptotic protein, tumour protein P53 (P53) was upregulated after 12hrs and downregulated after 48hrs (Fridman and Lowe, 2003).

Importantly, prostaglandin-endoperoxide synthase 2 was upregulated after both 12 and 48hrs, which would correspond to an increase in prostaglandin H<sub>2</sub> from arachidonic acid. Prostaglandin H<sub>2</sub> is a precursor for a suite of hormonally active compounds, some of which have immunological functions (Ricciotti and FitzGerald, 2011). Arachidonic acids can also be converted into immunologically active leukotrienes via 5-lipoxygenase (LOX5), which catalyzes both the conversion of arachidonic acid into hydroperoxyeicosatetraenoic acid (HPETE) and HPETE into leukotriene A<sub>4</sub>, a pro-inflammatory mediator (Samuelsson, 1983). Transcripts for LOX5 were downregulated after 12hrs and upregulated after 48hrs.

### *Gene level expression*

The sum of transcript expression values within the Trinity gene was also used to quantify changes in expression (Supp. Table 2). The Trinotate annotation pipeline does not provide annotations at the gene level and therefore annotations for this level were based on the consensus of transcript level annotations. The changes that were observed at the gene level show similarity to the transcript level. Of note, HSP71A and HSP30C were both consistently upregulated at the gene level. Multiple immunological genes were also altered included interferon induced protein 44-like (IF44L), immune-response gene 1 (IRG1), NLR family pyrin domain containing 3 (NALP3), and C-C motif chemokine ligand 20 (CCL20).

### *GO enrichment and KEGG pathways*

The Goseq package was used to quantify the enrichment of GO terms (biological processes, molecular functions, and cellular components) in the differentially expressed transcripts in each time point comparison, while REVIGO software was used reduce redundancy, cluster, and visualize these GO terms. One possible way to examine and interpret the Goseq results is to rank the enriched GO terms based on terms that contain the most differentially expressed transcripts (Table 6). The top terms enriched in 0hrs vs 12hrs were “extracellular region part”, “regulation of biological quality”, and “cellular response to stimulus”. The three most common terms in 0hrs vs 48hrs were “positive regulation of biological process”, “integral component of the membrane”, and “intrinsic component of the membrane”. Interestingly, the most common enriched terms from 12hrs to 48hrs were “localization”, “establishment of localization”, and “transport”. Most of these terms are extremely broad and therefore by default

will likely be more common. Additionally, in some cases they may be too broad to provide useful conclusions. Therefore, ranking the enriched terms based on P-value is another possible method to draw conclusions (Table 7). Compared to control, 12hrs in low salinity cause chaperone related GO terms to be most enriched based on P-value. Again, compared to control, 48hrs elicited “ribosome assembly” and “hormone activity”. Interestingly, from 12hr to 48hrs GO terms related to bacterial infections such as “cellular response to molecule of bacterial origin” and “cellular response to lipopolysaccharide” were strongly enriched.

REVIGO software was used to reduce redundancy and visualize clustered GO terms based on similarity of terms. A multitude of generalized functional groups were identified and of these, a select few were consistently enriched in each comparison (Fig. 10a, b, c). These consistent functional groups were “regulatory processes”, “signalling pathways”, and “response to stimulus or stress”. The cluster “cell differentiation and maturation” was only present comparing 0hrs with 48hrs. Other semi common clusters were “ion, molecular, and protein transport”, “protein and molecular complexes”, and “metabolic processes”.

There were no significantly enriched KEGG pathways, however, multiple pathways contained numerous transcripts that were differentially expressed. These include RNA transport, endocytosis, spliceosome, glycerophospholipid metabolism, general metabolism (Fig. 11-15). Of note, numerous transcripts within the endocytosis pathway functioning in the early-to-late endosome phase were differentially expressed (Fig. 11). Transcripts within the general metabolic pathways were sporadic and not limited to a single metabolic process (Fig. 14). Within the glycerophospholipid metabolism KEGG pathway, transcripts related to production of phosphatidylethanolamine and phosphoethanolamine (e.g. PISD, EPT1, PTSS2, EKI1) were variable in response, however, expression patterns indicate a reduction in phosphatidylethanolamines.

**Table 1.** Descriptive statistics of the filtered de novo kidney transcriptome produced by the Trinity pipeline

Statistics were calculated using online software gVolante online software and Trinity scripts (TrinityStats.pl and contig\_ExN50\_statistic.pl). Filtering of transcripts was performed using Trinity script filter\_low\_expr\_transcripts.pl with a minimum expression level of 1 TPM.

<b>Descriptive statistic</b>	<b>Value</b>
Total transcripts	479,976
Total genes	361,284
Total nucleotide	195,303,735
Longest sequence (nt)	26092
Shortest sequence (nt)	201
Average contig length	407
Median length	238
# of transcripts > 1k	30,843
# of transcripts > 10k	79
N50 value (nt)	361
Ex90N50 value (nt)	1,855
GC content (%)	45.39

**Table 2.** BUSCO scores of the *de novo* kidney transcriptome.

BUSCO scores were calculated using online software gVolante with the Vertebrata reference gene set. A higher percent of complete BUSCO's suggests a more complete transcriptome.

<b>Category</b>	<b>Percent</b>
Complete BUSCOs	74.8%
Complete and single copy	46.5%
Complete and duplicated copy	28.3%
Partial BUSCOs	8.2%
Missing BUSCO	17.0%

**Table 3.** Differentially expressed transcripts with the greatest fold change from control to 12 hrs in 65% SW.

Trinotate software was used to annotate the *de novo* assembly of the kidney transcriptome and edgeR was used to calculate differentially expressed transcripts. Fold change expression values are compared to control samples. P-values were adjusted for multiple comparisons using Benajmini-Hochberg correction.

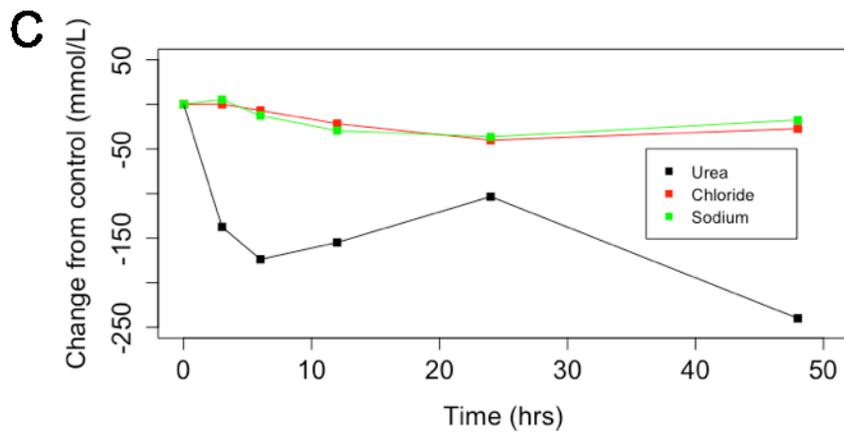

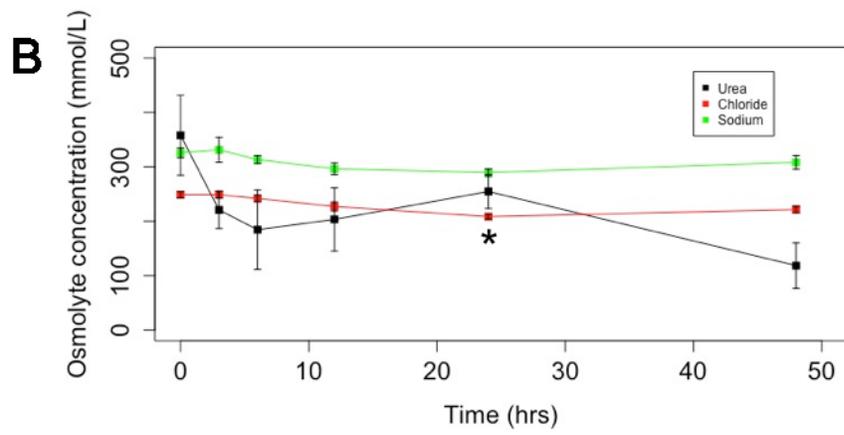

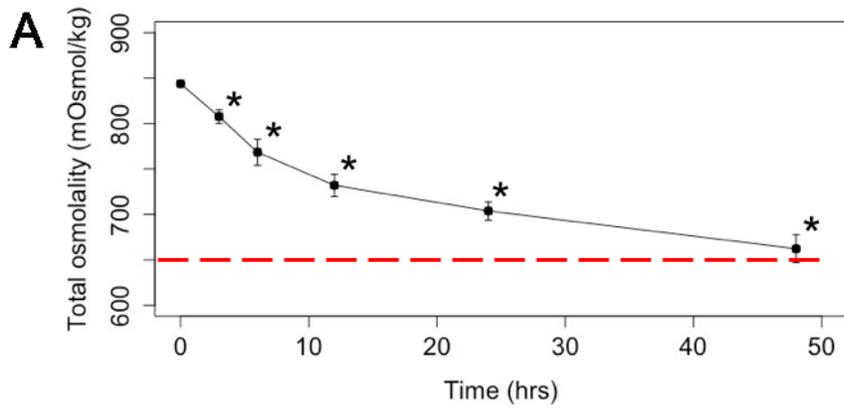

**Figure 2.** Correlational analysis of pairwise phylogenetic distance and pairwise difference in salinity tolerance.

The pairwise phylogenetic distance between each species in Figure 1 was quantified using the phylogeny in Naylor et al. (2012) plotted against to the pairwise difference in the lowest salinity (environmental or salinity) from Figure 1. Each dot represents a different species comparison. The red line indicates the linear regression.  $R^2 = 0.003$ .

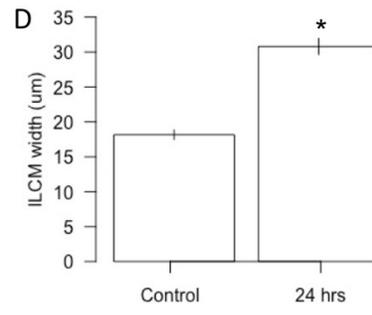

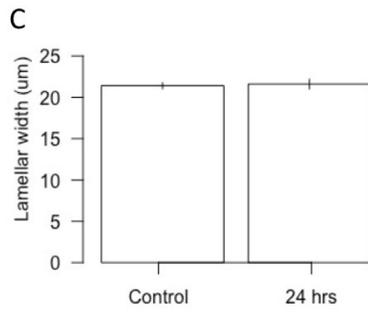

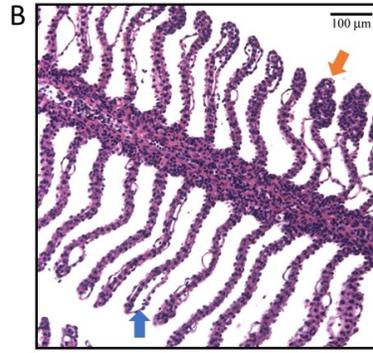

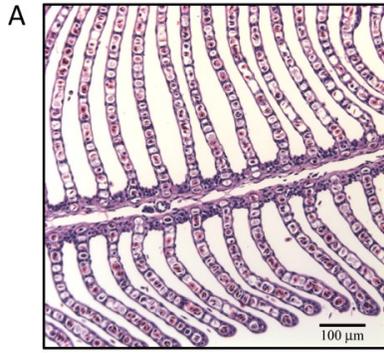

**Figure 3.** Plasma osmolality and osmolytes over 48hrs in 65% SW.

Time course (hrs) of the total osmolality ( $\text{mOsm kg}^{-1}$ )(A), osmolyte concentration ( $\text{mmol L}^{-1}$ )(B), and osmolyte change from control ( $\text{mmol L}^{-1}$ )(C) of the plasma in Pacific spiny dogfish following exposure to 65% SW ( $n \geq 3$ ). Values are presented as means  $\pm$  SEM. Significant differences from control (0hrs) are represented by \* ( $P < 0.05$ ) based on a ANOVA and Tukey's post-hoc test. The red dashed line (A) indicates the environmental salinity.

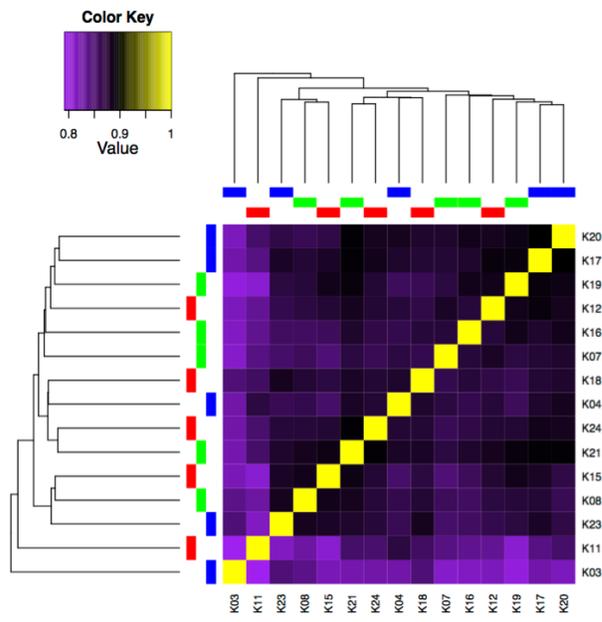

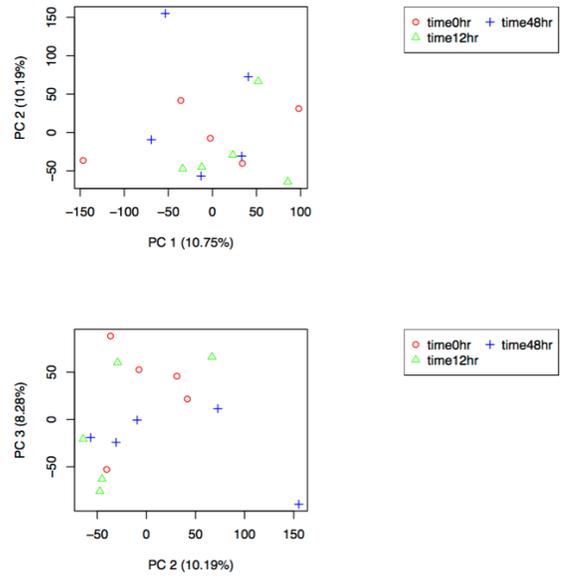

**Figure 4.** Alterations in gill morphology following 24hrs in 65% SW.

Representative light microscopy images with H&E staining of gills from Pacific spiny dogfish in control (A) and 24hrs in 65% SW (B). Morphological measurements of the gills were taken to quantify lamellar width (C) and interlamellar cell mass (D) (n=3). Values are presented as means±SEM. The orange arrow indicates an example of lamellar clubbing, while the blue arrow indicates epithelial lifting. Significant differences from control (0 hr) are represented by \* (P<0.05) and were calculated by unpaired Students t-test.

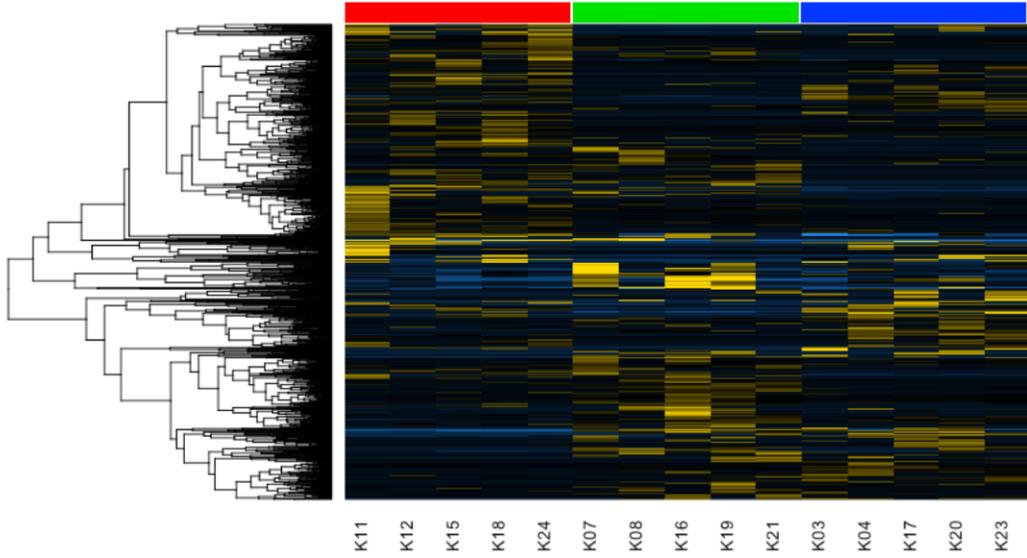

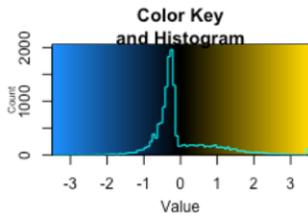

**Figure 5.** Correlation and variance within whole kidney transcriptome

A Pearson correlation analysis (A) was performed comparing the transcript expression ( $\log_2$  CPM) across all samples where purple indicates lower levels of correlation and yellow indicates high levels. The dendrogram in the margin depicts clustering based on similarity in expression. Time points are indicated by the colours in the margin; control (0hrs) = red, 12hrs = green, and 48hrs = blue. Rows and columns are both biological replicates. A principal component analysis (B) was computed from the  $\log_2$  CPM expression values of transcripts. Shown are PC1 vs PC2 (upper) and PC2 vs PC3 (lower).

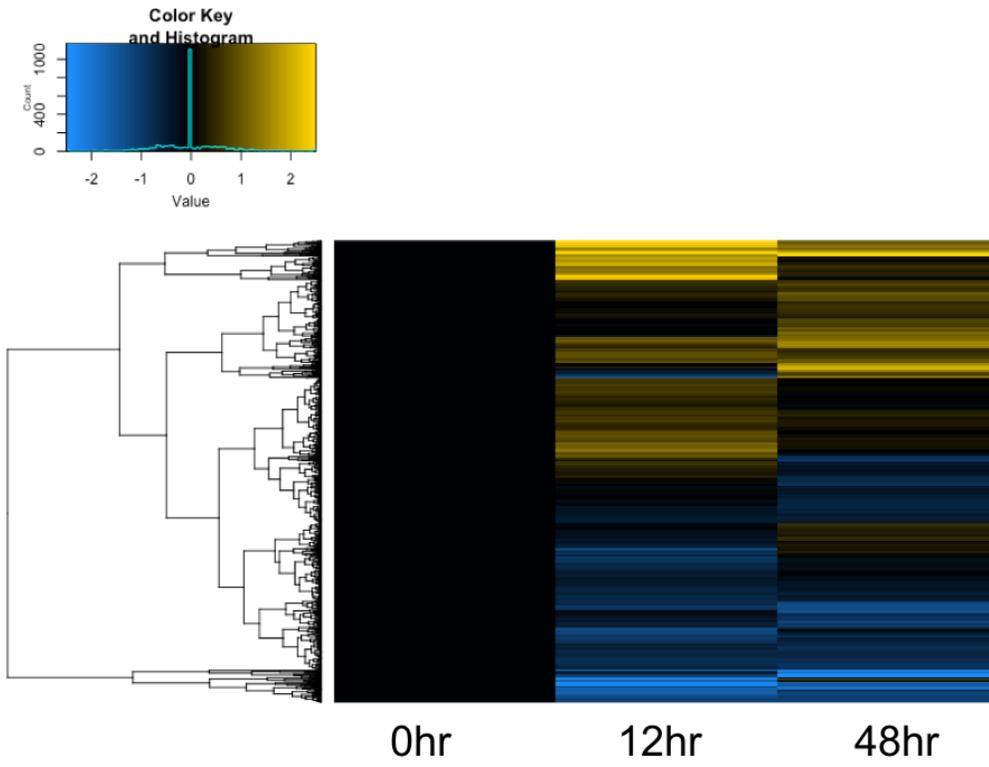

**A****B**

**Figure 6.** Differentially expressed transcripts from all biological replicates.

Heatmap of 1013 differentially expressed transcripts (cutoff  $P_{adj} < 0.05$  and  $\text{Log}_2\text{FC} > 1$ ) from kidney tissue in control (0hrs), 12hrs in 65% SW, and 48hrs in 65% SW. Each row indicates a differentially expressed transcripts and each column is an individual animal. Legend indicates the  $\log_2$ , median-centered expression (TMM-normalized TPM) values where yellow indicates upregulation and blue indicates downregulation. Columns under the red bar indicate control (0hrs) samples, while columns under the green bar and blue bar are after 12hrs and 48hrs in 65% SW, respectively.

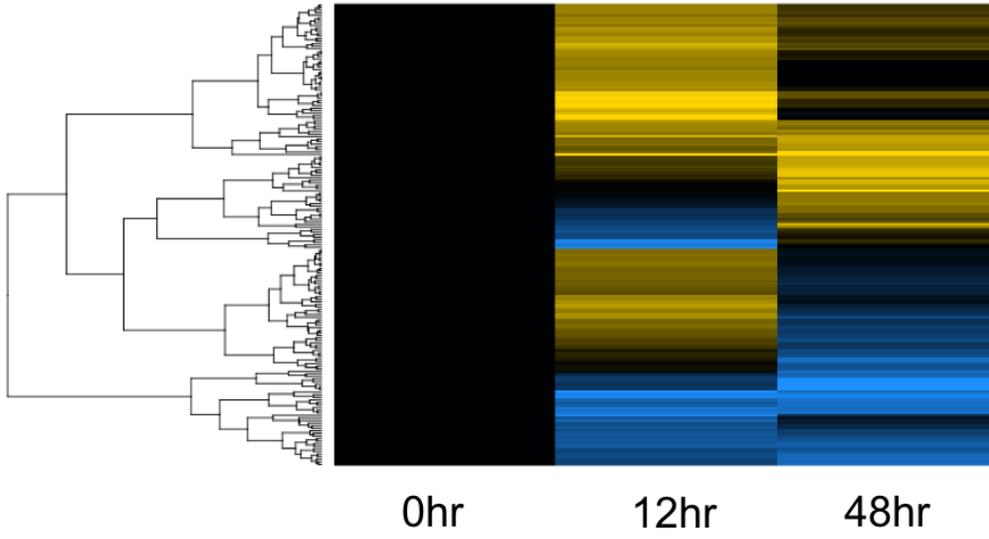

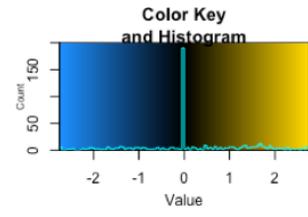

**Figure 7.** Differentially expressed transcripts of averaged values across time points. Heatmap of 1013 differentially expressed transcripts (cutoff  $P_{adj} < 0.05$  and  $\text{Log}_2\text{FC} > 1$ ) in control, 12hrs, and 48hrs in 65% SW. Each rows indicates a differentially expressed transcript and each columns is a different time point. The legend indicates the average  $\log_2$  expression (TMM-normalized TPM) centered on control expression levels (n=5). Colour corresponds to expression levels; blue indicates lower than control while yellow indicates higher than control. The dendrogram in the margin represents the clustering of different transcripts based on similarity in expression patterns.

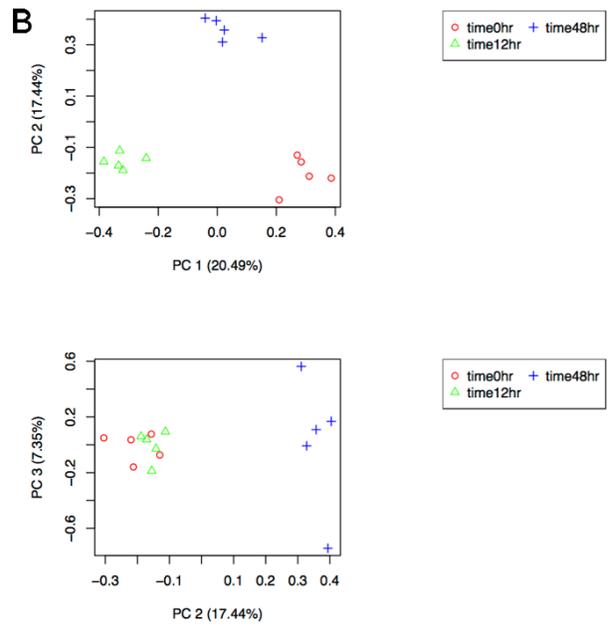

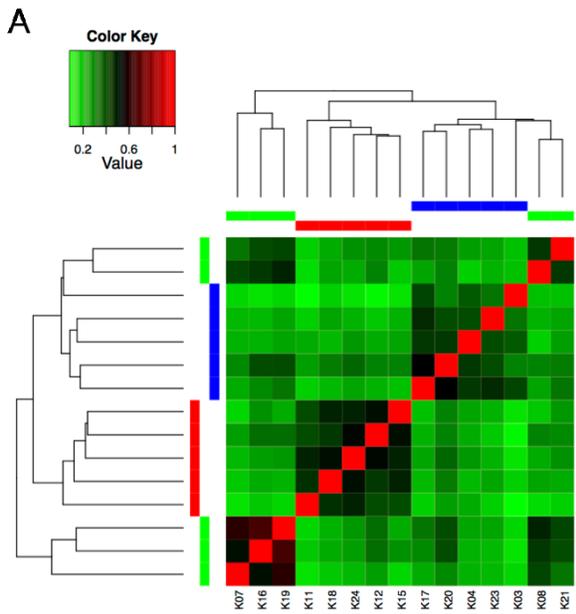

**Figure 8.** Differentially expressed genes following exposure to 65% SW

Heatmap of 179 differentially expressed genes in kidney tissue from animals exposed to 65%SW for 0hr (control), 12hrs, and 48hrs. Each rows indicates a differentially expressed gene and each columns is a different time point. The legend indicates the average  $\log_2$  expression value (TMM-normalized TPM) centered on control expression levels (n=5). Colour corresponds to expression levels; blue indicates lower than control while yellow indicates higher than control. The dendrogram in the margin represents the clustering of different transcripts based on similarity in expression patterns.

**Figure 9.** Correlation and variance within the differentially expressed transcripts

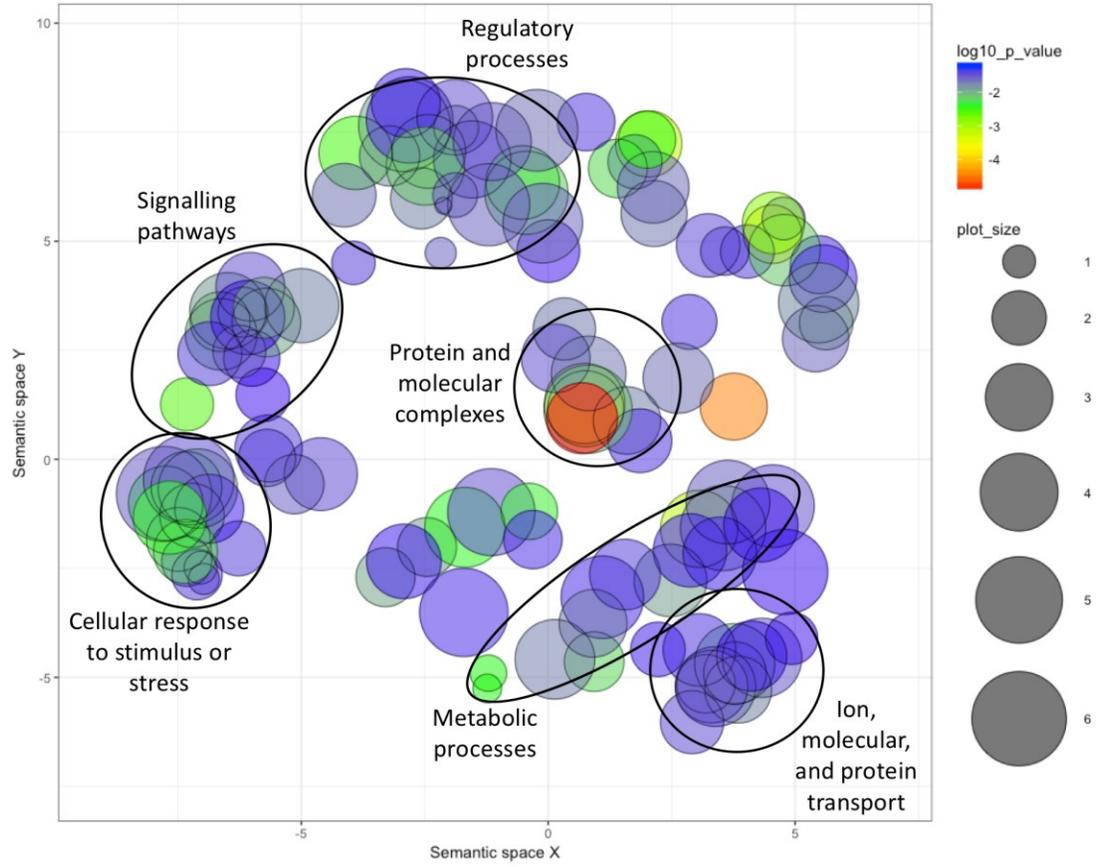

A Pearson correlation analysis (A) was performed comparing the expression of the salinity responsive transcripts ( $\log_2$  CPM) across samples where green indicates lower levels of correlation and red indicates high levels. The dendrogram in the margin depicts clustering based on similarity in expression. Time points are indicated by the colours in the margin; control (0hrs) = red, 12hrs = green, and 48hrs = blue. Rows and columns are both biological replicates. A principal component analysis (B) was computed from the  $\log_2$  CPM expression values of differentially expressed transcripts. Shown are PC1 vs PC2 (upper) and PC2 vs PC3 (lower).

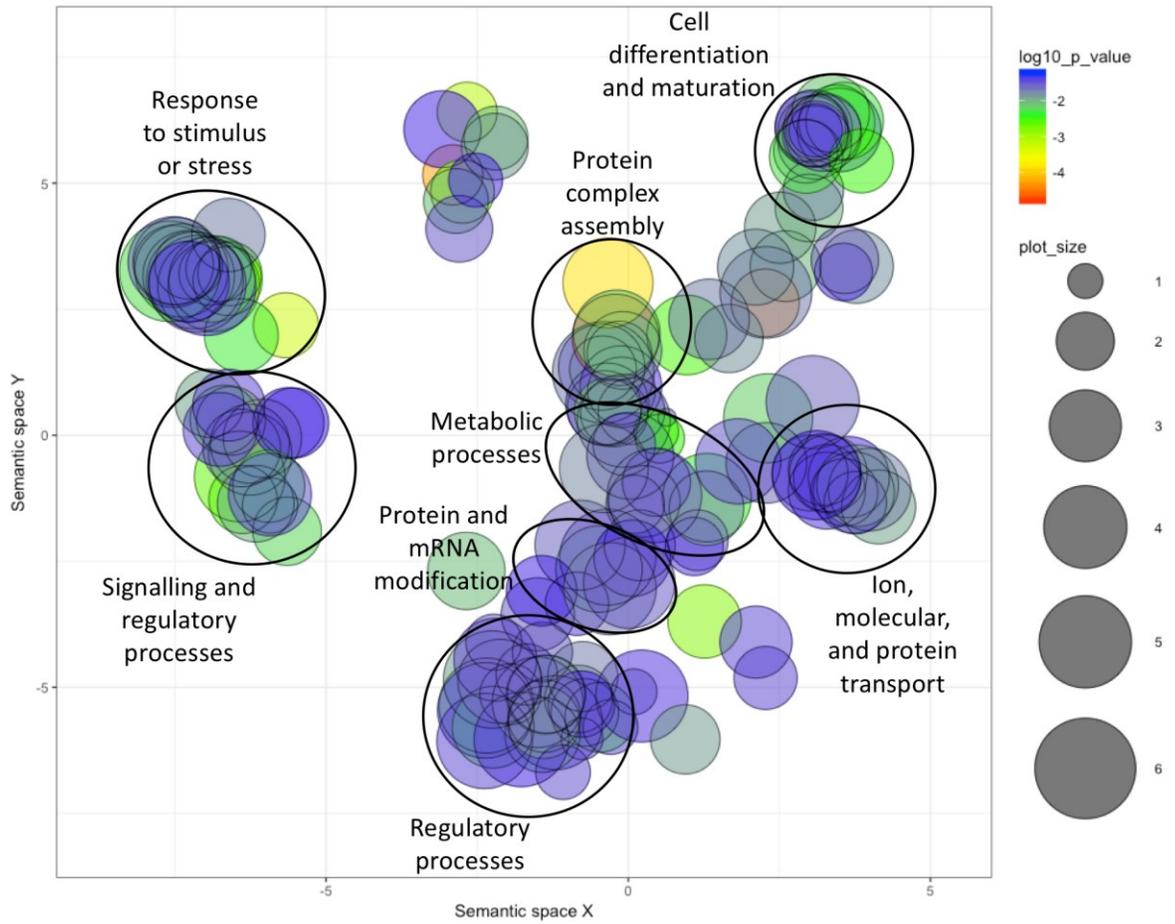

**Figure 10.** REVIGO analysis and clustering of significantly enriched GO terms

REVIGO software reduced redundancy in GO terms by collapsing similar terms, in addition to clustering and visualizing these collapsed terms in each statistical comparison, (A) 0hrs vs 12hrs, (B) 0hrs vs 48hrs, and (C) 12hrs vs 48hrs. Customized labels were added post REVIGO analysis. Individual bubbles indicate collapsed GO terms associated with the differentially expressed transcripts. Bubble colour indicates the P-value of enrichment. Bubble size indicates the frequency of the GO term in the reference data base (broader terms are larger). Each rows indicates a differentially expressed transcript and each columns is a different time point. The legend indicates the average  $\log_2$  expression (TMM-normalized TPM) centered on control expression levels (n=5). Colour corresponds to expression levels; blue indicates lower than control while yellow indicates higher than control. The dendrogram in the margin represents the clustering of different transcripts based on similarity in expression patterns.

## Discussion

The work presented within this thesis is the first example of using RNA-seq technology to quantify the differential expression of transcripts following an experimental exposure in elasmobranchs. The use of differential expression analysis, as opposed to catalogue-based studies (which have been previously performed), significantly improves the conclusions that can be drawn regarding responses to salinity stress. Furthermore, data presented here offers numerous possible directions for future studies to use biochemical and physiological techniques to test the results shown and expand further. The gill morphology presented in this thesis is similarly novel. Prior work has characterized alterations to protein localization via immunofluorescence and mRNA abundance in the gills following salinity challenge, however, this is the first study to characterize alterations to gross morphology of the gill lamellae (Reilly et al., 2011; Takabe et al., 2016). The gill morphology work in this thesis is in no way fully comprehensive, however, serves as an indication that further work should be devoted to this area.

### *Lack of relationship between phylogeny and extent of salinity tolerance*

Low salinity tolerance in teleosts has evolved independently multiple times (Schultz and McCormick, 2013). It is likely that a similar process has unfolded in the elasmobranchs, although with fewer apparent invasions into BW/FW based on current knowledge. The variety of apparent osmotic strategies used by elasmobranchs during BW/FW invasions can be inferred by the range in plasma urea following salinity challenges (Ballantyne and Robinson, 2010). Only the stenohaline FW potamotrygonid rays from the Amazon basin that have been inhabiting a complete FW environment for millions of years are no longer ureosmotic, while many of the other euryhaline elasmobranchs have a range of urea levels suggesting multiple strategies are likely being used for invasions (Lovejoy et al., 1998). The data presented within this thesis suggests the degree of BW/FW tolerance in the selachimorphs appears to have no relation to the phylogeny; supporting the hypothesis that it has arisen multiple times and that the genetic machinery used for invasions is a phylogenetically ancient trait. However, as research into this relatively understudied group of fishes progresses, the list of marginally euryhaline elasmobranchs continues to grow and thus this subject of a phylogenetic basis for BW/FW invasion should be regularly revisited.

### *Osmolytes and gill morphology perturbations following salinity challenge*

Consistent with other studies using dogfish, animals in the current study experienced a reduction in total osmolality which was primarily through the loss of urea (Deck et al., 2016; Guffey and Goss, 2014). This is part of the larger trend in the marginally euryhaline elasmobranchs which all experience a similar occurrence during hyposmotic exposure. However, a more substantial NaCl loss appears more prevalent in other species experiencing BW stresses (Cooper and Morris, 1998; Cramp et al., 2015; Dowd et al., 2010). Most selachimorphs are considered osmoconformers and therefore as environmental osmolality drops, plasma osmolality follows accordingly. This would function to maintain appropriate osmolyte gradients, minimizing homeostatic disturbances in water balance. However, the changes in plasma osmolytes and total osmolality are clearly not instantaneous and therefore animals were hyperosmotic for the length of exposure causing an inward gradient for water, as reflected by an increase in body weight detailed in Guffey and Goss (2014). The preservation of water balance in the face of this inward flux is suggested to occur via through increased kidney function, specifically via an increase UFR and GFR (Cooper and Morris, 1998; Schmidt-Nielsen et al., 1972). While these changes are insufficient to completely combat the water-loading, the involvement of the kidney in early stage (<48hrs) responses to lowered salinity is apparent.

Alterations to gross gill morphology have been noted previously in teleosts and are commonly associated with the osmo-respiratory compromise (Nilsson, 2007). This compromise is typically seen as hypoxia-induced remodelling of gill morphology to increase surface area for oxygen uptake, while simultaneously conceding ion balance due to increased surface area (Nilsson et al., 2012). This phenomenon has been demonstrated in elasmobranchs using dogfish wherein acute severe hypoxia elicited increased branchial urea and ammonia efflux (Zimmer and Wood, 2014). Changes to environmental salinity have also been shown to induce morphological changes in the gills of teleosts (Blair et al., 2018). In the current study, an increase in ILCM was observed following 24hrs in 65% SW. This likely corresponds to a decrease in total surface area of the gills and thus a smaller area for ion and osmolyte loss, possibly mitigating the effects of the increased gradients during hyposmotic challenge. Constant branchial urea loss, despite increased osmotic gradients, was seen in the euryhaline skate, *Raja erinacea*, remained stable following transfer from 100% SW to 75% SW (Payan et al., 1973). The influence of these changes on O<sub>2</sub> uptake has not been fully elucidated, however, total O<sub>2</sub> consumption was

unchanged in the dogfish (Guffey and Goss, 2014) and the Port Jackson shark (Cooper and Morris, 2004b). Alteration to morphology of the gills is likely only one of the numerous responses available to elasmobranchs. Other possible mechanisms that would work to maintain a constant branchial efflux rate of urea include increasing the cholesterol content of the gill epithelium or increasing the back transport rate of urea. The effects of low salinity exposure on the gross gill morphology of elasmobranchs should be further investigated with a more detailed microscopy study.

#### *Responding to salinity exposure through changes in transcript expression*

Given the key role of the kidney in responding to salinity stress, the main objective of my thesis focused on the transcriptome level responses of this tissue during the first 48hrs of BW exposure. This work revealed extensive modifications in multiple cellular processes. Below I will discuss some of these changes and how they might contribute to low salinity tolerance observed in the dogfish.

#### *Amino acid and regulation*

Following 65% SW exposure, there was upregulation of the neutral amino acid transporter SLC6A18. This protein functions in a sodium-chloride dependent manner and is the main amino acid transporter in the kidney (Singer et al., 2009). Increased reabsorption of amino acids via SLC6A18 may be required to accommodate increased protein synthesis needed for induction of new cellular functions. In opposition of this, multiple translation initiation factors were downregulated during hyposmotic exposure suggesting there were at least some decreases in function of specific protein synthesis pathways. Furthermore, multiple transcripts within the endocytosis KEGG pathway, particularly in the early to late endosome phase, were also downregulated. Correspondingly, numerous GO terms related to protein localization and secretion were enriched in the differentially expressed transcripts. This may be indicative of decreased protein turnover and protein trafficking, and as a result, a possible reduction in protein synthesis. Taken together, the data suggests protein synthesis was not the driving force for increased amino acid retention. An alternative cause for increased amino acid retention is an increased rate of amino acid catabolism (possibly as a nitrogen source) or conversion. However, there were minimal changes in amino acid degradation pathways and therefore this justification

is unlikely. The increased expression of SLC6A18 may also be due to the increased GFR and UFR that is associated with low salinity exposure (Cooper and Morris, 2004a; Schmidt-Nielsen et al., 1972). These higher filtration and flow rates increase the total filtrate passing through the nephron tubule, and thus increasing the rate of amino acid loss. Therefore, to maintain post-exposure amino acid levels similar to that of pre-exposure levels, there would need to be increased expression of transporters to offset the increased rates of loss by passive filtration. Intracellular amino acids contribute to a small, but notable portion of the total osmotic pressure within tissues (Yancey, 2015). Therefore, as urea is being offloaded amino acids may contribute more significantly to the total cellular osmolality. Clearly, further work is needed to characterize the role of amino acids and amino acid transporters in elasmobranch following low salinity exposure.

#### *Urea transporter expression*

Interestingly, no change was seen in the expression of UT-A2 transcripts. The reduction in plasma urea during hyposmotic exposure would suggest a decreased level of renal urea transporters. Following exposure to 50% SW the little skate (*Raja erinacea*) demonstrated a reduction in the skate urea transporter mRNA (Morgan, 2003b), while the Atlantic stingray (*Dasyatis sabina*) did not exhibit substantial changes (Janech et al., 2003). The mRNA levels of urea transporters in the collecting tubules of the banded houndshark (*Triakis scyllium*) showed a non-significant reduction following 30% SW exposure, however, protein levels were significantly diminished (Yamaguchi et al., 2009). Furthermore, this reduction in protein abundance occurred primarily in the apical membrane. This not only suggests that the response is species-specific (supporting the independent evolution of these adaptations), but also highlights the possible discontinuous relationship between mRNA expression and protein abundance (discussed below). The stable expression of UT-A2 observed in this thesis implies that the increased GFR and UFR rates may be sufficient in eliminating urea to remain isosmotic, however, further work at the protein level would be needed to confirm this.

#### *Regulating paracellular loss*

The differential expression of transcripts involved in paracellular transport of osmolyte was expected following hyposmotic exposure. The osmoconforming strategy of elasmobranchs

necessitates that osmolytes are lost to the environment and one possible route is via paracellular loss. Claudins are a major component of tight junctions and contribute greatly in regulating this loss (Krause et al., 2008). Within teleosts there are ~63 different claudin genes which produce functional proteins that act as either pore forming (anion or cation selective) or barrier forming (Kolosov et al., 2013). Unfortunately, no work has been done to examine the molecular identities of claudins in elasmobranchs. The claudin 10 gene displays multiple splice variants that encode for either cation and anion pores (Krause et al., 2008). The current study noted that two claudin 10 transcripts were differentially expressed and displayed opposite transcriptome profiles. One of the transcripts was upregulated following 12hrs and substantially downregulated after 48hrs, while the second was the inverse of this. The trend observed may be the result of splice variants with functional differences, though the identity as either an anion or cation selective pore is unknown for these two transcripts. However, all claudin 10 isoforms are pores and therefore a reduction in these would limit the loss of osmolytes. Previous work has demonstrated teleost claudins are altered by environmental salinity to maintain homeostasis (Bui and Kelly, 2014; Marshall et al., 2018). In the euryhaline Japanese medaka (*Oryzias latipes*), long term FW acclimation was associated with decreased mRNA expression of certain renal claudins compared to SW acclimated fish (Bossus et al., 2015). Importantly, this response was isoform specific; claudin 10b1 (anion pore) and 10b2 (cation pore) were both downregulated in FW, however 10c, 10d, and 10f showed no change. Thus, the variation in claudin 10 isoforms seen in Pacific spiny dogfish is reasonable. Furthermore, tight junction protein 1 (ZO-1) was downregulated slightly following 12hrs and upregulated to a much greater degree after 48hrs. This protein functions as a scaffold, tethering the transcellular tight junction proteins (such as claudins and occludins) to the intracellular actin cytoskeleton (Chasiotis et al., 2012). The significant upregulation of ZO-1 after 48hrs allows for increased localization of tight junction proteins (either pore or barrier), further contributing to regulation paracellular loss. Cadherin 1 and desmocollin 3 are both involved in cell-cell adhesion and were downregulated during low salinity exposure. The alteration to cell adhesion, in conjunction with changes in transcripts directly involved in tight junctions, strongly suggests paracellular loss is tightly regulated and important element of marginal euryhalinity in the Pacific spiny dogfish.

### *Regulation of tight junctions*

The MAPK signalling pathway has been shown to alter the expression of both barrier and pore forming claudins and the expression of ZO-1 (González-Mariscal et al., 2008). The primary effector of these actions is MAPK/ERK1. Therefore, alteration to the expression of MAP3K15 and MAP2K5 (upstream of MAPK), supported by enrichment of GO term “positive regulation of ERK1 and ERK2 cascade”, may function to enhance MAPK activity and consequently, alter tight junction leakiness. RhoA was upregulated after 48hrs in 65% SW and functions through different actions from MAPK to achieve the similar results (González-Mariscal et al., 2008). RhoA is an activator of the actin remodelling, and thus can regulate actin-myosin mediated contraction of the cell to break tight junctions between adjacent cells (Capaldo and Nusrat, 2009; Hall, 1998). Cytokines also have established effects on paracellular leakage including interleukins (Capaldo and Nusrat, 2009). Knockout of IL-10 from mice resulted in reduced localization of ZO-1 to the tight junctions (Mazzon et al., 2002). A similar occurrence may have occurred in dogfish kidney as a result decreased IL-10 expression. In conclusion, a multitude of factors may be working in unison to regulate paracellular loss through the presence of tight junction proteins, the localization of intracellular elements, and use splice variants.

### *Osmosensing transcription factors and proteins*

The lack of extensive modifications to key transcription factors previously implicated in salinity acclimation was surprising, though justifiable. An important regulator of cell signalling following an osmotic challenge is the osmotic stress transcript factor 1 (OSTF1). This transcription factor was first identified in Mozambique tilapia (*Oreochromis mossambicus*) as an early response gene that increased 6-fold after a 2hr transfer from FW to SW (Fiol and Kültz, 2005). It has since been identified in a variety of teleosts, although never in an elasmobranch (Tse, 2014). The early onset of this transcription factor, in addition to its primary localization in the gills, suggests that if it were detected, it may not have been differentially expressed. A mammalian homolog of OSTF1, TSC22D2, was detected however no change was observed, suggesting these early response transcription factors are present in the dogfish but may not contribute to acclimation in the kidney. The annotation as TSC22D2 rather than OSTF1 is likely due to the lack of OSTF1 in the databases used by Trinotate, highlighting the difficulties of using

non-model species. Lastly, the 14-3-3 gene has been implicated as a major regulator for branchial osmosensory signalling in the euryhaline teleost *Fundulus heteroclitis* (Kültz et al., 2001). 14-3-3 transcripts in this study showed no significant changes in the dogfish over the course of 48hrs. Similarly, no change in 14-3-3 mRNA levels were detected *F. heteroclitus* intestine, suggesting a strong tissue dependence (Scott et al., 2006). The presence of numerous osmosensing transcription factors suggests that elasmobranchs have the genetic machinery in place to elicit a response, however, the lack of differential expression suggests that the kidney is not involved in osmosensing. Therefore, this finding warrants further exploration using gill tissues and earlier time points during salinity challenges.

### *Protein damage and chaperones*

Heat shock proteins (HSPs) are a large family of protein chaperones that reduce unwanted conformational changes and prevent protein aggregation (Georgopoulos and Welch, 1993). The uniform upregulation of multiple HSP at both the transcript and gene level, and enrichment of GO terms “chaperone-mediated protein complex assembly”, “protein stabilization”, and “regulation of protein stabilization” following 12hrs in 65% SW suggests a dramatic increase in protein stress. Ubiquitin protein levels can function as an indirect measure of protein damage and in the absence of direct protein quantification, expression levels of ubiquitination transcripts was used (MacLellan et al., 2015). Surprisingly, differentially expressed ubiquitin were inconsistent in their expression patterns making it difficult to evaluate the degree of protein damage. However, the observation that HSPs operate predominantly in a time dependent manner (much greater FC after 12hrs than 48hrs compared to control) suggests that protein damage or stress had ceased, or reduced dramatically, after 48hrs. The dogfish appeared to be approaching the isosmotic line after 48hrs, and congruently, HSPs had almost returned to control levels at that point. Conversely, other studies have demonstrated that HSP levels in dogfish gills remained elevated after 48hrs in 70% SW and HSP abundance in school shark and gummy shark gills after 48hrs in 75% SW were decreased and unchanged, respectively (MacLellan et al., 2015; Morash et al., 2016). Likewise, teleost HSP expression levels are altered by salinity. A chronic salinity stress (8 months) challenge by Deane et al. (2002) using Black Sea Bream demonstrated that HSPs were more abundant in both hyperosmotic and hyposmotic

conditions and less in fish maintained in isosmotic water (12 ppt). In summary, the role of HSPs in salinity stress appears to be substantial yet vary with tissue and species.

#### *Immune functions*

Alterations to apoptotic factors and pathways have been previously identified in fishes following a salinity challenge, however, this response is typically studied in the gills (Blair et al., 2018; Ching et al., 2013; Kammerer and Kültz, 2009). Mozambique tilapia (*Oreochromis mossambicus*) undergo an extensive apoptotic process that is localized to the branchial MRCs following transfer from FW to SW (Kammerer and Kültz, 2009). This is suggested to increase the reorganization of branchial cell populations to replace FW MRCs with SW MRCs. This unique cell type has not been identified in the elasmobranch kidney, however, the increased expression of pro-apoptotic factors P53 and caspase 6 may still result in alterations to the makeup of renal cell populations. Multiple GO terms associated with the cell cycle and cell differentiation were enriched, particularly after 48hrs, suggesting this is temporally dependent response (e.g. “mitotic cell cycle”, “regulation of cell cycle process”, and “positive regulation of cell cycle arrest”). Thus, modifications to the cell populations may be occurring, however it is impossible to determine the exact changes in cell composition without using specific markers of cell types.

#### *Metabolic processes*

While I did detect alterations to certain transcripts with metabolic functions, the changes were spread across multiple pathways. Numerous transcripts involved in the glycerophospholipid pathway were differentially expressed and exhibited expression patterns that would contribute to reduced production of phosphatidylethanolamine (PE). This phospholipid is highly enriched in the inner membrane of the lipid bilayer and functions in membrane fusion (Chernomordik and Kozlov, 2008). Endocytosis and vesicle fusion was repressed transcriptionally and decreased levels of PE may act in concert to further reduce these processes. The functional outcome of this may lead to decreased transport of proteins inwards, reducing the protein turnover rates. PE also plays a role in cytokinesis during mitosis, enabling the separation of cells (Emoto et al., 1996). Therefore, decreased PE would also suggest a reduction in cell cycle rates, further supporting the conclusion that low salinity challenges require alterations to composition of renal cell populations. The phospholipid composition within teleost gills is altered in response to

environmental salinity, however, a similar occurrence has not been demonstrated in elasmobranchs (Shivkamat and Roy, 2005). No progress has been made to quantify changes in elasmobranch gill membranes in response to changes in salinity, however, composition of elasmobranch gills has been investigated (Fines et al., 2001). However, it is apparent that the specific membrane composition in the kidneys must be altered to accommodate the osmotic stress.

The downregulation of sarcosine dehydrogenase (SARDH), responsible for enzymatic conversion of sarcosine to glycine, suggests an accumulation of this organic osmolyte. This was unexpected due to the osmoconforming strategy of the dogfish and thus the need for offloading of osmolytes. A similar enzyme, sarcosine oxidase, isolated from *Raja erinacea* (a euryhaline skate) hepatocytes showed osmolarity-dependent activity wherein lower osmolarity induced activity (Ballantyne et al., 1986). It may be possible these divergent results can be attributed to different rates of sarcosine catabolism in these two tissues, and thus the functional outcome of downregulation in the dogfish may not contribute significantly to total sarcosine levels. Sarcosine can act to stabilize proteins and therefore increased retention of this compound, in conjunction with HSPs, may help to ensure functional proteins (Street et al., 2006). To my knowledge no studies have detailed the regulation sarcosine during salinity challenges.

#### *Limitations to the study*

There are several potential limitations to this thesis. The first is reliance on homologous annotation and the relatively low annotation rate. The use of non-model species in comparative physiology is particularly valuable in understanding how certain adaptations function, however, accompanying this value is the lack of genomic data and extensive gene annotation. While RNA-seq is able to overcome this problem via *de novo* assembly and large scale homologous annotation pipelines, it is not a perfect method and incomplete transcripts are often assembled that can be annotated incorrectly. Furthermore, homologous annotations are not always obtained unless a compromise in strictness of the annotation program is made, reducing the confidence in the results. Using the data generated to conduct further homology searches using multiple sequence alignments may be possible, however, time consuming. In this study, there were approximately 400 contigs that showed significant differential expressed during the exposure, yet no annotation was found. Identification of these 400 contigs could reveal a multitude of important transcripts and pathways involved in salinity tolerance. Second, the correlation

between transcript expression levels and abundance of protein is not always correct (Maier et al., 2009). However, it has been demonstrated that differentially expressed transcripts are more likely to match their protein counterpart levels, compared to transcripts that are unresponsive to an experimental treatment (Koussounadis et al., 2015). While it may not be a completely accurate representation of the true intracellular environment, RNA-seq still provides valuable clues that can be pursued using other specialized techniques, such as protein level assays. Without RNA-seq, these clues may be missed. Third, RNA-seq in this study was performed on whole tissue. This can be important for tissues such as the kidney where adjacent sections are functionally different and therefore any localized changes would likely be lost. It would be possible to overcome this limitation through detailed dissection of sinus zones and bundle zones, however, the complicated kidney morphology would likely make this difficult. A detailed understanding of changes in mRNA along the length of the kidney would be a substantial improvement to this study.

One particular caveat for the present study is that the health of many of the sharks held at Bamfield Marine Sciences Centre was compromised as ~2 weeks prior to experimentations with a likely bacterial infection. Many experienced lesions in the snout and had obvious eye infections. While animals used in this study were from this group as a whole, care was taken to select fish with minimal overt clinical signs (e.g. negligible nose wounds) for experiments described in this thesis. Upon sacrifice, a limited number of sharks that appeared healthy externally exhibited significant changes in the texture and consistency of the liver, and in addition, some displayed a substantial reduction in the size of a lobe. However, the presence of non-presenting effects of either infection or recent recovery may have some influence on the results of this study and care should be taken when interpreting the results. Regardless, all results are compared to control animals from the same population and I am therefore confident in the validity of the changes in gene expression resulting from salinity stress.

### *Future Directions*

The work described in this thesis is primarily concerned with changes in gene expression in the kidney. However, the kidney is not the only organ involved heavily in ion and water balance. During sacrifice, I also took tissue samples from the gills, rectal gland, intestine, and liver from all the same animals. Therefore, an immediate goal would be the sequencing of the

transcriptome from each of these important osmoregulatory tissues and to compare findings with the current study. These other tissues may display more prominent alterations to select cellular functions, such as metabolic changes in the liver or osmosensing and signalling in the gills.

An alternative, equally important approach to understanding salinity tolerance might be to use a similar RNA-seq approach, but instead expose dogfish to multiple salinities for a single duration, rather than multiple durations at a single salinity. This study design would identify whether the osmosensory system within these animals can operate in a graduated manner depending on environmental salinity to fine tune downstream response. Furthermore, the use of multiple salinities may reveal that the changes in expression are consistent across multiple, or conversely, the level of osmotic stress induces different responses. Using the Pacific spiny dogfish, a graduated range of salinities that could be test include 32ppt, 28ppt, 24ppt, and 21ppt. An additional treatment could be included to examine the recovery of animals in 32ppt after exposure to 21 ppt.

Diverging from physiological studies may be necessary to understand the ecological reasons of entering BW or FW environments. For instance, female bull sharks can give birth in FW and as the pups mature, they migrate down rivers as they become larger before finally entering the marine environment (Simpfendorfer et al., 2005). This is hypothesized to give the pups protection from larger predators found in marine environments (Ballantyne and Fraser, 2012). However, very little is known about the purpose of BW invasions for other marine elasmobranchs such as the dogfish. Furthermore, very little is known about the duration of incursions. There are multiple likely motives that these animals might move into BW. Similar to bull sharks pups, dogfish are prey for a number of other larger animals. BW environments may provide added protection as opposed to pelagic and benthic environments further from the coast. Additionally, BW environments have very high primary production can therefore support a high population of fishes (Correll, 1978; Houde and Rutherford, 1993). This may be an additional food source that the dogfish take advantage of during invasions into low salinity environments in estuaries. Therefore, ecological studies need to be performed where animals near estuaries are tagged with sensors for environmental parameters (salinity, water temperature, and depth) to record details of possible incursions. Ideally, recapture of these animals following BW or FW incursions would be performed to allow for inspection of the intestinal contents. This would give indications about food sources within the estuary and if they differ from marine environments.

A key element missing from the majority of this study is the role of hormonal influence on renal function. Transcripts involved in enzymatic synthesis of prostaglandins were altered in this study however the role of this compound in osmoregulation has never been investigated. There are at least four components that contribute to endocrine based ion and water homeostasis in elasmobranch including the hypothalamic-pituitary-interrenal axis, c-type natriuretic peptide (CNP), vasoactive intestinal polypeptide, and the renin-angiotensin system (Gelsleichter and Evans, 2004). Importantly, CNP in *Scyliorhinus canicula* increased renal clearances of osmolytes (Wells et al., 2006). This peptide is synthesized in response to water loading and therefore is likely contributing significantly during low salinity invasions (Anderson et al., 2005b). The receptors for CNP were detected in the dogfish kidney transcriptome, however no changes were observed. Further work needs to be done to explore the role of this peptide in these animals during BW/FW incursion. This could be accomplished via transfusion of blood from hyposmotically challenged dogfish into naïve sharks. If a response was elicited this would demonstrate that circulating hormones are the primary drivers signalling for alterations to renal function. This could be measured via osmolyte clearance rates and changes in protein abundance and mRNA expression of targets downstream of the receptor.

The central aim, of which the work in this thesis is just one component, is to understand the physiological mechanisms that permit BW and FW invasions in elasmobranchs, and contextualize this within the evolution of these traits. Therefore, comparative physiology is essential. Using the data generated from this thesis as a starting point, a similar study could be performed using a variety of marginally euryhaline elasmobranchs with varied salinity tolerances. Salinity challenge could either be in the form of each species lowest limit, or to a consistent level that can be tolerated by most species (e.g. 70% SW). Multiple tissues could be collected for each species and using either RNA-seq experiment or proteomic methods. This would elucidate interspecific differences in the same tissue, as well as the intraspecific differences in across tissues. There is the possibility that all elasmobranchs use generally the same trends just regulated to different levels, or conversely, different species use distinctive adaptations to overcome the same challenge. Both are exciting possibilities and may provide a new outlook on the evolution of BW and FW invasions.

## *Conclusions*

This thesis presented multiple novel aspects, the most prominent of which was the application of RNA-seq for differential expression analysis in an elasmobranch. My work revealed that the response of the kidney in the marginally euryhaline elasmobranch *Squalus suckleyi* was extremely multifactorial and complicated following low salinity exposure. Some of the important changes in mRNA expression were discussed and future studies that directly use the data presented within this thesis were reviewed. As the fields of transcriptomic and genomics progress in the future, the ease at which elasmobranch transcriptome data can be accurately mapped and annotated will only increase. My work is the first step in this direction.

## Appendix

**Table S1.** Complete list of the differentially expressed transcripts following 65% SW exposure. Differential expression analysis at the transcript level was performed using the edgeR software within the Trinity pipeline and annotation was performed using Trinotate. Log<sub>2</sub>FC represent fold change of time point B relative to time point A. P-values were adjusted using the Benjamin-Hochberg correction for multiple comparisons. The annotation provided states the UniProt protein identifier followed by the species.

**Table S2.** Complete list of the differentially expressed genes following 65% SW exposure. Differential expression analysis at the gene level was performed using the edgeR software within the Trinity pipeline and annotation was performed using Trinotate. Log<sub>2</sub>FC represent fold change of time point B relative to time point A. P-values were adjusted using the Benjamin-Hochberg correction for multiple comparisons. The annotation provided states the UniProt protein identifier followed by the species.

**Table S3.** RNA purity and integrity of extracted total RNA from kidney tissue

The RNA purity (via Nanodrop) and integrity (via Bioanalyzer) were both measured to ensure high quality samples were used in the cDNA library synthesis. Ideal ratios for 260/280 and 260/230 for RNA are ~2.0 and ~2.2. Mean RIN values for all samples was 9.33.

Sample	Time point	RIN	260/280 ratio	260/230 ratio
K11	0hrs	9.5	1.9	1.95
K12	0hrs	9.4	1.91	1.99
K15	0hrs	8.5	1.96	2.27
K18	0hrs	8.8	2.92	2.34
K24	0hrs	8.5	2.06	2.14
K07	12hrs	9.5	1.99	2.07
K08	12hrs	9.1	2	2.17
K16	12hrs	9.5	1.95	2.1
K19	12hrs	9.9	1.92	2.29
K21	12hrs	9.6	1.96	2.06
K03	48hrs	9.5	1.94	2.37
K04	48hrs	9.3	2.01	2.17
K17	48hrs	9.6	2	2.13
K20	48hrs	9.6	2	2.08
K23	48hrs	9.7	2.01	2.14

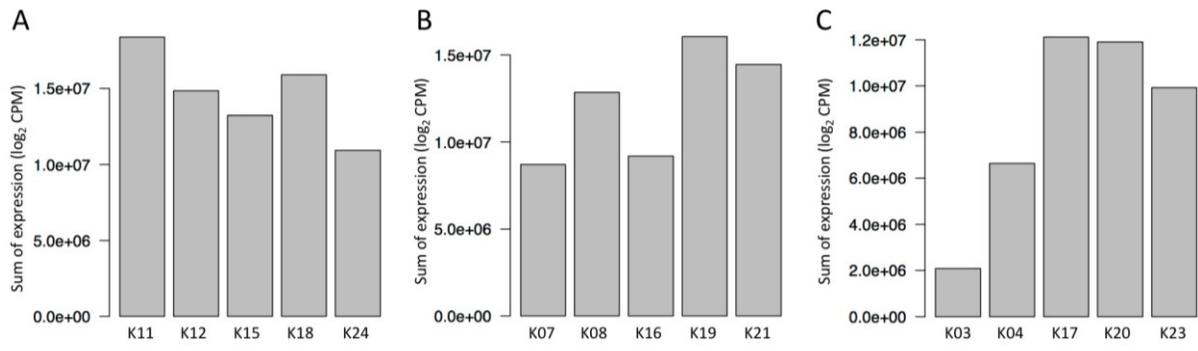

**Table S4.** Concordant and discordant alignment rates

Bowtie2 software was used to examine alignment of individual samples back to the *de novo* assembled transcriptome.

Mapping type	% Mapped
Paired reads with 0 concordant alignment	26.99
Paired reads with exactly 1 concordant alignment	16.84
Paired reads with more than 1 concordant alignment	56.17
Of paired reads with 0 concordant alignments, those with 1 discordant alignment	2.94
Of paired reads with 0 concordant alignments, mates that aligned 0 times	30.15
Of paired reads with 0 concordant alignment, mates that aligned 1 time	8.56
Of paired reads with 0 concordant alignment, mates that aligned >1 times	61.29
Overall alignment rate	92.75

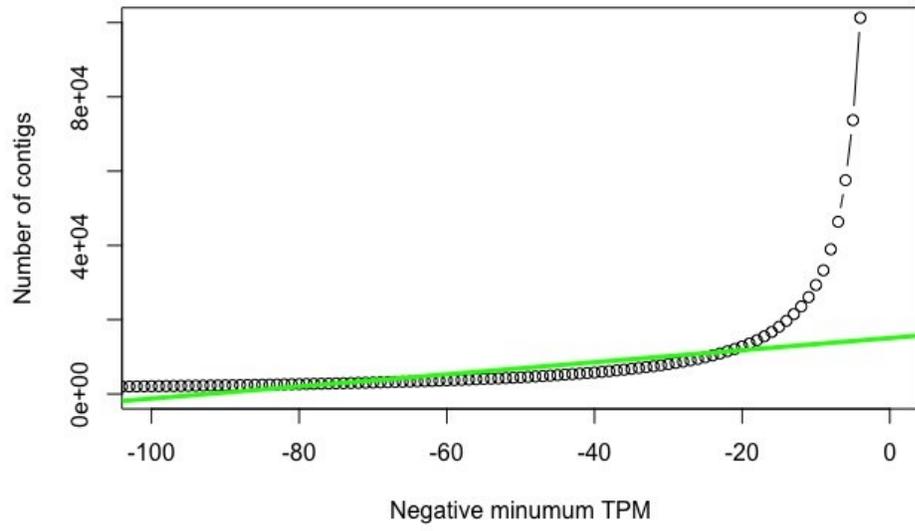

**Figure S1.** Sum of transcript expression in each replicate.

The Trinity PtR pipeline was used to obtain transcript counts that were CPM transformed and then  $\log_2$  transformed. The expression for each transcript was then summed to give the total mRNA expression from animals in (A) 0hrs, (B) 12hrs in 65% SW, and (C) 48hrs in 65% SW.

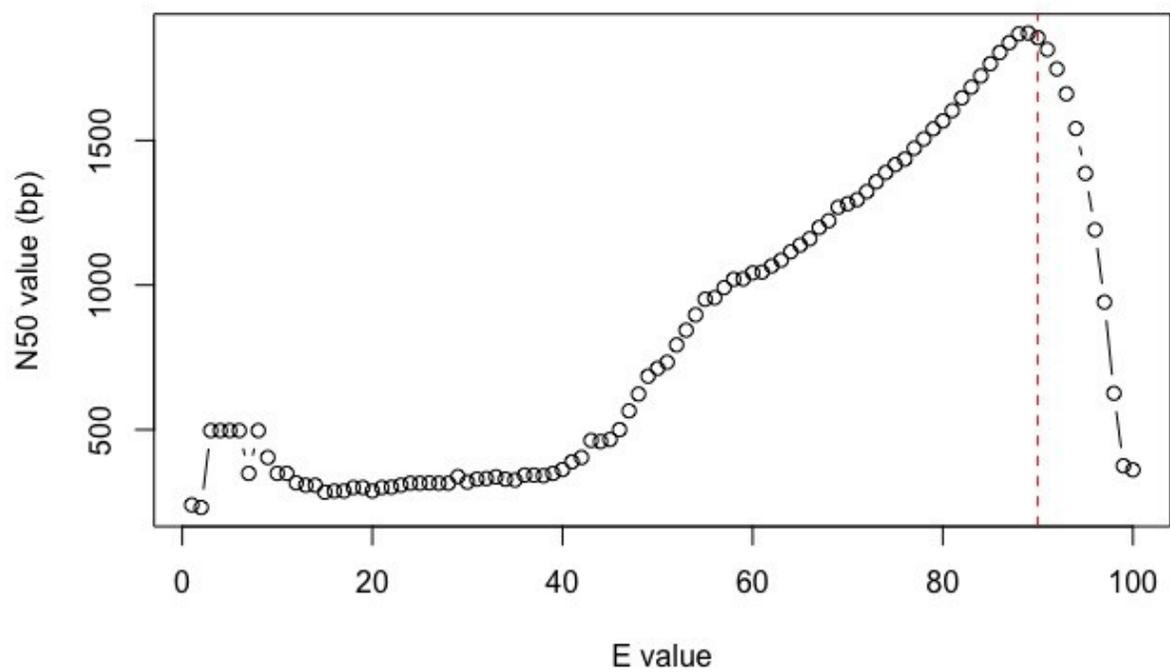

**Figure S2.** Estimation of true number of different transcripts in the kidney transcriptome

A method of approximating a more realistic level of gene (or transcript) expression is supported by the Trinity script *count\_matrix\_features\_given\_MIN\_TPM\_threshold.pl* which plots the number of transcripts as a function of minimum TPM threshold. The green line indicates the linear regression of transcripts below the cut a negative minimum TPM of 10. Where  $x=0$  is the estimation of the approximate number of contigs in the kidney transcriptome while ignoring the numerous lowly expressed contigs. The value approximated using this technique is 15082 transcripts.

**Figure S3.** Analysis of ExN50 values of the *de novo* assembled kidney transcriptome  
The Ex90N50 value is a better measurement of the quality of the transcriptome than the N50 value. Trinity script *contig\_ExN50\_statistic.pl* was used to generate N50 values for each percentile of the total normalized expression data. The red line indicates the Ex90 value where the contigs below this value comprise 90% of the highest expression data. The Ex90N50 value was calculated as 1,855 bp.

**Figure S4.** MA and Volcano plots for each statistical comparison

MA (left) and volcano (right) plots were generated using the Trinity PtR pipeline to visualize the trends (based on FC, counts, and  $P_{adj}$  value) of the differentially expressed transcripts (red dots) and their unresponsive counterparts (black dots) in each statistical comparison; (A) 0 vs 12, (B) 0 vs 48, and (C) 12 vs 48.
